Acknowledgements

I thank my wife Magdi for her patience during writing and for critical reading of the text. My daughter Mari introduced me into word processing. My son-in-law, Kirk has been very supportive. Granddaughters, Grace, Paige and Anne are most inspirational. I am grateful to countless numbers of colleagues on whose work this material is based and to whom I could not refer because of limitations of space. I am indebted to colleagues, especially to Dr. Csaba Koncz, Max-Planck-Institut, Cologne, Germany for many useful discussions. My students at the University of Missouri, Columbia, MO, and students and colleagues, particularly Dr. András Fodor, at the Eötvös Lóránd University of Basic Sciences, Budapest, provided purpose for undertaking this project. I am also indebted to Jane D Phillips, Director of Development for Life Sciences at the University of Missouri for her interest and encouragement.

Some of the chemical formulas are based on the Merck Index, on the Aldrich Catalog and Fluka Catalog.

During the preparation of the third edition, Mark Jarvis has been most helpful in resolving a variety of computer problems.

I appreciated the comments from the readers on the first and second editions. The first e-mail from Dr. SLC said: "Thank you for assembling such concise explanations of all genetic concepts in a single volume". Similar letters came from many others, which for reasons of space, I cannot quote here.

I am thankful to the public reviews for the constructive comments and suggestions.

Author is much indebted to Anil Chandy for expert advice, friendship, cooperation and understanding during all phases of the production of this book.

Cudweed by Konrad von Gessner (1597), the famous Swiss savant and zoological and botanical illustrator. Von Gessner's work has been borrowed by many, among them the German Joachim Camerarius (1500–1576) of Tübingen, a great authority on classics, religion and science and whose descendant Rudolph Jacob Camerarius (1665–1721) would become the first experimental geneticist, and discover the love life of plants.

Preface to the First Edition

The primary goal of this Manual is the facilitation of communication and understanding across the wide range of biology that is now called genetics. The emphasis is on recent theoretical advances, new concepts, terms and their applications. The book includes about 18 thousand concepts and over 650 illustrations (graphs, tables, equations and formulas). Most of the computational procedures are illustrated by worked-out examples. A list of about 900, mainly recent books, is provided at the end of the volume, and additional references are located at many entries and illustrations. The most relevant databases are also listed. The cross-references following the entries connect to a network within the book, so this is not just a dictionary or glossary. By a sequential search, comprehensive, integrated information can be obtained as you prepare for exams, or lectures, or develop or update a course, or need to review a manuscript, or just wish to clarify some problems. In contrast to standard encyclopedias, I have used relatively short but greater variety of entries in order to facilitate rapid access to specific topics. This Manual was designed for students, teachers, scientists, physicians, reviewers, environmentalists, lawyers, administrators, and to all educated persons who are interested in modern biology. Concise technical information is available here on a broad range of topics without a need for browsing an entire library. This volume can always be at your fingertips without leaving the workbench or desk. Despite the brevity of the entries, the contents are clear even for the beginner. Herbert Macgregor made the remarkable statement that in 1992 about 7,000 articles related just to chromosomes were scattered among 627 journals. Since then, the situation has become worse. Many publications—beyond a person's specialization—are almost unreadable because of the multitude of unfamiliar acronyms and undefined terms. Students and colleagues have encouraged me to undertake this effort to facilitate reading of scientific and popular articles and summarize briefly the current status of important topics. According to Robert Graves (a good poem) “makes complete sense and says all that it has to say memorably and economically”. I hope you will appreciate the sense and economy of this Manual. I will be much indebted for any comment, suggestion and correction.

“I almost forgot to say that genetics will disappear as a separate science because, in the 21st century, everything in biology will become gene-based, and every biologist will be a geneticist.” Sydney Brenner, 1993

Preface to the Second Edition

The majority of the users of the first edition considered this book as an encyclopedia because the cross-references tied the short entries into comprehensive reviews of the topics. In contrast to “big encyclopedias” in this work only a few entries exceed a couple of thousand words and that make it much faster to find the specific concept or term of interest. Unlike multi-author works this is practically free of redundancy and it is compact in size but not in depth of information. One of the reviewers pointed out that many of the topics covered could not be found in any other single book, including encyclopedias, dictionaries or glossaries. Another reviewer appreciated it as a broad resource of information that may take a lengthy search to uncover without it.

Since the publication of the 1st edition, I have steadily updated and improved on the topics. I have added many new concepts, illustrations, books and database addresses. (The database addresses are in an unfortunate flux and some may be out existence by the time you wish to log in; therefore I provided several to minimize the problem beyond my control.) This second edition contains about 50% more information and more than twice as many illustrations than the 1st edition. A new feature is the predominantly current, over 7,000 text references to journal articles. Their bibliographies may help to locate additional key and classical papers. The General References at the end include about 2,000 books. For additional medical genetics references I suggest the use of OMIM at The National Center for Biotechnology Information (<http://www.ncbi.nlm.nih.gov/>, see also Grivell, L 2002. *EMBO Rep.* 3:200). I have greatly expanded the cross-references among the entries because the users found this feature especially useful. Color plates were added to the end of the book. At the end of the files there are some historical vignettes.

Since the publication of the first edition the need for such a book became even more evident. In the literature unexplained concepts, terms and acronyms are on the increase and even a name DAS (*dreaded abbreviation syndrome*) has been coined for the malaise (*Science*, 283:1118). The users of the first edition agreed with the Nobel-laureate geneticist, HJ Muller who posed and answered the still current problem: “Must we geneticists become bacteriologists, physiological chemists and physicists, simultaneously with being zoologists and botanists? Let us hope so.” (*Amer. Nat.* 1922, 56:32).

The vision of genetics today is not less than the complete understanding how cells and organisms are built, how they function metabolically and developmentally, and how they have evolved. This requires the integration of previously separate disciplines, based on diverse concepts and tongues. Whatever is your specialization or interest, I hope you will find this single volume helpful and affordable.

Although I had the aim of comprehensiveness beyond all the available compendiums, there were hard decisions of what to include and what to pass. The same science may appear different depending on who, how and when looks at it (up or down) as Gerald H Fisher's art above (man or woman or both) illustrates the point.*

Thank you for the appreciation of the first edition. I will be much indebted for your comments and suggestions.

Preface to the Third Edition

“When I acquired the right words..., it was easier for me to understand what I was thinking: it is difficult to reason through a problem if you cannot articulate what the problem is.”

(John F Bruzzi 2006 *New England J. Med.* 354:665).

This volume is essentially an improved and enlarged new version of the previous, much-acclaimed book. The third edition has over 1,000 pages more of new material than the second. The latest progress in current hot topics such as stem cells, gene therapy, small RNAs, transcription factories, chromosomal territories, networks, genetic networks, ENCODE project, epigenetics, histone and protein biology, prions, hereditary diseases, and even patents are covered. The number of illustrations increased to nearly 2,000 and several hundreds are in four-color. The old entries have been revised, updated and expanded. Cross-references among entries have been increased. Retractions and corrigenda are pointed out. Nearly 1,800 database and web server addresses, about 14,000 journal paper references and more than 3,000 current book titles are included. Interesting historical vignettes lend some insight into the lighter sides of biology. I hope the reader finds the absence of laboratory jargon refreshing.

The encyclopedia will equip its reader to prepare journal papers, write or review research proposals or help organize a new course or update a current course. Students will find the topics useful for preparing for exams or for writing term papers. It may also appeal to basic and applied biologists and to practitioners of many other fields. The readers of previous editions appreciated the clarity of the basics in this book. A sample of what professional reviewers wrote about the book is carried for the reader's reference. In addition, about the current publications in general, the Editor of Science had the following comment. “Each specialty has focused in to a point at which even the occupants of neighboring fields have trouble understanding each others’ papers”... “The language used in Reports and Research Articles is sufficiently technical and arcane that they are hard to understand, even for those in related disciplines.” (Kennedy, D 2007 *Science* 318:715).

One of the most fascinating features of science is its continuous evolution. My goal was to emphasize the principles, provide numerical data and guide to resources that are more difficult to access from other publications. The book can assist the reader to make better use of the Internet but the Internet and textbooks are no substitutes for this book. Unlike the majority of books, this Encyclopedia will not be outdated because the continuously renewed and updated databases and web sites listed assure its usefulness even in the distant future. Describing individual genes in different organisms—with some exceptions—is no longer practical in a single book or even with the aid of an excellent resource such as PubMed due to the multitude of abstracts (more than 15,000,000 entries from more than 19,000 journals). The web sites—listed in this book—can however, provide great help in identifying many genes, their synonyms, functions and interacting partners as well as critical references to them. Although basic statistical concepts are explained in simple terms, most of the theoretical mathematical models or detailed laboratory procedures are not included because of the difficulties of describing the techniques within the limited space available in a single book. The abundance of references can lead the reader in the right direction.

Selection of papers for inclusion is also a continuous challenge. During 1992 to 2001 4,061 journals published more than 3.47 million peer-reviewed articles in health-related areas alone (Paraje, G et al. 2005 *Science* 308:959). Although this book is quite complex, integrated, and referenced, it does not include everything but it might be a useful guide to almost everything one needs in biology. For a proof of principle, I suggest that you look up any concept what you know or what you are uncertain or have doubts about.

I welcome all readers and I promise to respond to questions or comments.

First to Read for the Third Edition

The organization of the expanded and revised third edition is slightly different from that of the previous ones. The material is still in alphabetical order but in a somewhat different style. Numbers involved with the entries do not affect the order. Entries beginning with Greek letters are sorted as if they would be in Roman or the Greek letter follows the term. Words followed by a comma and another word precede entry words without comma, e.g., “antibody, secondary” is followed by “antibody detection”. Hyphenated entries are sorted as single words. The spelling of some terms vary because in the scientific literature some technical terms are written either with a *c* or *k* or with an *e* or *ae*. Some abbreviations are used in the literature as e.g., PGD or P.G.D. and both may not be used in this book. Here the most common usage is favored. Some entries are qualified by another word added after and in others the qualifier comes first. Most entries are followed by cross-references that guide to relevant topics. In particular cross-references qualifiers are not separated by comma even when they are with comma in the main list. In case you make electronic searches it is frequently more practical to use only part of the words because in the alphabetical list their ending may be different, e.g., maximum or maximal. An attempt has been made to guide the reader to the desired entry when necessary. In rare instances the reader may need to search for synonyms or related terms to find the desired entry. Thank you for your patience.

This book contains a large number of Internet addresses under the heading of “databases” and even more after many entries. Every effort has been made to keep the web addresses current. Unfortunately, they are altered frequently and it is likely that some will cease to exist or will change by the time the book gets to your hands. In some instances Word alone may not open the URL site directly, but Internet Explorer or Safari or even the search engines Google, Yahoo, AltaVista or others can be used to access the sites.

It must be remembered that data are not knowledge. The data must be integrated into science and the aim of the author has been the facilitation of such integration. The contents of the entries are based on the best information available in the literature at the time of the completion of the writing. As sources of information like most human products, are not always perfect, the author and publishers cannot claim perfection or assume legal responsibility for errors beyond their control.

“Knowledge...built on opinion only, will not stand”. Linnaeus, 1735

A

A: Adenine is a purine base of nucleic acids. ►adenine

2,5-A (adenine) oligonucleotides: Adenine oligonucleotides are generated by 2,5-A synthetase from double-stranded RNA. These oligonucleotides activate RNase L, which attacks infecting viruses of vertebrates. If the two genes encoding these two enzymes are transformed into plants, they provide resistance against RNA viruses. ►host-pathogen relationship, ►ribonuclease L

Å (ångström): A unit of length, 1/10 of 1 nm; 10^{-7} mm.

A6: *Agrobacterium tumefaciens* strain with a Ti plasmid coding for octopine production in the plant cell. ►Agrobacterium, ►opines, ►octopine

A20: A cytoplasmic Zn-finger protein that limits TNF-induced NF-κB responses. It reduces apoptosis. Its deficiency may increase inflammation and may result in death. ►TNF, ►NF-κB, ►apoptosis; Kumar-Sinha C et al 2002 J Biol Chem 277:575.

a: atto-, 10^{-18} , e.g., attomole/amole.

α: Average inbreeding coefficient, $\alpha = \sum p_i F_i$ where p_i is the relative frequency of inbred individuals with F_i coefficient of inbreeding. This value in most human populations is less than 0.001 while in isolated human groups it may exceed 0.02 or 0.04. ►inbreeding coefficient, ►error types

A Box: An internal control region of genes (5S ribosomal RNA and tRNA) transcribed by DNA-dependent RNA polymerase III; the consensus is 5'-TGGCNNAGTGG-3'. The tRNA genes also have an essential *intermediate segment* of about a dozen bases that has no consensus, yet its length is necessary for function. Nearby there is also another regulatory consensus, the B box 5'-GGTTCGAANNC-3'. The matrix attachment region (MAR) is also an A box (with a consensus of AATTAAC/AAA). ►MAR; Borovjagin AV, Gerbi SA 2001 Mol Cell Biol 21:6210.

A Chromosome: A member of the regular chromosome set in contrast to a B or supernumerary chromosome. ►B chromosome, ►accessory chromosome

α Complex: One of the alternate chromosome translocation complexes in *Oenothera*. ►β complex, ►translocation, ►Oenothera

A DNA: ►DNA

α Mating Type Factor of Yeast: Responsible for the secretion of the α factor (a pheromone), composed of 13 amino acids and it acts on *a* type cells. ►mating type determination in yeast

A Medium: For *E. coli*, g/L: K_2HPO_4 10.5, KH_2PO_4 4.5, $(NH_4)_2 SO_4$ 1.0, Na-citrate.2 H_2O , 0.5 plus glucose 0.4%, thiamin 1 mg/L, $MgSO_4$ 1 mM, and an appropriate antibiotic. For different bacterial culture media. Winkler U et al 1976 Bacterial, phage and molecular genetics. An experimental course, Springer-Verlag, New York; ►culture media

α Particles: ►alpha particles

A Priori: A philosophical concept indicating that certain knowledge does not presuppose experience. In contrast, *a posteriori* concept is based on the acquisition of certain prior information.

A Rule: Adenylic acid is the preferred nucleotide for incorporation opposite to an abasic site of the DNA during repair. abasic sites, ►DNA repair; Otterlei M et al 2000 EMBO J 19:5542.

α Satellite: The centromeric DNA that is normally heterochromatic. However, it may have important role in controlling chromosome segregation and other centromere functions. The 171-bp tandemly repeated sequence has been found in all human centromeric area. It is connected by 17 bp (missing in the human, mouse and green monkey Y centromeres) with protein CENP-B, a common autoimmune antigen. All human centromeres and neocentromeres apparently include also CENP-A, a histone H3-like protein. Introduction of exogenous alphoid DNA into the cells may cause chromosomal instabilities. The CENP-B protein bears sequence similarity to the pogo transposases. ►centromere, ►neocentromere, ►satellite DNA, ►heterochromatin, ►segregation, ►meiosis, ►human artificial chromosome, ►microchromosome, ►hybrid dysgenesis; Buno I et al 2001 Genome 44:120.

A Site (decoding site): A compartment on the ribosome; at the beginning of the translation process the first codon, Met or fMet lands at the P site and the next amino acid is delivered to the A site. Then the elongation of the peptide chain proceeds. The decoding site of the 16S ribosomal RNA has the universally conserved |A1492 and |A1493 nucleotides as the location. (see Fig. A1). ►protein synthesis, ►ribosome, ►aminoacyl-tRNA synthetase; Rodnina MV, Wintermeyer W 2001 Annu Rev Biochem 70:415.

 CG  CACC
 → UCAC 1412

Figure A1. Decoding site

AAA Proteins: AAA Proteins are ATPases, enzymes cleaving off phosphates from ATP. They are equipped with Walker boxes. AAA domain proteins are molecular chaperones and have important roles in vesicular transport, organelle biogenesis, microtubule rearrangements, etc. Some of this group of enzymes is related to the prokaryotic RuvA proteins. The Mgs1 protein (maintenance of genome stability) of yeast has homologs in all prokaryotes and eukaryotes. Their defects contribute to increased mitotic recombination. ▶ [ATP](#), ▶ [ATPase](#), ▶ [RuvABC](#), ▶ [chaperone](#), ▶ [Walker box](#), ▶ [MD1](#); Dalal S, Hanson PI 2001 Cell 104:5; Gadal O et al 2001 EMBO J 20:3695; Hishida T et al 2001 Proc Natl Acad Sci USA 98:8283; Sauer RT et al 2004 Cell 119:9; evolution and structure: Erzberger JP, Berger JM 2006 Annu Rev Biophys Biomol Struct 35:93.

AAAS: ▶ [ALADIN](#)

AAF: ▶ [alpha accessory factor](#)

α -Amanitin: A protein synthesis inhibitor fungal octapeptide. It blocks RNA pol II (0.1 μ g/mL); RNA polymerase III is also blocked by it but at much higher concentrations (20 μ g/mL), but pol I is insensitive to it even at 200 μ g/mL. LD₅₀ in albino mice is 0.1 mg/kg. ▶ [RNA polymerase](#), ▶ [pol](#), ▶ [LD₅₀](#); Begun DJ, Whitley P 2000 Heredity 85:184.

AAR1: ▶ [TUP1](#)

Aarskog Syndrome (Aarskog-Scott syndrome, facio-genital dysplasia): A genetic disorder that is autosomal dominant, autosomal recessive, X-linked (Xq12) recessive short stature, hypertelorism (increased distance between organs or parts), scrotum (the testis bag) anomaly, pointed hairline (Widow's peak), broad upper lip, floppy ears, etc. The basic defect involves the RHO/RAC member of the RAS family of GTP-binding proteins. ▶ [stature in humans](#), ▶ [head/face/brain defects](#), ▶ [RAS](#), ▶ [faciogenital dysplasia](#), ▶ [hypertelorism](#); Orrico A et al 2007 Am J Med Genet 143:58.

AATAAA: A consensus of 10–30 bp upstream from a CA dinucleotide at the site where cleavage, then polyadenylation of the mRNA commonly takes place. This consensus may also be a signal for transcription termination although normally, RNA polymerase II

continues to work after passing it. ▶ [polyadenylation signal](#), mRNA tail, ▶ [transcription termination](#); Curuk MA et al 2001 Hemoglobin 25:255.

AATDB: *Arabidopsis thaliana* database provided general information on all aspects of the plant, including genes, scanned images of mutants, nucleotide sequences, genetic and physical map data, cosmid and YAC clones, bibliographical information. <http://www.weeds.harvard.edu/index.html>, or e-mail curator@frodo.mgh.harvard.edu. ▶ [AIMS](#), ▶ [Arabidopsis thaliana](#), ▶ [databases](#)

AAUAAA: Consensus for polyadenylation of the mRNA. Apparently, the poly-A RNA polymerase enzyme and associated protein attach to this sequence before cleavage of the transcript and post-transcriptional polyadenylation take place. Yeast does not have this consensus. ▶ [AATAAA consensus's role in polyadenylation](#)

Ab: ▶ [antibody](#)

Ab Initio: Meaning from the beginning in Latin. For e.g., genes *ab initio* indicates the genes as first recognized by sequencing but the exact exon/intron structure had not been identified.

$\alpha\beta$ T Cells: Represent the early stages of T cell development in the thymus and later recognize the major histocompatibility complex-bound peptide antigens resulting in the differentiation of B and T lymphocytes. The expression of the co-receptor CD4 and CD8 may involve the formation of the double negative CD4⁻ CD8⁻ to CD4⁺ CD8⁺ and the CD4⁻ CD8⁺ and the CD4⁺ CD8⁻, a process requiring the rearrangement of the α and β subunits of the T cell receptor, and the ligands existing within the thymocytes. At the same time, the T cells differentiate into the rather distinct CD4 T-helper cell and the CD8 T-killer cells. The CD4 expression in the mature T cells corresponds to their specificity toward class II and the CD8 expression toward the class I major histocompatibility complex (MHC) molecules. The differentiation into this two cell lineages is a selective process controlled by the relative strength and duration of the engagement with the T cell receptor (TCR). The HD (helper deficient) recessive mutation in mouse cause loss of CD4 T cell development because these cells were switched over to the CD8 T cell path. This HD locus encodes the zinc finger transcription factor Th-POK (T helper-inducing POZ/Krüppel), which under constitutive expression mediates the development toward the class I MHC molecules. Thus, Th-POK is a master regulator of T lymphocyte development (He X et al 2005 Nature [Lond] 433:826). ▶ [lymphocytes](#), ▶ [MHC](#), ▶ [\$\gamma\delta\$ T cells](#), ▶ [T cell](#), ▶ [POZ](#), ▶ [Krüppel](#)

ABA (abscisic acid, 3-methyl-5-[1'-hydroxy-4'-oxo-2'-cyclohexen-1'-yl]-cis-2,4-pentadienoic acid): A terpenoid, synthesized from mevalonate and xanthins, apparently through two pathways. It has multiple physiological functions in concert with other plant hormones, particularly with gibberellins and cytokinins, by regulating seed dormancy, germination, leaf abscission, stomatal opening, drought response, etc. Glucose-conjugated ABA is biologically not active. Activation of glycosidase, however, rapidly increases the active pool of ABA and the concomitant physiological responses to environmental cues (Lee KH et al 2006 Cell 126:1109). In the ABA signal transduction farnesyl transferase seems to be involved. Cyclic ADP-ribose, regulated by Ca^{2+} , seems to be another signaling molecule for ABA. Ca^{2+} ion channels are activated by H_2O_2 produced by the guard cells upon the induction of ABA and thus the stomatal opening/closing is controlled. Responses to ABA are regulated by ABRC (ABA response complex) in the genes that include an ACGT box and a variable coupling element. A G protein-coupled receptor interacts with the G protein subunit GPA1 to mediate all known ABA responses in *Arabidopsis* (Liu X et al 2007 Science 315:1712). The RNA-binding protein FCA, which plays a role in the control of flowering, is a receptor of abscisic acid (Razem FA et al 2006 Nature [Lond] 439:290). The Mg-chelatase H subunit is an ABA receptor (Shen Y-Y et al 2006 Nature [Lond] 443:823). Several *aba* genes have been cloned.

New evidence indicates that in human granulocytes ABA stimulates phagocytosis, production of reactive oxygen species and nitric oxide (NO) and chemotaxis through a signaling pathway sequentially involving a pertussis toxin (PTX)-sensitive G protein/receptor complex, protein kinase A activation, ADP-ribosyl cyclase phosphorylation, and consequent cyclic-ADP-ribose overproduction, leading to an increase of the intracellular Ca^{2+} concentration. Thus, it can be considered as a pro-inflammatory cytokine in humans (Bruzzzone S et al 2007 Proc Natl Acad Sci USA 104:5759). ▶[abscisic acid](#), ▶[prenylation](#), ▶[farnesyl pyrophosphate](#), ▶[plant hormones](#), ▶[stoma](#), ▶[ion channels](#), ▶[glucosidase](#), ▶[chelation](#), ▶[G protein](#), ▶[pertussis toxin](#), ▶[protein kinase](#), ▶[ARF](#), ▶[cytokine](#); Lopez-Molina L et al 2001 Proc Natl Acad Sci USA 98:4782; Nambara E, Marion-Poll A 2005 Annu Rev Plant Biol 56:165.

Abasic Endonucleases (APE): APEs mediate base excision repair. Its deficiency in mouse leads to embryo lethality. Besides base excision, it is involved in acetylation-mediated gene regulatory function (Izumi T et al 2005 Proc Natl Acad Sci USA 102:5739). ▶[DNA repair](#), ▶[endonuclease](#), ▶[acetylation](#); Demple B, Harrison L 1994 Annu Rev Biochem 63:915.

Abasic Sites: Found in DNA where glycosylases (base exchange repair) have removed bases by cleaving the glycosylic bond. According to an estimate, approximately 100,000 abasic sites are generated per mammalian cell daily and their number increases by senescence. These sites may be intermediates in chemical mutagenesis and repair. DNA polymerases ζ and η can insert nucleotides opposite 8-oxoguanine (C) and O^6 -methylguanine sites (C or T). The repair may not be highly efficient. ▶[glycosylases](#), ▶[DNA repair](#), ▶[A rule](#), ▶[oxidative damages](#), ▶[DNA polymerases](#), ▶[apurinic site](#); Haracska L et al 2001 J Biol Chem 276:6861; Guillet M, Boitaux S 2003 Mol Cell Biol 23:8386; Auerbach P et al 2005 Proc Natl Acad Sci USA 102:17711.

Abaxial: That which is not in the axis of body or of an organ.

ABC Excinuclease: A 260,000 M_r protein complex containing the subunits coded for by the *uvrA*, *uvrB* and *uvrC* genes of *E. coli*. UvrA is an adenosine triphosphatase and brings into position UvrB, which after attaching to the DNA cuts it at the 3' position, and that provides the opportunity for UvrC to incise at the 5' position. UvrD, a helicase releases the damaged oligomer along with UvrC. Following these events, DNA polymerase fills in the correct nucleotides. In yeast, the RAD1, 2, 3, 4, 10, and 14, carry out the same tasks as the ABC excinucleases of bacteria. In humans, the XPA (a damage recognition protein, comparable to UvrA), binds to the XPF-ERCC1 (excision repair cross-complementing protein) heterodimer and to the human single strand binding replication protein, HSSB. XPF (3' cut) and XPG (5' cut) are nucleases. The gap-filling polymerases are pol δ and pol ϵ . XPB and XPD are helicase subunits of the TFIIH transcription factor. The excinuclease complex is released at the end of the process with the aid of the proliferating cell nuclear antigen (PCNA). This complex is capable of excision of cyclobutane pyrimidine dimers, 6-4 photoproducts (adjacent pyrimidines cross linked through C6-C $4'$), nucleotideadducts (molecules with added groups) formed by mutagenic agents. ▶[excision repair](#), ▶[adduct](#), ▶[DNA polymerases](#), ▶[DNA ligase](#), ▶[helicase](#), ▶[baseflipping](#), ▶[transcription factors](#), ▶[PCNA](#), ▶[cyclobutane](#), ▶[pyrimidine-pyrimidinone photoproduct](#); Zou Y et al 2001 Biochemistry 40:2923; Gu C et al 2006 Biochemistry 45:10739.

ABC Transporters (ATP-binding cassette transporters, 9q22-q31): ABC transporters constitute a large family of proteins, which hydrolyze ATP and mediate transfers through membranes. Altogether 56 ABC transporter genes are known and 38 of them are present in all vertebrates. These are now often called TAP. The ABC

A

transporters have two membrane-spanning (MSD) and the dimeric ATP-nucleotide binding domains (NBD). MSDs may show greater variations, depending whether they operate as a pump or a conductance channel. The NBD subunits play the role of the engines of the transport and interact through their arm 1 with the two MSDs. The ABCA4/ABCR mutations may account for Stargardt disease (STGD1), fundus flavimaculatus (FFM, retinitis pigmentosa (RP) and cone-rod dystrophy (CRD), all recessive with somewhat overlapping retinal symptoms. ABC transporters may affect adrenoleukodystrophy, cystic fibrosis, retinal degeneration, hypercholesterolemia and cholestasis (see Fig. A2). By 2001, 48 ABC transporters belonging to 7 gene families have been identified. ▶TAP, ▶protein-conducting channel, ▶TRAM, ▶signal hypothesis, ▶SRP, ▶translocon, ▶translocase, ▶Stargardt disease, ▶Tangier disease, ▶pseudoxanthoma, ▶Byler disease, ▶high-density lipoprotein, ▶multidrug resistance, ▶multiple drug resistance, ▶retinitis pigmentosa, ▶cone dystrophy, ▶dwarfism; Dean M et al 2001 Genome Res 11:1156; Neufeld EB et al 2001 J Biol Chem 276:27584; Chang G, Roth CB 2001 Science 293:1793 [this paper was retracted in (2006) because of software error]; Borst P, Elferink RO 2002 Annu Rev Biochem 71:537; Stacey G et al 2002 Trends Plant Sci 7:257; Dean M, Annilo T 2005 Annu Rev Genomics and Hum Genet 6:123; crystal structure of bacterial ABC transporter: Roger JP et al 2006 Nature [Lond] 443:180; structure with binding protein: Hollenstein K et al 2007 Nature [Lond] 446:213.

ABCD Model: An environmental matrix for the study of the performance of species (see Table A1).

Table A1. ABCD model

| | Environment 1 | Environment 2 |
|------------|---------------|---------------|
| Genotype 1 | A | B |
| Genotype 2 | C | D |

Abdomen in *Drosophila*: The body segment between the thorax and telson. ▶*Drosophila*

Abelson Murine Leukemia Virus Oncogene (*abl*): Mammalian homolog of the avian Rous sarcoma virus. It codes for a plasma membrane tyrosine kinase. When this enzyme acquires constitutive catalytic activity in the presence of the Philadelphia chromosome, it causes chronic myelogenous leukemia (CML) in humans. It is treated effectively by STI-571 tyrosine kinase inhibitor. ▶oncogenes, ▶Rous sarcoma, ▶tyrosine kinase, ▶leukemia, ▶Gleevec, ▶Philadelphia chromosome; Wang JY et al 1984 Cell 36:349; Shore SK et al 2002 Oncogene 21:8568.

Abembryonic: After fertilization, a blastomere is formed and its progeny generates the embryonic part of the blastocyst and another line of cells of the blastomere populates the space away from the embryo at the parietal trophoctoderm, and the more superficial abembryonic cell mass away from the embryo. ▶blastomere, ▶blastocyst

Aberrant Genetic Ratios: Occur when the chromosomes carrying the wild type or mutant allele of a gene, respectively, have reduced transmission through meiosis or the viability of the gametes is diminished. Depending on the chromosomal location of the defect, either the one (wild type), or the other (recessive) allele may appear in excess of expectation of normal phenotypic ratios.

Aberration Chromosomal: ▶chromosome breakage

Abetalipoproteinemia (microsomal triglyceride transfer protein deficiency, 4q22-q24): Abetalipoproteinemia involves very low levels of the very low density (VLDL), low density (LDL, apolipoprotein B, 2p24) and high density (HDL) of these lipoproteins (microsomal triglyceride transfer protein [MTP] defect). The rare recessive anomaly is accompanied by excretion of lipoproteins, malabsorption of fat, acanthocytosis (see Fig. A3) thorny type erythrocytes rather than the normal doughnut-shaped, retinitis pigmentosa (sclerosis (hardening), pigmentation and atrophy [wasting away] of the retina of the eye and irregular coordination of the nerves (ataxia). ▶neuromuscular disease, ▶beta-lipoproteins, ▶hypobetalipoproteinemia, ▶hyperlipoproteinemia

Figure A3. Abetalipoproteinemia

ABF-1: A nuclear transcriptional repressor belonging to the basic helix-loop-helix family. ▶[helix-loop-helix](#); Wong J et al 2001 DNA Cell Biol 20:465.

Abf (autonomously replicating sequence binding factor): Abf is involved in silencing of yeast mating types. Also it may bind to various promoters and thus may initiate replication or transcription. ▶[mating type determination in yeast](#), ▶[ARS](#), ▶[ORC](#), ▶[HML](#) and [HMR](#)

ABH antigens: In humans, ABH antigens are secreted in the saliva and other glycoprotein-containing mucus in the presence of the *Se* (dominant allele, human chromosome 19q13.13), and the gene codes for the α 2L-fucosyltransferase enzyme. The secreted glycoproteins, A and B are about 85% carbohydrate and about 15% protein. Approximately 75–80% of Caucasoids are secretors (homozygous or heterozygous for *Se*). The precursors of the antigens are Galactose(β 1-3)*N*-acetyl-D-glucosamine-R and Gal (β 1-4)*N*-acetyl-glucosamine-R (where R stands for the extension of the carbohydrate chain). Antigen H has the critical structure of that shown in figure (see Fig. A4). Antigenic determinant A is formed by *N*-acetylgalactosamine, and the B antigen by galactose addition at non-terminal position to the H antigen. Thus, the A, B and H antigens are different from each other by these carbohydrates and in some variants by the number of fucose molecules. The A and B alleles are codominant. The recessive O blood group lacks fucosidase activity that places a fucose, by an α 1-2 linkage on a galactose. The Lewis blood group (Le [Les], 19q13.1-q13.11) is distinguished on the basis that its dominant allele Le places fucose in an α -1,4 linkage to the *N*-acetylglucosamine. Individuals that have no secretor activity but are Le belong to the Lewis blood group Le^a whereas when both *Se* and Le are expressed they represent the Le^b type. ▶[ABO blood group](#), ▶[Bombay blood type](#), ▶[fucosyl transferase](#), ▶[secretor](#); Domino SE et al 2001 J Biol Chem 276:23748.

Figure A4. ABH antigens

Abilene (advanced networking for leading-edge research and education): Abilene is an advanced backbone network to connect aggregation points such as virtual laboratories, digital libraries and distance education at national and international scale. By the end of 2003, it is expected to communicate at 10 Gigabytes/ second. ▶[Internet2](#), ▶[BIRN](#); <http://abilene.internet2.edu/>.

ABL: ▶[abetalipoproteinemia](#)

ABL (Abelson murine leukemia virus oncogene): Located to human chromosome 9q34.1 and mouse chromosome 2. When translocated to human chromosome 22 it may transcribe a fusion protein with an abnormal protein tyrosine kinase activity, which is probably the cause of chronic myeloid leukemia. Acute lymphocytic leukemia is also associated with a similar translocation, the Philadelphia chromosome, but it appears that tyrosine kinase activation is different from that of the fusion protein. The ABL gene has about 300-kb intron down-stream from the first exon. This intron appears to be the target of the translocations and causes acute lymphocytic leukemia. Insertion of DNA sequence into the *abl* gene of mouse results in several morphological alterations and death. Abl also controls differentiation, cell division, and stress responses. The SH3 domain negatively regulates Abl activity and deletion of SH3 makes it an oncogenic protein. Mutations in the SH3, or in the catalytic domain or and in the linker region between the SH3 and SH2 domains are also oncogenic. ABL deficiency in mice leads also to osteoporosis. ▶[oncogenes](#), ▶[ARG](#), ▶[Philadelphia chromosome](#), ▶[leukemia](#), ▶[SH2](#), ▶[SH3](#), ▶[osteoporosis](#); Maru Y 2001 Int J Hematol 73:308.

abl: B cell lymphoma (Abelson leukemia). Oncogene encoding a non-receptor protein tyrosine kinase. Ionizing radiation and alkylating agents activate this oncogene. In the Philadelphia chromosome the contact between BCR and ABL most commonly leads to myelogenous leukemia. In the absence of ABL the JNK/SAP kinases (Jun kinase) are not stimulated. ▶[leukemia](#), ▶[lymphoma](#), ▶[JUN](#), ▶[JNK/SAP](#), ▶[Philadelphia chromosome](#), ▶[BCR](#), ▶[tyrosine kinase](#)

Ablation: Mechanical or chemical/toxin-mediated removal of cells or tissues of stem cells or plant meristems to study the role of those cells in differentiation and development. The purpose can also be achieved by obtaining genetic deletions in these areas, heterozygous for appropriate marker genes. The deletion of the dominant allele reveals the function of the recessives and permits tracing cell lineages on the basis of the visible sectors formed. Familial retina ablation may occur in animals as a hereditary abnormality. ▶[gene fusion](#), ▶[intercellular immunization](#), ▶[pseudodominance](#), ▶[deletion](#), ▶[cell lineages](#)

ABM Paper: ▶[diazotized paper](#)

A

ABO Blood Group: Represented by three major types of alleles (human chromosome 9q34) displaying codominance (see Table A2).

These blood types are extremely important because inappropriate mixing (in blood transfusion) results in agglutination that prevents the flow of blood through the veins and oxygen transfer, and it is potentially lethal. These antigens are actually carbohydrates (attached to polypeptides), and the genes A and B specify α -D-N-acetylgalactosaminyltransferase and α -D-galactosyltransferase enzymes, respectively. Gene O is not active as an enzyme. The A and B enzymes (M_r about 100,000) are dimeric and structurally similar to each other. The A and B molecules are identified as A and B antigens. Occasionally maternal antibodies against the A and B antigens may enter, through the placenta, the fetal blood stream and affect adversely the erythrocytes causing anemia and hyperbilirubinemia. In such cases medical treatment may be required. The ABO system has also a limited use in forensic medicine in paternity suites, in typing bloodstains, semen and saliva in criminal cases. Immunologically active forms may be recovered in old human remains and can also be used in archeological research. This blood group provided some correlative information in cancer research, e.g., in O individuals afflicted with carcinomas A antigen may be detected in 10–20% of the cases. The major clinical characteristics are as follows.

It appears, changes in glycosyltransferase activity are not uncommon in several types of tumors. The frequency of the various ABO alleles varies a great deal in the world population. It has been shown that the O blood type provided some protection against the most severe form of syphilis (*Treponema pallidum*) but somewhat higher susceptibility to diarrhea caused by some viral and bacterial infections.

The B blood group may have afforded some protection against smallpox, plague and cholera.

Universally compatible red blood cells can be obtained by two bacterial glycosidase gene families that provide enzymes capable of efficient removal of A and B antigens at neutral pH with low consumption of recombinant enzymes. The crystal structure of a member of the -N-acetylgalactosaminidase family reveals an unusual catalytic mechanism involving NAD^+ (Liu QP et al 2007 Nature Biotechn 25:454).
▶ABH antigen, ▶Lewis blood group, ▶blood groups, ▶*Treponema pallidum*, ▶forensic genetics; Race EE, Sanger R 1975 Blood groups in man, Blackwell, Oxford; Chester MA 2001 Transfus Med Rev 15:177; Patenaude SI et al 2002 Nature Struct Biol 9:685.

Aborigine: The first group of inhabitants, humans, animals or plants.

Abortion, Medical: Medical abortion is induced during the early period of pregnancy usually by antiprogesterin (mifepristone) in combination with prostaglandins (in countries where approved), or by the less costly and not very effective misoprostol. Progesterin is synthetic progesterone. In Western Europe, about 3.5/1000 pregnancies are medically terminated because of severe fetal anomalies. selective abortion, ▶contraceptives, ▶ensoulment, ▶prostaglandins, ▶mifepristone, ▶progesterone, ▶genetic screening, ▶family planning, ▶mortality

Abortion, Spontaneous: Spontaneous abortion is frequently caused by disease, stress, incompatibility genes or chromosomal aberrations. Various types of chromosomal defects were cytologically detected in 30–50% of the aborted fetuses. About 15–20% of the verified human pregnancies are aborted

Table A2. ABO blood group

| Blood Group (Frequency in Caucasoids*) | Genotype | Antigens Formed | Antibodies Formed | Clumping With | Blood Type Acceptable for Transfusion |
|---|------------------------|--------------------|----------------------|------------------|---|
| O (0.45) | $i^O i^O$ | neither | anti-A anti-B | A,B AB | O |
| A (0.44) | $i^A i^A$ or $i^A i^O$ | A | anti-B | B,AB | A,O |
| B (0.08) | $i^B i^B$ $i^B i^O$ | B | anti-A | A,AB | B,O |
| AB (0.03) | $i^A i^B$ | A,B | neither | neither | A,B,O |

*The frequency of these alleles varies in different populations. For the calculation of frequencies, see gene frequencies. Actually, the A type exists in $A_1 A_2$ forms; in about 1–2% of the A_2 and 25% of the $A_2 B$ individuals, anti- A_1 antigens occur.

spontaneously and an estimated 22% of the abortions occur before pregnancy is clinically detected (5 weeks after the last menstruation). For placentation, the main source of steroid, the corpus luteum is replaced by appropriate supply of estrogens and progesterone. Pregnancies of increased maternal level of cortisol are more likely to become aborted spontaneously during the first 3 weeks after conception (Nepomnaschy PA et al 2006 Proc Natl Acad Sci USA 103:3938). Different molecular mechanisms may account for abortion. Th2 lymphocytes and IL-10 and TGF- β may suppress incompatible paternal antigens in the fetus. Th1 cytokines, IL-2, INF- γ , and TNF- α may contribute to abortion. Indolamine 2,3-dioxygenase (IDO) by catabolizing tryptophan may help in suppressing allo-specific maternal T cells in the lining of the uterus (decidua). The special V α 14 natural killer T cells (NKT) when activated by α -galactosyl-ceramide or by glycosyl-phosphatidylinositols (the latter is present in blood parasites) may cause abortion. Perforin, TNF- α and INF- γ of the NKT cells may destroy the embryonic trophoblasts. Semi invariant natural killer cells (iNKT) recognize glycosphingolipids presented by monomorphic class I MHC-like glycoprotein molecules presented by CD1d (antigen-presenting molecules for T cells). In early gestation of mice a perforin like molecule and in later stages, a cytokine-dominated mechanism is responsible for pregnancy loss in a strain-dependent manner (Boyson JE et al 2006 Proc Natl Acad Sci USA 103:4580). ▶selective abortion, ▶trisomy, ▶chromosomal rearrangements, ▶chromosome breakage, ▶IL-2, ▶TNF, ▶INF, ▶T cells, ▶perforin, ▶CD1, ▶allospecific, ▶trophoblast, ▶ceramides, ▶inositines, ▶miscarriage, ▶family planning, ▶corpus luteum, ▶progesterone, ▶estradiol, ▶cortisol; Hamerton JL 1971 Human cytogenetics, Academic Press, New York; Hallermann FB et al 2001 Eur J Hum Genet 9:539.

Abortive Infection: Occurs when bacteria are infected with a phage capsule that carries bacterial rather than phage DNA and thus cannot result in the liberation of phage particles. Abortive response by infection of mammalian cells may be caused by any deficiency of the interacting system. (Hosel M et al 2001 Virus Res 81:1).

Abortive Transduction: When the transduced DNA is not incorporated into the bacterial genome and in the absence of a replicational origin, it can be transmitted but cannot be propagated. Therefore, the transduced fragment is contained in a decreasing proportion of the multiplied bacteria. ▶transduction, ▶transduction abortive; Stocker BAD et al 1953 J Gen Microbiol 9:410; Benson NR, Roth J 1997 Genetics 145:17.

Abraxane: A new type of anti-breast cancer drug consisting of taxol/paclitaxel, attached to blood serum protein as an injectable nanoparticle. Clinical trials indicate better effectiveness than taxol alone. ▶taxol, ▶nanotechnology, ▶breast cancer

Abrin: Agglutinin, a toxic lectin and hemagglutinin extracted from the seed of the tropical leguminous plant jequirity (*Abrus precarius*). Abrins A, B, C, D are glycoproteins of two polypeptide chains. The small A chain is an inhibitor of aminoacyl-tRNA binding and has nothing to do with agglutination. Abrin is more toxic to a variety of cancer cells (ascites, sarcomas) than to normal cells. ▶aminoacyl tRNA synthetase, ▶lectins, ▶hemagglutinin, ▶RIP; Wu AM et al 2001 Life Sci 69:2027.

ABRINE: *N*-methyl-L-tryptophan (α -methylamino- β -[3-indole]propionic acid). An inflammatory drug; unrelated to abrin. (See Richou R et al 1966 C R Acad Sci Hebd D [Paris] 263:308).

Abscisic Acid: It is a plant hormone regulating a variety of physiological processes, including modification of the action of other plant hormones (see Fig. A5). Originally, it was detected as a substance involved in the abscission of leaves. ▶ABA, ▶plant hormones, ▶stoma; Hugouvieux V et al 2001 Cell 106:477; Finkelstein RR 2002 Plant cell 14:S15.

Figure A5. Absciscic acid

Abscission Zone: The thin-walled tissue layer (low in lignin and suberin) formed at the base of the plant organs before abscission (falling off) takes place. ▶abscisic acid

Absinthe: A green liqueur, containing thujone, and it is a GABA antagonist. ▶GABA

Absolute Dating: Determines the age of archeological objects by using either radiometry (using the rate of decay of radioactive isotopes), or electron spin resonance (measures age of crystals from a few thousand to 300,000 years), or thermoluminescence (Heated objects release light and energy. When they are heated again the time elapsed since they were heated last can be estimated). (Renne PR et al 2000 Sci Progr 83:107).

Absolute Linkage: There is no recombination between (among) the genes in a chromosome. ▶recombination, ▶linkage

A

Absolute Risk Increase/Decrease: Change in risk when from an old therapy the patient is subjected to a new one compared to the risk without the treatment.

Absolute Weight: The mass of 1000 seeds or kernels after appropriate cleaning.

Absorption: Uptake of compounds through cell membranes or through the intestines into the bloodstream.

Absorption Spectrum: The characteristic absorption peaks of a compound at various wavelengths of light, e.g., guanine has maximal absorption at about 278 nm at pH 9 but its maximum at pH 6.8 is at ca. 245 nm ultraviolet light; chlorophyll-a has an absorption maximum in benzene at ca. 680 and 420 nm visible light, whereas chlorophyll-b maxima are at ca. 660 and 460 nm, respectively. These characteristics vary according to the pH and the solvents used and are determined by spectrophotometers.

Abundance: Average number of molecules in cells.

Abundant mRNAs: A small number of RNAs that occur with great numbers in the cells. ▶[mRNA](#)

Abzymes: Monoclonal antibodies with enzyme-like properties. If these antibodies can recognize the transition state analogs of enzyme-substrate reactions, they might have enzymatic properties. These abzymes would have numerous chemical and pharmaceutical applications. monoclonal antibody, ▶[antibody](#), ▶[catalytic antibody](#), ▶[transition state](#); Takahashi N et al 2001 Nature Biotechnol 19:563.

Ac—Ds (Activator-Dissociator): The first transposable element system recognized on the basis of its genetic behavior in maize. It contains 4563 bp and bordered by 11 bp imperfect, inverted repeats. The independently discovered *Mp* (*Modulator of p1* [pericarp color]) is the same transposon. *Ac* is an autonomous element and can move by its own transposase function. The *Ac/Mp* element makes a 3.5 kb transcript, initiated at several sites upstream, and a 2,421 base mRNA. A defective (deleted) version of it, *Ds* (*Dissociator*), is non-autonomous and requires the presence of *Ac* for transposition. *Ds* was originally discovered on the basis of frequent chromosome breakage associated with it. The *Ds* elements are quite varied in size but practically identical at the terminal sections to *Ac*. These elements have been identified first on the basis of mutation at known loci (*a*, *Adh*, *sh*, *wx*, etc.) upon insertion and reversions when the inserted element is evicted (see Fig. A6).

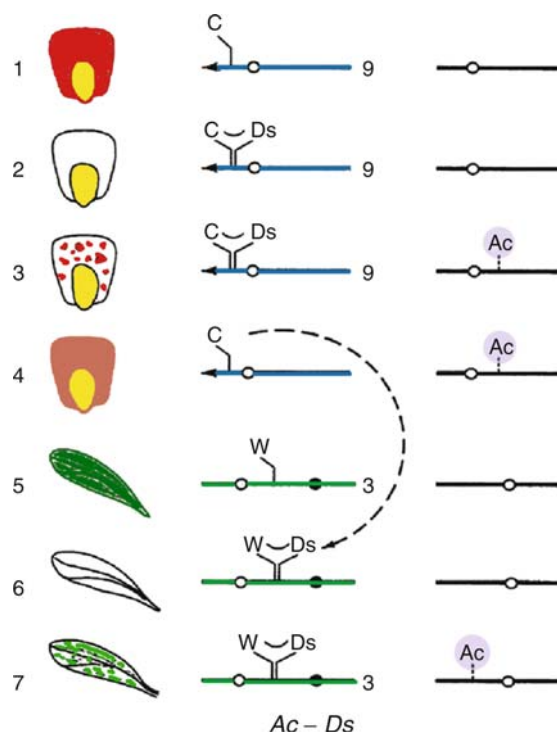

Figure A6. *Ac-Ds*. The possible phenotypic expression of genes in the presence of the *Ac-Ds* elements in maize. (1) The expression of the *C* allele in chromosome 9 in the absence of the transposable elements. (2) If *Ds* is introduced into the locus the function of *C* is disrupted and the kernel becomes colorless (2). If *Ac* (transposase) is introduced into any other location of the genome, it may cause the movement of the transposable element and colored spots appear (3). In case *Ds* is entirely dislodged from the germline, in the following generation full or partial function of the *C* gene is restored, depending whether the original site was completely restored or some modifications took place, and only diluted color appears (4). The *W* allele in chromosome 3 controls the development of green leaf color (5). If *Ds* moves into the gene it may disrupt its function and albinism is observed (6). In case *Ac* is introduced by crossing, *Ds* may move as indicated by the green stripes (7). Remember, *Ds* lacks transposase function although *Ac*, which carries the transposase, may move it

More recently it has been shown that many of the insertions do not lead to observable change in the expression of the genes or their effect is minimal and only sequencing of the target loci may then reveal their presence. The *Ac* element is transposed by a non-replicative manner and after meiosis only one of the sister-chromatids displays *Ac/Mp* at the original site (called *donor site*). In the other chromatid the element may be at another location (*recipient site*)

and the original location becomes “empty.” The recipient sites are most commonly in the same chromosome and quite frequently within the vicinity of the donor site. The *Ds* element frequently initiates a series of events resulting in chromosomal breakage by the mechanism of *breakage-fusion-bridge cycles* and duplications between the original donor and recipient sites. The *Ds* element may move in an inverted manner to the vicinity of a locus and thus, the revertants may still contain a *Ds* element. In the control of transposition the 11-bp inverted terminal repeats and – in addition – sequences 0.05 to 0.18-kb have importance. The *Ac-Ds* target sites display 8-bp duplication, which remains even after the removal of the element. The empty target sites may show internal deletions and rearrangements. A transposase enzyme that can mobilize the *Ac* element, which codes for it, mediates the transposition but it may act on the *Ds* elements too (which are transposase-defective *Ac* elements). It appears that an increase in the number of some but not of other *Ac* elements results in proportionally smaller revertant sectors, and the genetic background, developmental specificities (e.g., somatic or germline tissues) and physiological factors may influence the timing and frequency of transposition. There is evidence in favor of methylation being one of the factor(s) affecting *Ac* expression. This family of transposable elements has additional members such *MITE* (miniature transposable element) that has the same termini but it is very short. The *Ds1* element is similar to *Ds* but it carries retrotransposons within its sequences. *Ac* has been successfully transferred to other species such as tobacco, *Arabidopsis* and yeast and it functions there similarly as in maize. The *Ac-Ds* system can operate also in zebrafish and mammalian cells (Emelyanov A et al 2006 Genetics 174:1095).
 ▶controlling elements, ▶transposable elements, ▶hybrid dysgenesis, ▶insertional mutation, ▶transposase; Fedoroff NV 1989 Mobile DNA, In: Berg DE, Howe MM (eds) American Society of Microbiology, Washington, DC, pp. 377–411; Ros F, Kunze R 2001 Genetics 157:1723; AC distribution; Kolkman JM et al 2005 Genetics 169:981.

Acanthocytosis: ▶*abetalipoproteinemia*, ▶*elliptocytosis*; Wong P 2004 Med Hypotheses 62:966.

Acanthosis Nigricans: Hyperkeratosis and hyperpigmentation of the skin that may accompany the Crouzon syndrome and the Berardinelli-Seip syndrome. Interleukin IL-22 mediates interleukin IL23-induced dermal inflammation and acanthosis (Zheng Y et al 2007 Nature [Lond] 445:648).

AcAP: An anticoagulant protein isolated from *Ancylostoma caninum* hookworm (see Fig. A7).

Figure A7. Hookworm

ACAT: ▶sterol

Acatalasemia (CAT, 11p13): A rare dominant/semi-dominant/recessive trait involving the deficiency of the enzyme catalase. This enzyme has a protective role in the tissues by removing the H_2O_2 . Symptoms include small painful ulcers around the neck, gangrenes in the mouth and atrophy of the gum and very low catalase activity in the blood and other tissues. The heterozygotes have intermediate levels of catalase activity. Acatalasemia may be classified into different groups according to the clinical symptoms, both in humans and in animals. The gene extends to 34 kb with 14 introns. It is closely linked to WAGR. ▶Wilms tumor

Acatalasia: ▶*acatalasemia*

ACC (1-aminocyclopropane-1-carboxylic acid): A precursor of the plant hormone ethylene. ▶ethylene

Accelerator Mass Spectrometry (AMS): Quantifies isotopes such as C^{14} , H^3 , Ca^{41} , Cl^{36} , Al^{26} , in biological, archeological, pharmacological, or other materials with attomole sensitivity and high precision. It can be used to study the tissue distribution, metabolism, pharmacokinetics, and radiological hazards of isotopes. It is also a potent tool for paleontological analysis and dating archeological remains. ▶MALDI/TOF/MS

Acceptable Daily Intake: The safe dose of a chemical substance proven by experiment and it is generally divided by 100 for caution.

Acceptor Splicing Site: The junction between the right end of one exon and the left end of the next exon.
 ▶introns, ▶splicing

Acceptor Stem: A part of the tRNA, including the site (5'-CCA-3') where amino acids are attached. aminoacyl-tRNA.

Access Time: The time interval between callings in a piece of information from a storage source to the actual delivery of that information to the caller.
 ▶real time

A

Accessibility: Genetically determined ability of the genome to provide access for the V(D)J recombinase to rearrange the immunoglobulin genes. The accessibility depends on the increased activity of the loci, i.e., status of transcription, demethylation and increased DNase-sensitivity. ▶V(J)D recombinase, ▶RAG, ▶immunoglobulins, ▶CDR, ▶RSS

Accession: A stable strain isolated or collected from natural habitat. ▶provenance

Accession Number: In bioinformatics, accession number identifies permanently a particular molecular sequence submitted to a database. ▶BankIt, ▶Bio-seq, ▶gi, ▶ASN.1. Accession number is used by various biological collections for the identification of specimens such as plants in a herbarium, differently acquired strains of organisms.

Accessory Cells (companion cells): Epidermal cells next to the guard cells around the plant stomata that appear different from the usual epidermal cells. In animals, they promote adaptive immunity although they are not directly involved in antigen recognition.

Accessory Chromosome: ▶B chromosome

Accessory DNA: A product of DNA amplification in the cell. ▶amplification

Accessory Gland: A relatively minor tissue aiding the function of a gland. ▶epididymis

Accessory Pigments: Complement chlorophylls in absorbing light (carotenoids, xanthophyll, phycobilins).

Accessory Proteins: Accessory proteins such as transcription factors bind to upstream DNA elements for controlling transcription and other binding proteins that take part (not necessarily the main part) in a particular function. Accessory host proteins are also involved in the orientation or directionality of transposons. ▶transcription factors, ▶transposable elements, ▶Transposons

Accessory Sexual Characters: The structures and organs of the genital tract including accessory glands and external genitalia, but not the gonads, which are the primary sexual characters. ▶sex determination, ▶gonad, ▶sex phenotypic, ▶secondary sexual character

Accommodation: ▶decoding, ▶ribosomal

Accuracy: The percentage of correct identification of carcinogens and non-carcinogens based on mutagenicity tests. The mutagenicity tests are much faster and less expensive than direct carcinogenicity assays but it is important to know how well these simpler tests reveal the carcinogenic (or non-carcinogenic) properties of the chemicals tested. Accuracy also means when a measurement conforms to a prediction based on physical-chemical properties of the structure

of a protein. ▶sensitivity, ▶specificity of mutagen assays, ▶predictivity, ▶bioassays in genetic toxicology; Rédei GP et al 1984, Mutation, cancer and malformation, In: Chu EHY, Generoso WM (eds) Plenum, New York, p. 689.

Accuracy of DNA Replication: ▶DNA replication error

ACE (angiotensin converting enzyme): ▶angiotensin

ACE (affinity capillary electrophoresis): A procedure to test the binding strength of ligands.

Ace.mbl: Shotgun and directed sequencing evaluation program. ▶shotgun sequencing, gene predictor.

ACEDB: A *Caenorhabditis elegans* (a nematode, useful for genetic analyses) database. ▶*Caenorhabditis elegans*

Acenaphthene: A spindle fiber poison and thus polyploidization agent (see Fig. A8); it is also a fungicide and insecticide. ▶polyploid, ▶colchicine, ▶spindle poison

Figure A8. Acenaphthene

Acentric Fragment: The broken off piece of a chromosome that lacks centromere and therefore, its distribution to the poles during nuclear divisions is random and often lost. Acentric fragments are frequent consequences of irradiation of cells with X rays and other ionizing radiations (see Fig. A9). Chromosomal inversions may generate bridges (shown between the two poles) and three acentric chromosome fragments of substantial size that drift in the middle of the cell and are not distributed to the poles. ▶centromere, ▶chromosome morphology

Figure A9. Acentric fragment

Aceruloplasminemia (3q23-q24): Generally recessive deficiency of ceruloplasmin resulting in dementia, ataxia, diabetes, etc. Ceruloplasmin mediates the peroxidation of transferrin FeII to the FeIII form. ▶ceruloplasmin, ▶transferrin, ▶iron metabolism; Hellman NE et al 2002 J Biol Chem 277:1375.

Acervulus: A disk-like conidia-bearing reproductive structure of fungi. ▶conidia

Acesims (affinity capture-release electrospray mass spectrometry): Acesims uses biotinylated tags similarly to ICAT to capture conjugates in complex biological mixtures and to target specific enzymes that have role is metabolic defects such as disease. ▶MALDI, ▶ICAT, ▶proteomics; Turecek F 2002 J Mass Spectrom 37:1.

Acetabularia: Single-celled green algae that may reach the size of 2–3 cm and may be differentiated into rhizoids, stem and cap. It can survive enucleation for several months. The rhizoids, containing the nucleus, may regenerate into complete plants; $x \approx 10$. enucleate (see Fig. A10).

Figure A10. *Acetabularia* species are useful objects for developmental genetic studies and show dramatically the role of the cell nucleus. Grafting of the nucleus-containing section of the cell of *A. wettsteinii* to *A. mediterranea* caused *A. mediterranea* to develop a cap according to the instructions of the nucleus donor species. Experiment of J. Hämmerling in the 1940s. (Modified after Goldschmidt RB 1958 Theoretical Genetics. Univ. California Press. Berkeley, CA, USA)

Aceto-Carmine: ▶stains

Acetonitrile (methyl cyanide): A highly poisonous liquid with ether-like odor, flash point 12.8 °C (beware of the vapors) a polar solvent used (among others) for the separation of oligonucleotides by reverse-phase chromatography on silica gels.

Aceto-Orcein: ▶stains

Acetosyringone: (4-acetyl-2,6-dimethoxyphenol) and hydroxyacetosyringone are produced in plant cells (tobacco) and are one group of the compounds that induce the *vir* gene system of the *Agrobacterium* Ti plasmid. ▶*Agrobacterium*, ▶transformation [plants], ▶virulence genes of *Agrobacterium*

Acetyl Coenzyme A: ▶acetyl-CoA

Acetyl Group: Derived from acetic acid CH_3COOH ; the R stands for different chemical groups (see Fig. A11). ▶acyl group

Figure A11. Acetyl group

Acetylation: Acetylation of histones opens the nucleosomal structure for transcription of the DNA. Acetylation of H3 and H4 histones may generate bromodomains for protein-protein interactions. Several non-histone proteins involved in the regulation of transcription are also acetylated. HMG proteins, nuclear import proteins and tubulins are also acetylated primarily at selected lysine sites. In the DNA-binding transcription factors (p53, E2F1, EKLF, GATA), the sites near to the binding domain is acetylated and this increases binding. Acetylation of some of the HMG-BOX proteins results in reduced binding to DNA. Acetylation of TCF may disrupt its binding to other proteins or acetylation may prevent binding together of some regulatory proteins. Acetylation may increase protein half-life (e.g., E2F1, α -tubulin) and may enhance protein targeting (e.g., p53). Signaling molecules may provide cues for acetylation. The roles of acetylation may bear similarity to that of kinases although the number of acetyltransferases is much much smaller than that of kinases. (See terms ▶mentioned under separate entries, ▶GCN5, ▶histone acetyltransferases; Kouzarides T 2000 EMBO J 19:1176).

Acetyl-CoA (acetyl coenzyme A, ACoA): A heat-stable cofactor involved in the transfer of acetyl groups in many biological reactions (citric acid cycle, fatty acid metabolism, etc.). It has three major domains: the β -mercapto ethylamine unit, the pantothenate unit and adenylic acid. ▶epinephrine, ▶sirtuin (see Fig. A12).

A

Figure A12. Acetyl coenzyme, Li salt

Acetyl-CoA Carboxylase Deficiency (ACAC): The recessive ACACA is in human chromosome 17q21. The cytosolic ACACA is primarily expressed in the liver and in adipose tissues. ACACB (12q24.1) is in the mitochondria and expressed mainly in the heart and muscles. ACAC causes multiple interferences with gluconeogenesis, fatty acid and the branched-chain amino acid metabolism. ACACB deficiency leads to continuous oxidation of fatty acids and reduced fat storage in mice. Acetyl-CoA carboxylase (also called ACCase) is a biotin-dependent enzyme in the pathway of long-chain fatty acids located in the cytosol and in the chloroplasts of plants. ACC1 deficiency is lethal for mouse embryos but ACC2-null mice are viable (Abu-Elhaiga L et al 2005 Proc Natl Acad Sci USA 102:12011). This enzyme is the target of oxyphenoxypionate and cyclohexanedione herbicides. ▶[branched-chain amino acids](#), ▶[herbicides](#), ▶[obesity](#), ▶[fatty acids](#), ▶[obesity](#); Mao J et al 2003 Proc Natl Acad Sci USA 100:7515.

Acetylcholine (ACh, M_r 149): The acetylcholine receptor provides the connection between synapsing neurons and it is thus a signal transmitter. When acetylcholine binds to a receptor a Na^+/K^+ channel opens. The muscarinic acetylcholine receptors are activated by the fungal alkaloid, muscarine, whereas the nicotinic acetylcholine receptors are operating in the nerve and muscle cells. Acetylcholine receptors are diffusely distributed on the embryonic myotubes but become highly concentrated in a minute area in the post-synaptic membrane and they tether the synaptic cytoskeletal complex. ▶[ion channels](#), ▶[synapse](#), ▶[cytoskeleton](#), ▶[rapsyn](#), ▶[myotube](#), ▶[neuregulin](#), ▶[agrin](#), ▶[neurotransmitters](#), ▶[acetylcholine receptors](#), ▶[muscarinic acetylcholine receptors](#), ▶[myasthenia](#), ▶[memory](#), ▶[game theory](#), ▶[organophosphates](#); Smit AB et al 2001 Nature [Lond] 411:261; Miyazawa A et al 2003 Nature [Lond] 423:949.

Acetylcholine Receptors: Acetylcholine regulated cation (Na^+ , K^+ and Ca^{2+}) channels between the motor neurons and the skeletal muscles. The receptor in the

skeletal muscle contains five transmembrane polypeptides, encoded by four separate yet similar genes. When acetylcholine attaches to the receptor, a conformational change ensues resulting in a brief opening of the channel. They are easily isolated from the electric organs of some fishes. ▶[muscarinic acetylcholine receptors](#), ▶[nicotinic acetylcholine receptors](#), ▶[ion channels](#), ▶[agrin](#); Brejc K et al 2001 Nature [Lond] 411:269.

Acetylcholinesterase (ACHE): Encoded in human chromosome 3q25.2 by codominant alleles. It hydrolyzes acetylcholine into acetate and choline and it restores the polarized state in the postsynaptic nerve membranes. ACHE inhibitors are insecticides and drugs. Nerve gases are also ACHE inhibitors. ▶[acetylcholine](#), ▶[acetylcholine receptors](#), ▶[pseudocholinesterase deficiency](#), ▶[NTE](#), ▶[organophosphates](#)

Acetylglutamate Synthetase Deficiency: A form of autosomal recessive hyperammonemia. ▶[hyperammonemia](#)

Acetyltransferases: When first identified, it was believed that such enzymes acetylated histones but several enzymes became known later that acetylate other proteins and some that do not acetylate ▶[histones](#), ▶[histone acetyltransferases](#); Yang X-J 2004 Nucleic Acids Res 32:959.

ACF (ATP-utilizing chromatin assembly and remodeling factor): ▶[chromatin remodeling](#) (Fyodorov D, Kadonaga JT 2002 Nature [Lond] 418:897).

aCGH: A microarray-based Comparative Genomic Hybridization (aCGH) technique used to identify and characterize DNA copy number variations across the genome. (See <http://genome-www.stanford.edu/aCGH/>; <http://asterias.bioinfo.cnio.es/>; ▶[microarray hybridization](#)).

Achaete-scute Complex: A complex X-chromosomal (1-0.0) locus of *Drosophila* regulating bristle formation and nerve differentiation. The posterior dorso-central bristles are usually missing and the hairs are also sparse in that area. The *achaete* phenotype is generally due to some type of chromosomal rearrangement or loss (see Fig. A13). ▶[complex locus](#)

Figure A13. *Achaete-scute* complex. (From Bridges, C. & Brehme, K. Carnegie Inst. Washington 552: 12)

Achalasia-Addisonianism-Alacrima Syndrome (AAA, 12q13): Also known as triple A syndrome it is a complex glucocorticoid/adrenal/ deficiency causing failure of some muscles to relax, hypotension and weakness, failure in shedding tears normally and various nervous anomalies. The basic defect may involve a WD-repeat protein. Using a mutant of nucleoporin protein ALADIN^{L482S} it was shown that karyopherin- α/β -mediated import pathway was reduced and consequently DNA single-strand break repair (mediated by aprataxin protein) and ligase I activities were diminished leading to the symptoms of the disease (Hirano M et al 2006 Proc Natl Acad Sci USA 103:2298). ▶WD-40; Handschug K et al 2001 Hum Mol Genet 10:283.

Acheiropodia: Recessive 7q36 developmental human anomaly (incidence ~ 0.000004) involving bilateral amputation of the extremities, hands and feet (see Fig. A14). The corresponding mouse locus is *Lmbr1*. It may be accompanied by polydactyly and can occur in both hands and feet.

Figure A14. Acheiropodia

Achene: A single-seed dry fruit.

Achiasmate: Nuclear division without the formation of chiasmata. Chiasma is generally a requisite for orderly segregation of the meiotic chromosome. In male *Drosophila* chiasma and crossing over are usually absent yet chromosomes segregate normally. Stromalin (member of the cohesin family) and *Modifier of Mdg4 in meiosis* (MNM), a member of the SMC family assure the normal process. ▶meiosis, ▶recombination, ▶chiasma, ▶distributive pairing, cohesin, ▶SMC, ▶Mdg; Thomas SE et al 2005 Cell 123:555.

Achilles' Heel Technique: A technique applicable to systems where there is abundant sequence information, and it permits the cleavage of only a small set of restriction sites. It works this way: DNA sequences around the site or set of sites are synthesized and added to the genomic DNA along with RecA, and a methylase. After deproteinization, a restriction enzyme is added. All the (methylated) restriction sites are protected from cleavage except those that were covered by the RecA-DNA complex. ▶DNA sequencing, ▶Rec, ▶methylase, ▶methylation of DNA, ▶restriction enzyme; Szybalski W 1997 Curr Opin Biotechnol 8:75.

Achondrogenesis: Achondrogenesis has been described in two or more autosomal recessive forms involving deficiency in bone formation at the hip area and large head, short limbs, stillbirth or neonatal death. The phenotypes show variations and clear-cut differentiation of the symptoms is difficult. ▶achondroplasia, ▶hypochondroplasia, ▶stature in humans, ▶collagen

Achondroplasia (ACH): A rather common chromosome 4p16.3 dominant (homozygous perinatal lethal) type of human dwarfness that was observed (see Fig. A15), e.g., in Denmark at a frequency of 1.1×10^{-4} . Its mutation frequency (predominantly of paternal origin) was estimated to be within the range 4.3 to 7×10^{-5} .

The proximal bones in the limbs are most reduced. Large head with disproportionally small mid-face, abnormal hip and hands are characteristic. The heterozygotes are generally plagued by heart, respiratory and other problems. Hypochondroplasia appears to be allelic to achondroplasia. The so-called Swiss type achondroplasia is recessive and the afflicted individuals show reduced amount of leukocytes (lymphopenia) and agammaglobulinemia. Pseudo-achondroplastic dysplasias (PSACH, spondyloepiphyseal dysplasia) are autosomal recessive (19p13.1) but some ambiguities were noted regarding the pattern of inheritance because of apparent gonadal mosaicism. PSACH is apparently due to defect in the cartilage matrix. The different forms do not have clear phenotypic distinctions within the group and from the dominant achondroplasia. Some of the skeletal reductions and defects are aggravated by face, eye defects, cleft palate and muscle weakness. Achondroplasia is caused by defects in lysosomal targeting of the fibroblast growth factor receptor 3 (FGFR-3), located

Figure A15. Autosomal dominant type achondroplasiac adolescent. (Courtesy of Dr. Rimoin DL Harbor General Hospital, Los Angeles, CA, and Dr. Judith Miles)

A

in human chromosome 4p16.3. A recurrent missense mutation in a CpG doublet of the transmembrane domain of FGFR-3 caused an arginine substitution for glycine. Achondroplasia with developmental delay and acanthosis nigricans and thanatophoric dysplasia are also defective in fibroblast growth-factor receptor 3. Achondroplasiacs usually display normal intelligence. ▶stature in humans, ▶hypochondroplasia, ▶pseudoachondroplasia, ▶achondrogenesis, ▶Ellis-van Creveld syndrome, ▶agammaglobulinemia, ▶cleft palate, ▶fibroblast growth factor, ▶dwarfism, ▶receptor tyrosine kinase acanthosis nigricans, ▶thanatophoric dysplasia; Cho JY et al 2004 Proc Natl Acad Sci USA 101:609.

Achromatic: Parts of the cell nucleus, which are not stained by nuclear stains. A microscope lens that does not refract light into different colors is achromatic.

Achromatopsia: Recessive inability to distinguish colors, low visual acuity and involuntary eye movements (nystagmus) is a rod monochromatism due to defects in the α -subunit or β -subunit of the cone cyclic nucleotide-gated cation channel (8q21-q22). This normally generates the light-evoked electrical responses of the cone receptors. Another locus 2q11-q12 with defect in the α -subunit of the cGMP gated ion channel debilitates the cone photoreceptor, and a third locus (Xp11.4) with cone dystrophy cause achromatopsia.

Acid-Base Catalysis: Acids and bases are common catalysts of organic reactions in proportion of the presence of H^+ or OH^- ions in the medium. Enzymes are particularly well-suited catalysts because they can carry out either acid or base, or simultaneously both acid and base catalysis. Ribozymes are also potential acid/base catalysts. ▶transition state

Acid Blob: A sequence of acid amino acids (negatively charged), responsible for activation of a transcription factor. ▶transcription factors; Almlof T et al 1995 J Biol Chem 270:17535.

Acid Fuchsin: A histological stain used to detect connective tissue and secretion granules (Mallory's acid fuchsin, orange G and aniline blue, and in the Van Gieson's solution of trinitrophenol staining of connective tissue of mammals). ▶stains

Acid Maltase Deficiency: A type II glycogen storage disease involving defect(s) in α -1,4-glucosidase activity. The disease causes accumulation of glycogen in most tissues, including the heart. The first symptoms appear by 2 months after birth and by 5–6 months death results due cardiorespiratory (heart and lung) failures. Although it is classified as an autosomal recessive trait in humans (GAA, 17q25.2-q25.3), the heterozygotes may be distinguished

clinically. ▶glucosidase, ▶Gaucher diseases, ▶glycogen storage diseases

Acid Phosphatase: Cleaves phosphate linkages at low pH. Its levels are increased in most lysosomal storage diseases, particularly in Gaucher's diseases involving glucosyl ceramide lipidosis (defect in lipid metabolism involving cerebroside, a complex of basic amino alcohols [sphingosine], fatty acids and glucose). Other diseases may also cause increase of acid phosphatase. In plants, only acid phosphatases are found in appreciable quantities. Yeast has at least 4 genes with acid phosphatase function; one of them is constitutive, others are repressed by inorganic phosphate. ACP1 is in human chromosome 2p25, ACP2 in 11p12-p11. ▶alkaline phosphatase

Acid Reflux: Retrograde movement of stomach acid and bile to the throat and mouth. ▶Barrett metaplasia

Acidic Dyes: Stain basic cellular residues.

Acidic Sugars: ▶sialic acids

Acidocalcisomes: ▶organelle

Acidosis: A reduction of buffering capacity of the body resulting in lower pH of fluids.

Acid-Sensing: Acid-sensing is mediated by proton-gated ion channels in the sensory neurons. ▶ion channels

Acinar Cells: Exocrine cells, for e.g., mammary gland cells that secrete milk, lacrimal cells that secrete tears, etc. Acinar cells resemble sacs. ▶exocrine

Acinus (apoptotic chromatin condensation inducer in the nucleus): Apparently the substrate of caspase-3 and this cleavage activates pyknosis in the cell nucleus. ▶pyknosis, ▶karyorrhexis, ▶apoptosis, ▶caspase, ▶CAD; Seewaldt VL et al 2001 J Cell Biol 155:471.

Acinetobacter: Oxidase-negative, Gram-negative coccobacilli of widespread habitat but become infective primarily in hospitals affecting immune-compromised or wounded individuals. (Rahal JJ, Urban C 2000 Semin Resp Crit Care Med21(4):341). The bacteria are resistant to the majority of antibiotics and cause up to 40% death. ▶nosocomial; Huys G et al 2005 J Med Microbiol 54(Pt 9):851.

ACIS (automated cellular image analysis): Detects rare cells (e.g., metastatic tumor cells occurring at a frequency of 10^{-6} to 10^{-7}) after immunocytochemical staining. Its efficacy far exceeds that of the manual detection. metastasis, ▶FAST; Bauer KD et al 2000 Clin Cancer Res 6:3552.

AcMNPV (*Autographa californica* nuclear polyhedrosis virus): AcMNPV can be used for the construction

of insect and mammalian transformation vector.
 ► [baculovirus](#), ► [polyhedrosis virus](#)

Acne: Inflammation of the sebaceous glands (that secrete oily stuff on the skin). It does not appear to be under strict genetic control, but rather caused by various environmental conditions, including bacterial infections, mechanical irritation, cosmetics, etc. It usually appears in puberty and disappears after but may leave behind permanent scars. Occasionally it occurs on infants. *Propionibacterium acnes* is one of the major causes of acne has a completely sequenced genome of 2,560,265 base pairs contains about (2333) genes and can cause several other diseases (Brüggemann H et al 2004 Science 305:671). ► [skin diseases](#)

Aconitase: An enzyme controlling the dehydration of citrate to cis-aconitate and the hydration of the latter to isocitrate. This enzyme has also an important role in the transport of iron. Iron-containing proteins regulate many processes in both prokaryotes and eukaryotes. In eukaryotic cells, the level of the storage protein ferritin increases when soluble iron level increases in the cytosol. The control of the process is mediated by a 30-nucleotide *iron-response element* to what aconitase binds and then blocks the downstream translation of RNA. Aconitase is an iron-binding protein, and the increasing level of iron within the cell dissociates it from the ferritin mRNA resulting in about two order of magnitude increase of ferritin by releasing the translation suppressor from the ferritin mRNA. The increased level of iron also decreases the stability of several mRNAs encoding the receptor that binds the iron-transporting transferrin and thereby reduces the amount of the receptor. Aconitase also binds to the 3' untranslated tract of the transferrin receptor mRNA and enhances the production of the receptor, probably by stabilizing the mRNA. The human ACO1 gene is in chromosome 9p22-p14 and the mitochondrially located ACO2 is encoded in 22q11-q13. The mitochondrial aconitase, besides its metabolic function, contributes to the maintenance of mitochondrial DNA (Chen XJ et al 2005 Science 307:714). ferritin, ► [translation repressor protein](#), ► [IRE](#), ► [rabbit reticulocyte in vitro translation system](#); Bulteau A-L et al 2004 Science 305:242.

α -CPM: (α -connecting peptide domain): Connects the α and β chains of the $\alpha\beta$ T cell receptor but it is absent from the $\gamma\delta$ T cell receptor. This domain is required for positive selection of T cells although negative selection may take place in its absence. ► [T cell](#), ► [T cell receptor](#), ► [positive selection of lymphocytes](#)

Acquired: Alteration that occurred during the lifetime of an individual. ► [constitutional](#)

Acquired Characters, Inheritance of: An ancient idea supposing that the minor and major environmental

effects may cause long-lasting heritable changes in the genetic material. This view was proved incorrect by the advances of biology in the ninetieth century. However, poorly trained ideologues of Marxism, the followers of Mitchurin and Lysenko, revived it in the Soviet Union. Modern biologists, who claim the existence of environmentally inducible selective mutations, periodically resurrect it. Most of these recent experiments remain controversial because alternative explanations of the experimental data seem to be as good or even more satisfactory (see directed and local mutagenesis). Genetic transformation by plasmid vectors has been compared with inheritance of acquired characters. However, substantial differences exist between the two phenomena; in transformation, the actual transfer or loss of genetic material (DNA or RNA) has been demonstrated by standard molecular methods. In many cases, claims of inheritance of acquired characters in higher plants and animals have not been demonstrated. Landman (1993 BioScience 43:696) states "so far as I know, only changes in nucleic systems can be transmitted through the germline." Nevertheless, Landman (1991 Annu Rev Genet 25:1) lists a few apparent exceptions (unicorns in the garden, in the words of Frank Stahl) such as the cortical inheritance of *Paramecia* or the epigenetic changes in histone methylation or prions. Recently observed paramutation-like unorthodox cases of inheritance in plants and animals are rather unorthodox phenomena. These examples are in sharp contrast to those published during the soviet era, which do not meet the current scientific standards because the experiments did not use reliable controls and the genetic constitution of the material was either obscure or obviously contaminated.

Advantageous frameshift backmutations may take place, however, under selective conditions by recombination. The inheritance of acquired characters has also been attributed to a mechanism of canalization. The change in the environment permits selection of hidden variations in chaperones adapted to the environmental change. Even after the release of the stress, the selected new forms of the chaperones may persist and simulate inheritance of acquired characters. ► [Lamarckism](#), ► [Mitchurinism](#), ► [Lysenkoism](#), ► [soviet genetics](#), ► [graft hybridization](#), ► [transformation](#), ► [recombination](#), ► [frameshift](#), ► [backmutation](#), ► [chaperones](#), ► [canalization](#), ► [evolution](#), ► [epimutation](#), ► [paramutation](#), ► [cortical inheritance](#), ► [epigenesis](#), ► [epigenetics](#), ► [prions](#), ► [transformation genetic](#); Zirkle C 1946 The Early History Of The Idea Of The Inheritance Of Acquired Characters And Pangenesis. American Philosophical Society, Philadelphia; Lindegren CC 1966 The Cold War In Biology, Planarian Press, Ann Arbor, Michigan.

A

Acquired Immunity (adaptive immunity): The consequence of natural infection or vaccination or direct transfer of antibodies or lymphocytes from an appropriate donor. The acquired immunity is based on potential variations in the immunoglobulins in response to invading antigens. Somatic gene rearrangements lead to the generation of immune receptors in lymphocytes and the activated lymphocytes are clonally propagated. This immunity system consists of CD4⁺ and CD8⁺ T cells. T cells recognize antigens after being processed by the antigen presenting cells (dendritic cells, macrophages and B cells), which express MHC class II molecules. After the recognition, T helper cells (T_H-1 and T_H-2) differentiation begins. T_H-1 cells characteristically produce gamma interferon (INF- γ), which attacks intracellular invader microbes. For T_H-2 cells interleukin-4 (IL-4) is diagnostic. T_H-2 cells requires MHC class I molecules while T_H-1 cells depend on MHC class II. Both helper T cells utilize a variety of cytokines for the development of effector function, i.e., to be fully activated. In insects (*Drosophila*) the phagocytic plasmatocytes represent the cellular defense. In addition, the humoral reaction develops to microbial challenge by the secretion antimicrobial peptides into the hemolymph. ►innate immunity, ►immune system, ►immunity, ►vaccine, ►antimicrobial peptide; Crowe JE Jr et al 2001 J Immunol 167:3910; in vivo test model for human adaptive immunity in mice: Traggiai E et al 2004 Science 304:104; evolution of adaptive immunity: Cooper MD, Alder MN 2006 Cell 124:815.

Acquired Immunodeficiency Syndrome (AIDS): Caused apparently by the HIV-1 (HTLV-III) and HIV-2 (human immunodeficiency virus [lentivirus]), retroviruses. The general structure of the HIV-1 virus includes three major structural proteins: gag, pol and env, and several regulatory and accessory proteins: vif, vpr, vpu, vpt, tev/tnt (see Fig. A16).

The gag proteins serve as structural elements: 132 amino acid matrix [MA], 152–231 amino acid capsid [CA], 55 amino acid nucleocapsid [NC] and 51 amino acid p6 [vpr-binding protein]. The pol is processed into the dimer of two 99 amino acid protease [PR], reverse transcriptase [RT] is heterodimer of 560 and 440 residues, and the tetrameric, and the tetrameric integrase [IN] of 288-residue monomers. The reverse transcriptase generates the enzyme, which transcribes RNA into DNA and this viral copy can be inserted into the human chromosome and survive there for a long time as a provirus. The protease processes the polyproteins into the various enzymes of the virus and integrase facilitates the entry of the virion into the host cells. When HIV-1 traverses the inner nuclear envelope of the cell (macrophages) it contacts the emerin protein that facilitates viral integration into the

Figure A16. HIV-1. The schematic structure of the HIV-1 virus. The gp120-gp41 heterodimer associate in a trimer to form the spikes. This and the envelope determine antigenicity and immunogenicity (gp indicates envelope glycoproteins). Cryoelectron microscopy tomography revealed ~14 spikes per HIV-1 virions and ~73 spikes per particle of SIV. The surface gp120 of the trimeric SIV spike contains a primary mass with two secondary lobes. The transmembrane glycoprotein stalk of each trimer is composed of three independent legs projecting from the trimer head in tripod-like form (Zhu P et al 2006 Nature [Lond] 441:847)

chromatin (Jacque J-M, Stevenson M 2006 Nature [Lond] 441:641). The von Hippel–Lindau binding protein 1 (VBP1), a subunit of the prefolding chaperone, is an integrase cellular binding protein that bridges interaction between integrase and the cullin2 (Cul2)-based von Hippel–Lindau (VHL) ubiquitin ligase. VBP1 and Cul2/VHL are required for proper HIV-1 expression at a step between integrase-dependent proviral integration into the host genome and transcription of viral genes. VBP1 and the Cul2/VHL ligase cooperate in the efficient polyubiquitylation of integrase and its subsequent proteasome-mediated degradation (Mousnier A et al 2007 Proc Natl Acad Sci USA 104:13615).

The env envelope protein includes a surface glycoprotein, gp120 [SU] and a transmembrane glycoprotein, gp41 [TM] that are processed from gp160 molecule. Protein gp120 facilitates binding the virus to the cell membrane and gp41 promotes fusion to the membrane. Human monoclonal antibody may block the virus by binding a critical region of gp41 epitope and may offer an approach of prevention of infection (Miller MD et al 2005 Proc Natl Acad Sci USA 102: 145759). The processing facilitates the interaction of the virus with the CD4 host cells and the CXCR4 and CCR co-receptors. The envelope protein vpr (14 kDa) accelerates replication

and infection. Vpr facilitates the transport of the viral core into the nucleus, stimulates the expression of viral genes and mediates cell cycle arrest at the G₂ stage (de Noronha CMC et al 2001 Science 294:1105).

Rev (19 kDa) is transcribed from two exons, regulates viral replication and its basic amino acid domain (nuclear export signal, NES) interacts with the Rev response element (RRE, within *env*) targeting the viral transcripts to the cell nucleus. Within the nucleus, the exportin-1/CRM1 protein represents a receptor for NES. Tat (14 kDa, two exons) is the primary regulator of the virus. Vpu (15–20-kDa) membrane protein attacks CD4 with the assistance of the proteasome degradation pathway. Nef (25–27 kDa) mediates the degradation of CD4 on the cell surface and promotes endocytosis through the clathrin-coated pits. Nef and Tat proteins may be produced before the integration of HIV into the chromosome. These two proteins activate quiescent T cells, a requisite for viral integration and replication. Activation of CD4⁺ T lymphocytes and apoptosis that follows is an important sign of infection by HIV-1 and the Nef gene mediates this process through the T cell receptor-CD3 complex. The majority of other lentiviruses down-modulate this complex and less likely to give infection.

If Nef is inactivated AIDS progression slows down because T cells are not destroyed. Thus, it appears that human HIV-1 evolved by the loss of this function of Nef, resulting in immune evasion and AIDS (Schindler M et al 2006 Cell 125:1055).

Active genes are preferential targets of integration. (Schröder ARW et al 2002 Cell 110:521). Nef also inhibits the cellular protein ASK1, an apoptosis signaling serine/threonine kinase. That protects the infected cells from apoptosis although neighboring cells may die through bystander effect. Successful entry and productive infection requires the cooperation of the cellular protein cyclophilin A. In case cyclophilin is inhibited, HIV cannot infect neighboring cells even if HIV is within the originally infected cell. Similarly, by blocking the activity of MAPK, virulence of HIV is reduced. The viral Vif (virion infectivity factor) protein (23 kDa) is also required for the assembly of the viral coat proteins after infection (see Fig. A17). Vif also prevents deamination of cytidine into uracil by host APOBEC3 to avoid the

damage to viral RNA (Priest S et al 2005 Mol Cell 17:479). Non-permissive host cells produce the CEM15 protein, which prevents viral infectivity of Vif-deficient HIV. CEM15 is absent from permissive cells and this permits infection by Vif-deficient virus (Pomerantz JR 2002 Nature [Lond] 418:594). For entry into the cell nucleus, the virion needs the nuclear localization signal (NLS) provided by the uncoated viral nucleoprotein pre-integration complex (PIC). Viral protein Vpr interacts with PIC and thus assists nuclear localization of HIV. The virus is not transmitted through the germline. The *tat* gene functions only through the 5' RNA hairpin TAR (transactivation response element, 59 nucleotides) present within the repeat region (R) of the 5' LTR. The 5'LTR includes also the basal core promoter, the core enhancer and a modulatory region. The eukaryotic eIF2 elongation initiation element recognizes TAR. The 5' LTR serves also as the binding sites for a large number of host transcription factors (Pereira LA et al 2000 Nucleic Acid Res. 28:663). The Tat (14 kDa) primarily regulates the elongation of the transcript, generated by host RNA polymerase II. Pol II starts working at the 5' LTR. The Tak-associated kinase (TAK) complex phosphorylates the COOH end (CTD) of transcriptase pol II. The phosphorylation is the job of Cdk9 (formerly called (PITALRE). Cdk9 is bound to Tat by cyclin T (CycT) and enhances the specificity of Cdk9 to 5'-TAR. The TATA box is situated –24 to –28 positions from the GGT initiator codon. Further upstream in the enhancer region are the binding sites for the USF (upstream enhancer), Ets-1 (thymocyte-enriched protein), LEF (lymphocyte-specific high-mobility group protein), NK-κB (nuclear factor κ binding protein) and Sp1 (a mammalian transcription factor) binding proteins within the region –166 to –45 in the 5'-LTR. Around the transcription initiation site are the overlapping SSR (initiator) and IST (initiator of short transcripts) sequences. The virus does not have known genetic repair system and displays great antigenic variability; therefore, it is difficult to develop an effective vaccine against it (Rossio JL et al 1998 J Virol 72:7992; Gaschen B et al 2002 Science 296:2354; cardiolipin).

The Nef protein protects the infected primary cells from cytotoxic T cells. The viral coding RNA genome

Figure A17. Genetic organization of HIV-1

A

is about 9 kb. HIV1 and lentiviruses are suitable for the construction of transformation vectors that may integrate into non-dividing cells. Two of the viral proteins interact with nuclear import and mediate the active transport of the HIV pre-integration complex into the nucleus through the nuclear pores. The infection begins when the virus penetrates the cell membrane and its own lipid membrane fuses with the cell membrane and the viral core is released into the cell. Inside the cell, the viral reverse transcriptase synthesizes DNA copies of its RNA genome, and this DNA provirus integrates into the host genome with the aid of its terminal repeats, characteristic also for all types of insertion elements yet HIV is not transmitted through the germline. The HIV contains genes for proteins and their regulation. HIV does not have a lytic phase so it does not kill the cells directly. Instead, it assembles its particles in the cytoplasm and then infects other cells.

Upon infection by the HIV, monocytes, macrophages, endothelial cells and fibroblasts overproduce IL-1, IL-6 and TNF α . The anti-inflammatory IL-1ra and IL-10 are also hyperproduced. The latter ones inhibit the synthesis of the inflammatory lymphokines and IL-12. Soluble tumor necrosis factor receptors (sTNFR) hinder the binding of TNF to the cell membrane receptors. *Staphylococcus*-stimulated monocytes produce an order of magnitude less IL-12. After HIV infection CD4⁺ T cells lower the output of IL-2. Since IL-2 stimulates several players of the immune system, the immune response decreases. The dysregulation of cytokine balance results in a deficiency of cell-mediated immunity. The delayed-type hypersensitivity reaction (DTH) cannot control then the intracellular microorganisms. The main cause of the immunological failures is the defect in the CD4⁺ T cells, in the antigen presenting cells and the destruction of the CD4⁺ T cells although several billion CD4⁺ T cells are produced every day after the infection. A portion of the AIDS patients—upon induction by a gp41 peptide—express the natural cytotoxicity receptor, NKp44 and consequently the natural killer cells deplete the CD4 T cells and increase HIV load (Vieillard V et al 2005 Proc Natl Acad Sci USA 102:10981). The killer cell immunoglobulin-like receptor (KIR) family members similar to other NK cell receptors are expressed on T cells as well as on NK cells. Activating *KIR3DS1* allele in combination with *Bw4-80I*, associates with protection against HIV disease progression, as well as against opportunistic infections in HIV⁺ individuals. *KIR3DL1* and *HLA-B Bw4* combination effectively increases the protective effect of NK (killer T cell) against HIV (Martin MP et al 2007 Nature Genet 39:733).

The primary targets are the helper T lymphocytes carrying the CD4 receptors. The immune system is

debilitated when impairing these cells and that is the primary cause of the disease. In the endoplasmic reticulum of the infected cell 845–870 amino acid protein precursors of the viral envelope are formed. After the addition of asparagine-linked mannose chains, the glycoprotein gp160 precursor is synthesized. The trimeric gp160 is carried to the Golgi apparatus where through proteolysis the gp120 envelope protein and gp41 transmembrane proteins are formed.

Targeting the gp41 carboxy-terminus by a small protein, called 5-Helix, inhibits the entry of HIV-1 into the cell. A 20-residue peptide, called virus-inhibitory peptide (VIRIP) similar to the C-proximal region of $\alpha 1$ antitrypsin protease inhibitor interferes HIV-1 entry by targeting gp41 envelope protein of the virus. A few amino acid replacements in this natural peptide may increase its potency by two orders of magnitude (Münch J et al 2007 Cell 129:263). The binding of CD4 on the lymphocytes, monocytes, dendritic cells and brain microglia by the gp120 viral surface protein results in a conformational change in gp120. These changes may make available binding sites for chemokine receptors (primarily CCR5 and ligand CXCR4) to secure the necessary second receptors for the viral entry into the cell. Sulfated tyrosines of the CCR5 co-receptor play an important role in binding the gp-120 viral glycoprotein and HIV-1 infection (Choe H et al 2003 Cell 114:161). Mutation in CCR5 (CCR5 Δ 32) reduces the chance of HIV infection and disease progression (Agrawal L et al 2004 J Virol 78:2277). A chemically modified RANTES through inhibition of CCR5 provides protection against vaginal infection of simian/human immunodeficiency virus (Lederman MM et al 2004 Science 306:485). Polymorphism of these receptors and the stromal-derived factor (SDF-1) may either accelerate or retard the progression of the disease. Organ culture method permitted the identification of HIV infection sites in the vaginal and cervical mucosa and the virion binding can be reduced by pre-treatment with antibodies against $\beta 1$ integrin (Maher D et al 2005 Proc Natl Acad Sci USA 102:11504). Another approach would be populating the vaginal, cervical or rectal mucosa with bacteria secreting antiviral peptide. Such initiatives indicate that such a procedure might be effective (Rao S et al 2005 Proc Natl Acad Sci USA 102:11993).

The feline immunodeficiency virus uses directly the chemokine receptors and the V3 loop of the variable region is the most important for binding of the chemokine receptors. The constant regions in between the V regions are folded into the core of the glycoprotein. A so-called bridging sheet that binds to CD4 connects the outer and inner domains of the core. Mutations in the core area may influence infectivity and may serve as target for medical attack on the virus.

The CD4 induced antibodies (CD4i and its 17b epitope) may block the binding of the gp120—CD4 complexes to the chemokine receptors. The crystal structure of the V3-containing core of gp120 is known (Huang C-c et al 2005 Science 310:1025).

For neutralizing HIV probably the CD4BS epitopes, directed to the gp120 inner core are most significant. The 2G12 antibody recognizes the outer domain of gp120. The antigenic surface of gp120 is largely shielded from humoral immune responses by the glycosylation and other barriers. Conformational changes in gp120 provide additional structural means for the evasion of the immune reactions.

Avoidance of infection through body fluids (blood, semen, saliva, etc.) is the only effective defense until a clinically effective immunization or cure can be developed.

Human monoclonal neutralizing antibody b12 recognizes a conformational epitope that overlaps with the CD-4-binding site of the HIV-1 gp120 (see Fig. A18). In animals, b12 has a broad specificity.

Figure A18. The b12 antibody (blue) to the HIV-1 exterior glycoprotein (red). The sugar (gray) occludes most of the gp120 surface from recognition. The blue surface (the epitope) marks where the receptor CD4 binds overlapping the b12 recognition site. (Courtesy of Peter D. Kwong and Jonathan Stuckey, Vaccine Research Center, NIAID/NIH)

Unfortunately b12-like antibodies are rarely produced in infected and vaccinated human subjects, indicating that the b12 epitope is poorly immunogenic for gp120—gp41 proteins. The gp120 viral glycoprotein has great ability to evade the human immune system.

The crystal structure of a constructed and stabilized gp120 molecule, which stays in the CD4-bound

conformation even in the absence of CD4 was tested regarding antibody binding. The broadly acting antibody b12 in complex with this gp120 molecules was stabilized to various extents in the CD4-bound conformation and revealed the functionally conserved surface that allows for initial CD4 attachment, but also provides an atomic-level description of the b12 epitope, which serves as a key target for humoral neutralization of HIV-1. Thus, a site of vulnerability was revealed that shows promise for antibody targeting HIV-1 (Zhu T et al 2007 Nature 445:732; see structure diagram). Another type of vaccine using gp140R2 immunogen induced antibodies that achieved 50% to 80% neutralization of diverse HIV-1 subtypes (B and C and others) tested on rabbits. The effectiveness of gp120R2 induced antibodies was less good. The rare R2 type was selected because it had unusual CD4-independent phenotype and the exceptionally broad neutralizing response in the infected donor. Neutralization was IgG-mediated and HIV-1-specific. These results demonstrate that induction of truly broad-spectrum neutralizing antibodies is an achievable goal in HIV-1 vaccine development (Zhang PF et al 2007 Proc Natl Acad Sci USA 104:10193).

Generally, the first sign of the disease is the susceptibility to *Pneumocystis carinii*, an opportunistic fungal pathogen causing influenza-like symptoms. This happens because the AIDS patients have only 200 CD4 helper cells per mL of blood versus 800 in normals. The other, most critical, diagnostic feature of AIDS is the development of Kaposi's sarcoma, a disease causing bluish eruptions all over the body that becomes cancerous. In tissue culture, the infected and uninfected cells fuse into syncytia and this and immunological methods are used as laboratory diagnostic procedures for the infections. AIDS, one of the most dreaded diseases of the twentieth century is now being battled with the most advanced techniques of molecular genetics; yet no effective cure has been devised till year 2008.

Although the majority of the specialists in medical virology and molecular biology maintain the view that the causative agent of the disease is HIV, some reject this assumption and others look at the mechanism with some reservations. They find likely or conceivable that AIDS is the result of the synergistic action of viral and other requisites such as the use of drugs (antibiotics, etc.), some types of autoimmune predisposition, and thus has multifactorial origin.

The AIDS disease has infected >21 million people worldwide and their numbers are increasing daily by 8,500–14,000 individuals. There are now three main groups of HIV-1: (i) M type, which is the most widely spread, (ii) the O group in Cameroon, Gabon and equatorial Guinea and a new (iii) N type found in (1998) in Cameroon, Africa. There are also 10 known

A

subtypes of the virus. The three main types appear to have originated independently from the chimpanzee virus SIVcpz. The HIV-2 strains seem to be originated in West Africa from the simian virus strain SIVsm of the sooty mangabeys (*Cercopithecus atys*). Adaptation to infectious forms of the virus required mutation as well as recombination. There are at least 10 host genes involved in the degree of susceptibility (Heeney JL et al 2006 Science 313:462).

A whole-genome study identified polymorphisms that explain nearly 15% of the variation among individuals in viral load during the asymptomatic set-point period of infection. One of these is found within an endogenous retroviral element and is associated with major histocompatibility allele human leukocyte antigen (HLA)-B*5701, whereas a second is located near the HLA-C gene. An additional analysis of the time to HIV disease progression implicated two genes, one of which encodes an RNA polymerase I subunit (Fellay J et al 2007 Science 317:944).

The suggestions that the AIDS epidemics originated through SIV contamination of the early polio vaccines do not seem to have scientific basis.

The pharmaceutical industry is developing various drugs to combat the disease. None of the drugs so far provides a full cure or prevention, yet definite progress is made. The first and best-known chemicals (AZT) attack the viral replication system; protease inhibitors are aimed at the assembly process of the viral coat protein in order to prevent multiplication of HIV (Prejdova J et al 2004 Curr Drug Targets Infect Disord 4(2):137). The virus depends on cutting and processing of host cellular protein and uses protease to this end. Unfortunately, the protease inhibitors may cause very unpleasant side effects and HIV may develop resistance against the drugs by inhibiting primarily the mitochondrial DNA polymerase γ and possibly other DNA polymerases (Feng JY et al 2001 J Biol Chem 276:23832). None of the current drugs actually kills and/or removes the virus; instead only limit its functions. Halting the treatment may lead the virus to re-emerge from its hiding place in the lymph nodes. Other potential drug targets may be the cells' entry sites and CXCR4 and CCR5 receptors. According to some estimates HIV may produce >10 billion virions daily. Since its genome contains 10^4 nucleotides, the virus can readily test all possible mutational combinations. The estimated number of mutations/replication/nucleotide is 3×10^{-5} . The generation time is about 2.5 days. Drug resistance is based primarily on new mutation rather than on transmission of resistant virus. In addition, recombination facilitates the production of new variants. The combination of two nucleoside-analogs and protease inhibitor may reduce the level of the viral RNA copies

from 20,000 and 1,000,000 copies/mL plasma below detectability (i.e., below 200 to 400 copies/mL). These figures are concerned with viral levels in the blood. The newer techniques may detect even 20 virions/cell and reveal that the best medication available in (2001) cannot completely deplete the virus from the body. The lymph nodes and other sanctuaries may regenerate the virus after the discontinuation of the therapy. Additional problems may arise from the irreversibility of the tissue (thymus) damage. HIV-1 replication requires the REV oncogene cofactor and eukaryotic peptide elongation factor EIF-5A. Some mutations in the elongation factor retained the ability to bind to the HIV-1 REV response element: REV complex, and were expressed in human cells. When such T lymphocytes were infected with replication-competent virus, replication was inhibited. RNA decoys of the Tat and Rev genes may mimic the viral TAR and RRE RNAs but are non-functional yet sequester HIV-1 regulatory functions needed for the viral replication and gene expression. RNA polymerase III synthesizes these decoys and the transcript is a tRNA-TAR chimera. The decoys may, however, tie up some cellular molecules that could interfere with TAR and RRE. Type III RNases Dicer and Drosha, responsible for miRNA processing, inhibited virus replication both in peripheral blood mononuclear cells from HIV-1-infected donors and in latently infected cells. In turn, HIV-1 actively suppressed the expression of the polycistronic miRNA cluster miR-17/92. This suppression was found to be required for efficient viral replication and was dependent on the histone acetyltransferase Tat cofactor PCAF (Triboulet R et al 2007 Science 315:1579).

Antisense/ribozyme RNAs against various (TAR, U5, *tat*, *rev*, *pol*, *vpu*, *gag*, *env*) transcripts have also been explored. Double-stranded 54-mer oligodeoxynucleotide (ODN), which consists of an antisense strand targeting the highly conserved polypurine tract of HIV, and a second strand, compatible with triple-helix formation, interferes with viral replication. Upon treatment of HIV-infected cells with ODN early after infection no viral nucleic acids, syncytia or p24 viral antigen expression was observed (Moelling K et al 2006 FEBS Lett 580:3545). ODN prematurely activates RNase H and thus inhibits the synthesis of the 2nd strand of retroviruses.

RNAi has been shown to be an effective inhibitor of HIV replication. Unfortunately, the virus can mutate at the siRNA recognition sites and escape the inhibition by producing an alternative secondary structure of the target (Westerhout EM et al 2005 Nucleic Acids Res 33:796). The viral Tat protein can abrogate the cellular RNA-silencing defense by subverting the Dicer enzyme (Bennasser Y et al 2005 Immunity 22:607).

The latent provirus, integrated into the cells, may possibly be eliminated from the body by induced apoptosis of the cells harboring the provirus. CD4 protein, conjugated with ricin or *Pseudomonas* exotoxin, may home on the gp120 viral surface proteins and may destroy the infected cells. For the incapacitation of the HIV virus self-inactivating E-vectors, removing the encapsidation signal (Ψ , psi) from the 5' LTR have been designed. Vectors containing the Cre/LoxP system are also capable of deleting the packaging signal (Ψ) and replacing it with a desired sequence. An emerging novel approach would be to employ substrate-linked protein evolution of a tailored recombinase that recognizes an asymmetric sequence within an HIV-1 LTR. This type of recombinase efficiently excised integrated HIV proviral DNA from the genome of infected cells. This approach is different from others because it would actually remove HIV from the infected human genome. Preliminary data are promising yet it is not clinically applicable (Sarkar I et al 2007 Science 316:1912). Other current research attempts are focusing on the immune system to prevent infection. Although several interpretations are available, it is still uncertain why the period required for the development of full scale AIDS requires such a different length of latency after the initial infection. It had been assumed that the immune system is weakened by the ever-increasing viral diversity. Others believe that an immune dysregulation is responsible for the outbreak. Others suggest that the cellular immune system against AIDS be directed to both conserved and variable epitopes. It is assumed that the cytotoxic T lymphocytes alone cannot eliminate the virus and there is a need to achieve a balance between the viral load and the CD4⁺ T lymphocytes. After a period, the increasing variations in the HIV-1 population deplete and foul up the immune system. In the so-called non-progressor individuals, AIDS may not develop for more than 10 or even 20 years after the infection (HIV-exposed persistently seronegatives [HEPS]). There are high levels of CD8⁺ CD38⁺ cytotoxic lymphocytes, high peripheral blood CD8⁺ major histocompatibility class I-restricted anti-HIV cytotoxic lymphocytes in the cells of such a person, and those stay at an even level. There is also a strong CD8⁺ non-MHC-restricted HIV suppressor activity and high level of antibody against HIV. Most untreated HIV-1-infected individuals have continuous viral replication and ultimately progress to AIDS. However, a rare subpopulation of HIV-infected patients spontaneously controls viral replication for long periods in the absence of treatment. These individuals, called HIV controllers (HIC), are characterized by undetectable plasma HIV-1 RNA. Some of these are infected by replication-incompetent

viruses yet these individuals display a potent immune response to HIV-1. The controllers generally exhibit a strong CD8⁺ T cell specific response and high frequencies of HIV-specific CD8⁺ T cells despite very low levels of viral antigens. These HIC cells express the activation marker HLA-DR but not CD38. The HIV-specific CD8⁺ T cells from HIC are thus qualitatively different from those of progressors. Some HLA-B haplotypes (e.g., B27 and B57) are over represented in HIC suggesting an important role of class I-restricted CD8⁺ T cells and multi-epitopic and *de novo* CD8⁺ T cell responses are associated with suppression of viremia despite cytotoxic T lymphocyte escape mutations (Saez-Cirión, A et al 2007 Proc Natl Acad Sci USA 104:6776).

The window of opportunity to clear HIV and prevent long-term, established infection might close permanently once a pool of latently infected cells is in place. This aspect of HIV infection puts it in sharp contrast with almost all other viral infections, in which the initial rounds of viral replication do not establish a permanent reservoir of infection. For this reason, HIV poses a greater challenge to the classic vaccination paradigm in which prevention of clinically relevant infection ultimately leads to the eradication of the microbe, even though initial rounds of viral replication may occur (Johnston MI, Fauci AS 2007 New England J Med 356:2073).

Any vaccine developed against HIV should stimulate CD4⁺ and/or CD8⁺ cytotoxic T lymphocytes. Several vaccines are under clinical trials. These are based on various viral vectors (Canary pox virus, replication defective adenovirus, adeno-associated virus) carrying some HIV-1 protein genes. The viral spikes carry gp120 and gp41 glycoproteins and facilitate viral entry of the host cells. The host cell produces an N-linked glycan on its membrane surface and this protects HIV from recognition by the host immune system. Some spike proteins evade detection by host antibodies. The spike protein gp120 can fuse to CD4⁺ before the host antibody could recognize and neutralize the viral spikes. In addition, the virus has great natural diversity and all these factors combined make vaccine development difficult. In vaccine development, two functions of the virus must be targeted: preventing HIV from finding cellular co-receptors and reducing the chance of effective fusion between the virus and the host. Antibody b12 can prevent CD4 binding or antibodies 2F5 and 4E10 can interfere with fusion. Various molecular designs are under development that creates new epitopes that elicit effective response by host paratopes. It is of consideration that the antibodies function not only in the circulation system but be expressed effectively at mucosal anatomical sites of the viral entry. CD4⁺ memory T cells may reduce viremia upon challenging

A

SIV-protein vaccinated monkeys during the initial phase of SIV infection and improves survival. The survival was associated with the preservation of memory CD4⁺ T lymphocytes and this feature may guide the evaluation of AIDS vaccines in humans (Letvin NL et al 2006 Science 312:1530). There is no vaccine available in (2006) that would prevent the infection for sure or attenuate the progression of the diseases (Douek DC et al 2006 Cell 124:677).

In case of chronic HIV infection CD8⁺ lymphocytes are impaired, display low cytokine production and reduced ability for proliferation. The cause of this is that the PD-1/PDCD1 (programmed death) and its ligand (PD-L/CD274) inhibit T cell function by antibodies to CD3 immunoglobulins. Blocking the engagement of PD-1 to PD-L1 restores lymphocyte function and reduces viral load in the cells (Trautmann L et al 2006 Nature Med 12:1198; Day CL et al 2006 Nature [Lond] 443:350). These new findings may improve the chances of fighting AIDS.

Studies indicate that in the non-progressors the gene coding for the chemokine receptors (of the non-syncytium inducing viral isolates [NSI]) CCR2 or CCR5 is mutated (contain deletion[s]), and thus it appears that CCR5 and 2 assist infection by HIV-1. These receptors are ligands for a group of CC-chemokines (CC, CXC) and MIP α and β and RANTES produced by CD8⁺ T lymphocytes. These and siRNA are able to suppress HIV replication in vitro probably by competition for the CCR5 receptors (Quin X-F et al 2003 Proc Natl Acad Sci USA 100:183). Mutation in HIV may facilitate the use by other members of the chemokine receptor family, including CCR3 and CCR2. Mutations in CX₃CR1 reduce the binding to the chemokine fractalkine and enhance the progression toward the development of AIDS. In late-disease stage cases the chemokine CXCR4/SDF1 may be used for entry into the cell. The CCR5 receptors may be polymorphic. Homozygosity and heterozygosity for the mutant alleles of CCR5 of the cells also appear to convey reduced susceptibility to infection. The viral protein gp120 reduces the response to chemokines. The frequency of the mutant alleles in Caucasian populations is about 0.092 and thus, the predictable frequency of homozygosity ($0.092^2 \approx 0.0085$) is about 1%. This type of mutation seems to be much less common in African and Japanese populations. It is also likely that some non-progressors were infected with less aggressive HIV variants. The residual genetic constitution of the infected individual may also affect the course of the disease.

A (2005) study revealed that homozygosity for a mutation in the chemokine receptor CCR5 (synonym CKR5) and CCR2 protects against HIV infection and heterozygosity may be of some advantage. Segmental duplication in human chromosome

7q11-q21 may involve one or more copies of the (CCL3L1) chemokine ligand 3-like gene (synonym MIP-1 α) and similar effects are conveyed by CCL4L1 (MIP-1 β -like). CCL3L1 is a suppressor of HIV-1 and a co-ligand of CCR5. Individuals with low copy number of CCL3L1 had 69 to 97% higher risk of infection by HIV, and an increasing risk of rapid progression to AIDS and death. Interestingly, however, various African populations—with high rates of AIDS—displayed higher copy numbers (mean 5.95) of the gene than European and other populations (2.99). Similarly, chimpanzees had higher copy numbers (9.30). The absolute gene copy number was however, substantially confounded by the overall genetic constitution. Nevertheless, in the large and diverse populations examined 42% of the infections and about 30% of the accelerated progression was attributed to CCL3L1 and CCR5 (Gonzalez E et al 2005 Science 307:1434). HIV infection takes place through these receptors. The average rate of HIV transmission was 0.0082/coital acts within approximately 2.5 months after seroconversion of the index partner, 0.0015/coital acts within 6–15 months and 0.0028/coital act 6–25 months before the death of the index partner. Higher HIV load, genital ulcer disease, and younger age of the index partner were significantly associated with higher rates of transmission in African populations (Wawer MJ et al 2005 J Infect Dis 191:1403).

A homozygous mutant form of the chemokine SDF-1 gene, which codes for the principal ligand of a co-receptor of CXCR4 of the CD4 T cells of the HIV-1 virus, substantially restricts AIDS pathogenesis. It seems to offer better protection than the CCR5 and CCR2 chemokine receptor variants. Heterozygosity for the HLA class I loci A, B and C conveys longer survival after infection by HIV-1. The latest evidence indicates that HLA-B restricted HIV-1 more than two-fold through CD8⁺ T lymphocytes than HLA-A (Kiepiela P et al 2004 Nature [Lond] 432:769). But the presence of alleles B*35 and Cw*04 potentiate rapid progression of the disease. Screening of the blood donations for possible HIV infection is based on the determination of the proportion of CD4/CD8 molecules. The normal ratio is about 2 and in infected blood it is below 1. It has been claimed that in infants, the HIV-1 infection may be transient but further analysis of these cases did not confirm the claims. None of the HIV vaccines tested so far provided protection. Attenuated live HIV with *nef* gene deletions appeared successful at first, but because of the high viral mutation rate, infective virus is recovered by time. In macaques the *nef*-defective SIV vaccine was protective. Compounds that inhibit the virus attachment to cells (CMPD167, C52L, BM-378806) applied to the vagina of rhesus monkeys

provided protection against simian-HIV-1 (SHIV-162P3) infection (Veazey RS et al 2005 Nature [Lond] 438:99). The HIV-1 virus can infect Old World monkeys but reverse transcription is blocked in these species. SIV and HIV infection involves the general destruction of 30 to 60% of memory CD⁺ T cells and indicates the onset of immunodeficiency symptoms (Mattapallil JJ et al 2005 Nature [Lond] 434:1093). The host cytoplasmic body component TRIM5 α appears to block uncoating of the retroviral capsid (Stremlau M et al 2004 Nature [Lond] 427:848). Recombinant envelope-protein-subunit vaccines also failed to elicit envelope-specific CTL or antibody-specific immune responses that could effectively neutralize HIV-1 in humans. Attempts to provide immunological protection against the V3 hypervariable loop of the viral envelope protein (essential for the viral gp120—CD4—chemokine interaction) is still being explored. Recombinant vaccinia virus carrying HIV protein fragments raised some hopes because similar constructs were effective in monkeys against SIV. Another possibility is to use engineered avian pox viral vectors, which have shown some promise (displaying some CTL activity), yet the immunogenicity generated may be too low. Unfortunately, in immuno-suppressed humans, serious side effects were encountered and the vaccines became impractical. BCG and other bacteria have also been considered as a potential vaccine vectors. DNA vaccines provide CTL activation and immune response but so far, the levels are very low to be effective. In rhesus monkeys infected with SIV lacking N-linked glycosylation at the 4th, 5th and 6th sites of the envelope protein reduced the immune evasion of the virus. Normally cytotoxic T lymphocytes (CTL) recognize the invading HIV by their surface Tat peptides. Unfortunately, through mutation this Tat peptide mutates very rapidly and becomes unrecognizable by CTLs. Immunization before infection by an appropriate Tat vaccine may provide a headway for CTL to gain control over the virus. Antisense RNA, complementary to the viral genome or to messenger RNA may also curtail viral functions by blocking transcription, translation or activation of RNase H. RNase H may significantly reduce the effectiveness of drugs inhibitory to viral replication (Nikolenko GN et al 2005 Proc Natl Acad Sci USA 102:2093)

Gene therapy using a suicide gene under the control of the HIV promoter may be activated by TAT and all the infected lymphocytes may be eliminated before the virus replication gets out of control (Caruso M et al 1995 Virology 206:495). RNA decoys that curtail replication of the virus have also been targeted at TAT. Transdominant Rev has also been used to limit productive infection (Escaich S et al 1995 Hum Gene Ther 6:625). Intrabodies were also explored as a protective measure (Marasco WA et al 1999 J

Immunol Methods 231:223). siRNA may also inhibit HIV-1 infection (Novina CD et al 2002 Nature Med 8:681). New type of drugs attempts to block the entry of the virus (Moore JP, Doms RW 2003 Proc Natl Acad Sci USA 100:10598). The integrase inhibitor drug, naphthyl pyridine carboxamide (L-870812), blocks the integration of the viral nucleic acid into the chromosome. Other well-established drugs target the reverse transcriptase (Hogberg M et al 1999 J Med Chem 42:4150), or the protease (Lebon F, Ledecq M 2000 Curr Med Chem 7:455), or both. HIV-susceptible transgenic outbred Sprague–Dawley rats can be used as an animal model for rapid and predictive preclinical evaluation of the inhibitory potency and of the pharmacokinetic properties of antiviral compounds targeting early steps in the HIV replication cycle (Goffinet C et al 2007 Proc Natl Acad Sci USA 104:1015).

So far the most effective protection from AIDS is behavioral, the avoidance of exposure to the virus. Infection by the virus is the easiest through blood cells, plasma or cerebrospinal fluids. The semen transmits 10 to 50 times more viruses than the vaginal/cervical fluids. Injection of drug, contamination by tainted blood and sexual transmission are major risk factors in the disease worldwide (Piot P et al 2001 Nature [Lond] 410:968). In the USA, the major route of infection is male homosexual contacts whereas in Africa heterosexual copulation is the predominant means of spreading the disease. ►retroviruses, ►CD4, ►CD8⁺, ►CD38, ►antibody, ►HLA, ►proteasome, ►clathrin, ►endocytosis, ►cyclophilin, ►MAPK, ►fusin, ►telomere, ►T cells, ►thymus, ►CTL, ►MIP-1 α , ►NF- κ B, ►Sp1, ►kissing loop, ►TBP, ►RANTES, ►AZT, ►TRIM5, ►Nevirapine, ►circumcision, ►SDF-1, ►TIBO, ►NF- κ B, ►Sp1, ►HMG, ►enhancer, ►herpes, ►gene therapy, ►chemokines, ►CCR, ►CXCR, ►SIV, ►cyclam, ►primates, ►chimpanzee, ►hominidae, ►vaccinia virus, ►BCG, ►immune system, ►immunization genetic, ►anti-trypsin, ►therapeutic vaccine, ►antibody neutralizing, ►antisense technologies, ►RNAi, ►seronegative, ►Kaposi sarcoma, ►HIV-1, ►integron, ►antisense technologies, ►peptide nucleic acid, ►RNAi, ►antivector cellular immunity, ►ribosome, ►ricin, ►exotoxin, ►apoptosis, ►CD4, ►E vector, ►Cre/LoxP, ►liposome, ►raft, ►biolistic transformation, ►DC-SIGN, ►DNA flap, ►reverse transcriptase and protease sequences, ►retroviral restriction factors, ►Pneumocystis carinii, ►decoy RNA, ►numt, ►APOBEC3G, ►enfuvirtide, ►von Hippel-Lindau, ►cullin, ►ubiquitin, ►prefoldin; Science 288:2129 ff; Amara RR et al 2001 Science 292:69; Nature [Lond] 410: 963 ff; Pognard P et al 2001 Annu Rev Immunol 19:253; Englert Y et al

Figure A19. Acriflavine

Acrocentric Chromosome: Has a near terminal centromere and one arm is very short (see Fig. A20); acrocentric chromosomes may fuse or become translocated and may generate biarmed chromosomes. ►Robertsonian translocations

Figure A20. Acrocentric chromosome

Acrocephalosyndactyly: ►Apert syndrome; ►Pfeiffer syndrome

Acrodermatitis Enteropathica (8q24.3): A recessive blistering of the skin usually accompanied by lack of hairs on the head, eyebrows and eyelashes, and partial pancreatic hyperplasia and thymus hypoplasia. The deficiency in zinc-binding is characteristic and causes low levels of zinc and alkaline phosphatase (a zinc metalloenzyme) in the plasma. The treatment with zinc is very successful. ►alkaline phosphatase, ►zinc

►fingers, ►skin disease, ►Wilson disease, ►Menke disease, ►hemochromatosis, ►hyperkincemia; Wang K et al 2002 Am J Hum Genet 71:66.

Acrodysostosis: An autosomal dominant defect of bone development of paternal origin and increased occurrence by the age of the father.

Acromesomelic Dysplasia: A type of dwarfism based on shortening of the forearm and foreleg and other bones because of defect in the bone morphogenetic protein-1 gene (AMDM, 9p13-q12). The Hunter-Thompson dwarfism is based on a defect of the cartilage-derived morphogenetic protein-1 (CDMP1, 20q11.2). ►bone diseases

Acromegaly: Increased growth due to over-production of the pituitary hormone. (See for review: Melmed S 2006 New England J Med 355:2558).

Acropetal: The youngest leaf on the stem is at the tip of the stem of the plant.

Acrosomal Process: A spike-like actin structure on the head of the sperms of several animals and at its base is the acrosome, a sac of hydrolytic enzymes destined to facilitate the penetration through the gelatinous coat of the egg. Before acquiring competence for fertilization the spermatozoa must be activated by bicarbonate mediated soluble cAMP. The process is enhanced by progesterone, probably by acting on a GABA_A receptor. In the starfish egg jelly *ARIS* (polysaccharide with repeating units of sulfated pentasaccharide), *Co-Aris* (steroid saponin) and *asterosap* (a variety of 34 amino acid peptides) are required for the acrosomal process. In sea urchins, FSP (sulfated fucose polymer) activates the acrosomal process. In mammalian egg, the three ZP (zona pellucida) proteins bind to the receptors on the sperm plasma membrane and stimulate the exocytosis of the acrosomal vesicle in the front part of the sperm. Activated sperm contains nitric oxide synthase and nitric oxide is important for fertilization. Phospholipase Cδ4 is also required for the process. ►acrosome, ►sperm, ►GABA, ►progesterone, ►fertilization, ►ICSI; Tulsiani DR, Abou-Haila A 2001 Zygote 9:51; Kang-Decker N et al 2001 Science 294:1531; acrosome structure: Schmid MF et al 2004 Nature [Lond] 431:104.

Acrosome: ►acrosomal process (see Fig. A21)

Figure A21. Acrosome

Acrosome Reaction: ►acrosomal process

Acrosyndesis: A spurious end-to-end pairing of the chromosomes during meiosis.

Acrylaldehyde: It is a toxic compound made from allyl alcohol by the enzyme alcohol dehydrogenase. Cells defective in this enzyme permit the selective survival on allyl alcohol as it is not converted to acrylaldehyde. ►mutant isolation, ►alcoholdehydrogenase

Acrylamide: In the presence of ammonium persulfate and TEMED (*N,N,N',N'*-tetramethylethylenediamine) it is polymerized into chains with various length depending on the concentration used. In the presence of *N,N'*-methylenebisacrylamide it becomes cross-linked and pores are formed depending on the length of the chains and the degree of crosslinking. It can be used to separate nucleotides by electrophoresis from 2000 to 6 bp, depending on the pore size of the gels. Acrylamide is a potent neurotoxin and potential carcinogen. It can be absorbed through the skin. Although the polymerized form is considered non-toxic, it should be handled only with gloves because of the trace amounts of monomers. Acrylamide may be formed in small quantities in deep-fried starchy food. ►electrophoresis, ►gel electrophoresis; Mottram DS et al 2002 Nature [Lond] 419:448.

ACT: Activator of CREM (in the testis) by binding through a LIM domain. ►CREM, ►LIM

ACT: An Artemis based DNA sequence comparison viewer program. ►Artemis; <http://www.sanger.ac.uk/Software.ACT/>.

ACTH (adrenocorticotropin hormone): ACTH controls adrenocortical growth and steroidogenesis. The hypothalamus controls the ACTH releasing factor and in response to that, the anterior pituitary releases this hormone. ACTH is encoded in human

chromosome 2. ►animal hormones, ►adrenocorticotropin, ►cAMP, ►steroid hormones, ►hormone-response elements, ►pituitary gland, ►brain, ►POMC

Actin: A protein of the cytoskeleton and the thin muscle fibers. Actin gene number varies in different organisms; yeast has only one, *Dictyostelium* 8, *Drosophila* 6, *Caenorhabditis* 4, humans about two dozen at dispersed locations. The cytoplasmic actins involved in cellular motility are similar in all eukaryotes. α -Actins are located in the smooth, skeletal and cardiac muscles. The smooth muscles have in addition γ -actin. In the cytoplasm of mammals and birds, there are β - and γ -actins. The amino acid sequence and composition of the actins is rather well conserved and differences exist mainly at the amino terminals. Actin genes have different numbers of introns and pseudogenes, permitting evolutionary inferences partly because the flanking sequences are much more variable than the genes. Some proteins bind actin in monomeric or filamentous form such as myosin (a contractile protein in muscles), α -actinin (involved in cross-linking actins). Profilin (mediates the formation of actinin bundles), fimbrin (cross-linking parallel actin filaments), filamin (promotes the gel-formation by actins), tropomyosin (strengthens actin filaments), spectrin (attaches filaments to plasma membranes), gelsolin (fragments filaments), etc. The natural products jasplakinolide and latrunculin B have opposite effects on actin filaments (see Fig. A22), the former is stabilizing while the latter is destabilizing the filaments. ►cytoskeleton, ►podosome, ►myosin, ►filament, ►microfilament, ►microtubule, ►myofibril, ►tropomyosin, ►cofilin 1, ►CDC42, ►mRNA migration, ►Wiskott-Aldrich syndrome, ►cardiomyopathy dilated, ►glomerulosclerosis, ►cytoskeleton, ►pollen, ►nemaline myopathy, ►pollen; Geeves

Figure A22. Jasplakinolide and Latrunculin B

MA, Holmes KC 1999 Annu Rev Biochem 68:687; Higgs HN, Pollard TD 2001 Annu Rev Biochem 70:649; Quinlan ME et al 2005 Nature [Lond] 433:382.

Actin Contractile Ring: Formed prior to the separation of the dividing chromosomes and contracts after anaphase. It may be involved in the formation of the septum between the two cells. ►[cell cycle](#)

Actinin, α (M_r 120 K): Antiparallel peptide in muscle Z lines, focal adhesion and intermediate junction structures. Actinin α 2 (1q42-q43) and actinin α 3 (11q13-q14) are somewhat different, yet partially compensate for each other. Their function is required for fast (not the enduring) muscle function, and the frequency of the latter gene (R577X) is significantly higher in athletes who require high velocity muscle functions (sprint, judo, short distance cyclists, speed skaters). In 18% of healthy white population, the R577X is inactive because of homozygosity of a stop codon in the gene. The female sprint athletes also show higher frequencies, however, they are generally heterozygous for the 577RX allele (Yang N et al 2003 Am J Hum Genet 73:627). ►[glomerulosclerosis](#), ►[actin](#), ►[CAM](#), ►[junction complex](#)

Actinomorphic: A structure (flower) in multiple symmetry patterns (see Fig. [A23](#)).

Figure A23. Actinomorphic

Actinomycetes: Filamentous prokaryotes rather than fungi as they once were assumed to be. ►[Streptomyces](#), ►[streptomycin](#), ►[actinomycin](#)

Actinomycin D: An antibiotic from *Streptomyces*; it is an inhibitor of transcription because it intercalates into the DNA between neighboring GC base pairs and hinders the movement of the transcriptase on the DNA template without interfering with replication; it is used in reverse transcriptase reactions to prevent self-primed second strand synthesis. Actinomycin D is a teratogen and carcinogen. (There are several other actinomycin antibiotics). ►[Actinomycetes](#), ►[Streptomyces](#), ►[transcriptase](#), ►[reverse transcription](#); Graves DE 2001 Methods Enzymol 340:377.

Action Potential: Rapid, transient, self-propagating electrical excitation in muscle or neuron membranes. It may mediate long-distance nerve signaling.

Action Spectrum: A representation of a degree of response to certain type of treatment(s),

e.g., photosynthesis in relation to wavelength of irradiation. ►[photomorphogenesis](#)

Activating Enzyme: ►[aminoacylation of tRNA](#)

Activation Analysis: A nuclear technique used for the very sensitive detection of radionuclides for various purposes including forensic analysis. ►[radionuclide](#)

Activation Domain: Generally, a loop of the proteins where phosphorylation takes place at serine, threonine or tyrosine residues.

Activation Energy: The energy required for converting 1-gram molecular weight of a compound from the ground state to the transition state. It is required, from outside, by molecules and atoms to undergo chemical reaction(s). ►[transition state](#)

Activation of Genes: ►[suppression](#), ►[activator proteins](#)

Activation of Mutagens: Many mutagens (and carcinogens) require chemical alterations to become biologically active. The mutagenic and carcinogenic properties of many agents overlap and thus active in mutagenesis and carcinogenesis. The activation generally requires enzymatic reactions. The most important enzymes are the mixed-function oxidases contained by the cytochrome P-450 cellular fraction. These reactions require NADPH and molecular oxygen and the general process is: RH (reduced reactant) + $NADPH + H^+ + O_2 \rightarrow ROH + NADP^+ + H_2O$. These enzymes occur in multiple forms and can utilize a variety of substrates, hydrocarbons, amines and amides, hydrazines and triazines, nitroso compounds, etc. They occur in different tissues of animals, primarily in the endoplasmic reticulum of cells what is generally called microsomal fraction after isolation following grinding and centrifugal separation of the cellular fractions. These enzymes are subject to induction by phenobarbitals, methylcholanthrene and a variety of substrates. Other related activating enzymes are flavoprotein N-oxygenases, hydrolases, and reductases. Other enzymes of activating ability include various transferases that add glucuronyl, sulfuryl, glutathione, acetyl and other groups and either detoxify the compounds or further enhance their reactivity. The cellular and membrane transport, protein binding, excretion affect these reactions. Genetic differences exist among the species and individuals. Differences by age, circadian rhythm and nutritional status, etc., are known. If the clearance of these compounds from the body is slow, the risk for the individuals increases. ►[promutagen](#), ►[proximal mutagen](#), ►[ultimate mutagen](#), ►[environmental mutagens](#), ►[mutagen assays](#), ►[Ames test](#), ►[bioassays of mutagenesis](#), ►[cytochromes](#), ►[P450](#); Baum M et al 2001 Chem Res Toxicol 14:686.

Activation Tagging: Random insertions of transcriptional enhancers of the 35S cauliflower mosaic virus promoter with the aid *Agrobacterium* vector into the plant genome resulting in misexpression and overexpression of many different genes concerned. ▶cauliflower mosaic virus, ▶T-DNA, ▶Ti plasmid; Weigel D et al 2000 Plant Physiol 122:1003.

Activator: *Ac*, the autonomous element of the *Ac-Ds* controlling element system of maize (see *Ac*). Also, any DNA binding protein that enhances transcription, a positive modulator of an allosteric enzyme. More than one activator of transcription may operate at different activator binding sites of a single promoter. Their action may be synergistic, or each may have special affinity to a separate surface of the RNA polymerase II molecule or one stabilizes the other activator. ▶allosteric control, ▶modulation, ▶transcriptional activator, ▶*Ac-Ds*

Activator A: Synonymous with RF-C, a cellular replicator. ▶RF-C

Activator I: Same as ▶RF-C

Activator Proteins: Stimulate transcription of genes by binding to TATA box binding protein (TBP) and the recruitment of TFIID complex to the promoter. Sometimes they require coactivator metabolites for function. The primary role of these is probably the remodeling of the nucleosomal structure so DNA-binding proteins can access their target. The DNA has multiple binding sites for activators in the promoter region. The potency of the activation domains of the activators may vary. An activator may turn into a repressor by binding a corepressor. ▶transcription factors, ▶TBP, ▶regulation of gene activity, ▶promoter, ▶co-activator, ▶corepressor, ▶transcriptional activator, ▶enhancer, ▶chromatin, ▶nucleosome, ▶VDR, ▶recruitment, ▶suppression, ▶signal transduction, ▶chromatin remodeling, ▶GCN5; Evans R et al 2001 Genes Dev 15:2945.

Active Immunity: ▶immunity

Active Site: A special part of an enzyme where its substrate can bind and where the catalytic function is performed, the catalytic site. ▶substrate, ▶enzymes, ▶catalysis

Active Telomeric Expression Site: Variable surface glycoprotein (VSG) genes are responsible for the diversity of antigenic variants in *Trypanosomas*. These generate different antigenic properties of the parasite. There are about thousand genes in this gene family and their activation is interpreted by their transposition to the vicinity of the telomere, the expression site of the silent copies. ▶*Trypanosomas*, ▶mating type determination in yeast, ▶silent site; Borst P, Ulbert S 2001 Mol Biochem Parasitol 114:17.

Active Transport: Passing solutes through membranes with the assistance of an energy donor required for the process. ▶passive transport

Activin: Soluble protein that may contribute to the formation of dorsal and mesodermal tissues in the developing animal embryo; its activity may be blocked by *folliculin*. *Activins* belong to the family of *transforming growth factor-β* superfamily of proteins. They are serine/threonine protein kinases. Activins respond to Smad signal transducers. Activin receptor-like kinase 1 (ACVRLK1) modulates TGF signaling in angiogenesis. Its absence or deficiency results in lack of response to TGF-β family growth factors and mice afflicted by mid-gestation die due to fusion of major arteries and veins. Cultures rich in activin A facilitate endoderm production up to 80% of the experiments (D'Amour KA et al 2005 Nature Biotechnol 23:1534). ▶protein kinases, ▶TGF, ▶organizer, ▶folliculin, ▶SMAD, ▶angiogenesis, ▶fibrodysplasia ossificans progressiva; Luisi S et al 2001 Eur J Endocrinol 145:225.

Activity-Based Protein Profiling: Monitors the expression dynamics of a family of proteins on the basis of chemical tagging with common inhibitors. This type of test reveals more important information on the role of proteins in health and disease than measuring the quantity of proteins (See Liu Y et al 1999 Proc Natl Acad Sci USA 96:14694; Okerberg ES et al 2005 Proc Natl Acad Sci USA 102:4996).

Activity Coefficient: Obtained by multiplying with it the concentration of a solute to obtain its thermodynamic activity.

Actomyosin: A complex of actin and myosin. ▶actin, ▶myosin

ACTR (acetyl transferase): ▶acetyl transferases

Actuarial Analysis: Analysis of life expectancy; it is generally compared in a cohort. ▶cohort, ▶life expectancy

Acuminate: Tapered (see Fig. A24).

Figure A24. Acuminate

Acupuncture: A traditional Chinese method of releasing pain by strategically employed punctures to the body by needles. The methods are not standardized and is used by different styles. Although the physiological bases are not understood, it may be an effective treatment. (See Ahn AC, Kaptchuk TJ 2005 Altern Ther Health Med 11:50).

A

Acute Transforming Retrovirus: Contains a v-oncogene and it is an efficient oncogenic transformation agent.

►v oncogene, ►oncogenes, ►retrovirus

Acyclovir: see ►gancyclovir

Acyl Group: See Fig. A25 where R can be a number of different chemical groups. ►acetyl group

Figure A25. Acyl group

Acyl-CoA Dehydrogenase Deficiency (ACAD): Three different diseases have been described with short (SCAD, 12q22-qter), long (LCAD, 2q34-q35) and medium chain defects (MCAD, 1p31) involving β -oxidation of fatty acids. The clinical symptoms include hypoglycemia, dicarboxylaciduria, hyperammonemia, fatty liver, etc. Some of the symptoms overlap with those of the Reye syndrome and maple syrup urine disease. ►Reye syndrome, ►isovaleric acidemia, ►isoleucine-valine biosynthetic pathway

Acylation: Attaching one or more acyl groups to a molecule. ►acyl group

Acylcyclohexanedione: An inhibitor of gibberellin biosynthesis. ►plant hormones

Ad4BP: ►SF-1

Ad5 E1B: An adenovirus oncoprotein. ►adenovirus, ►oncogenes

ADA: Zn-containing proteins that transfer methyl groups to their own cysteine and thus repair aberrantly methylated DNA (e.g., 6-O-methylguanine), and by binding to specific DNA sequences it activates genes involved in conveying resistance to methylation. Some of the ADA proteins are involved in repression of transcription. ►adenosine deaminase, ►histone acetyltransferase

Adactyly: The absence of digits of the hand or foot. It may occur as part of several syndromes (see Fig. A26). ►Holt-Oram syndrome, ►polydactyly, ►ectrodactyly

Figure A26. Adactyly

ADAM (a disintegrin and metalloprotease): A family of metalloprotease enzymes such as KUZ (kuzbanian), responsible for partitioning of neural and non-neural cells during the development of the central and peripheral nervous system. ADAMs may have proteolytic, cell adhesion, signaling and fusion functions of cell surface molecules. It is apparently involved with the Notch receptor function. ADAM motifs are found in the aggrecanase enzyme eroding cartilage in arthritis. ADAM 10 (α -secretase) cleaves also the amyloid precursor protein (APP). ►neurogenesis, ►bone morphogenetic protein, ►CAM, ►Notch, ►fertilin, ►cyritestin, ►arthritis, ►secretase, ►Alzheimer disease, ►metalloproteinase, ►cardiomyopathy hypertrophic; Stone AL et al 1999 J Protein Chem 18:447; in cancer: Fridman JS et al 2007 Clin Cancer Res 13:1892.

ADAM Complex (amniotic band sequence, congenital constricting band, amputations): Acronym for Amniotic deformity, Adhesions, Mutilations phenotype complexed with other anomalies caused by mechanical constriction of the amniotic sac, but there is evidence for the role of autosomal recessive inheritance. The phenotype may include bands on fingers, and loss of finger bones or even parts of legs (amputations), etc. ►limb defects; Keller H et al 1978 Am J Med Genet 2:81.

Adams-Oliver Syndrome: Autosomal dominant mutilations of the limbs, skin and skull lesions yet apparently normal intelligence. ►ectodermal dysplasia

Adaptation: Process by which organisms develop fitness to a special environment. Mutation provides the genetic variations from which the evolutionary process selects the genes that convey the best adapt.

Adaptation may be acquired by major mutations although most commonly it is based on mutations with small cumulative effects without serious deleterious pleiotropic or epistatic consequences. R.A. Fisher expressed adaptation in “geometric” terms (see algebraic figure)

$$\frac{1}{2} \left(1 - \frac{r}{d} \right)$$

where r is the distance to what a mutation moves the population in a sphere (d) from the sphere of previous adaptation of A . If r is very small, the chances are equal to bring improvement or becoming deleterious. When however r moves beyond the sphere of A , he considered no chance for improvement. “The chance of improvement thus decreases steadily from its limiting value $1/2$ when r is zero, to zero when r equals d .” The probability for adaptive change—he concluded—is rapidly diminished when the change (d/\sqrt{n}) has manifold effects (n). Adaptation

actually limits diversification in bacterial populations (Buckling A et al 2003 Science 302:2107). In physiology, it defines adjustment to specific stimuli. Long-term evolutionary changes can be best studied under defined conditions by using bacterial cultures for thousands of life cycles (Elena SF, Lenski RE 2003 Nature Rev Genet 4:457). ▶fitness, ▶shifting balance theory of evolution, ▶plasticity, ▶noise, ▶reaction norm; Travisano M 2001 Curr Biol 11: R440; Orr HA 2005 Nature Rev Genet 6:119.

Adapter Ligation PCR: ▶capture PCR, ▶polymerase chain reaction

Adaptins (AP-1, AP-2, AP-3): Major coat proteins in a multisubunit complex on vesicles. These proteins bind the clathrin coat to the membrane and assist in trapping transmembrane receptor proteins that mediate the capture of cargo molecules and deliver them inside the vesicles. ▶clathrin, ▶cargo receptors, endocytosis, ▶epsin, ▶AP1, ▶AP180, ▶arrestin; Robinson MS, Bonifacione JS 2001 Curr Opin Cell Biol 13:444.

Adaptive Amplification: A concept somewhat similar to adaptive mutation. It has been argued that the two are different because adaptive amplification—unlike mutation—is a flexible and more readily reversible alteration. The argument has been that if the days required to reform colonies equals the number of days after selection when, e.g., the original *Lac*⁺ colony arose the original revertant was preexisting. If the days required to reform colonies is less than the number of days after selection when the revertant emerged, then the alteration permitting growth on lactose is attributed to an adaptive response to the selective condition. ▶adaptive mutation; Hastings PJ et al 2000 Cell 103:723.

Adaptive Convergence: Similarity in morphology and function among unrelated species within a particular environment, e.g., fins on fishes and mammalian whales.

Adaptive Enzyme: Same as inducible enzyme. ▶*Lac* ▶operon

Adaptive Evolution: A theory that claims evolution is largely based on mutations that increase fitness of the individuals and species involved. In contrast, the neutral mutation theory postulates the significance of the role of random neutral mutations based on synonymous codon substitutions. The relative abundance of synonymous (D_s) and non-synonymous (D_n) mutations can be estimated as (a = adaptive substitution):

$a = D_n - D_s (P_n/P_s)$ where P_n and P_s stand for the numbers of non-synonymous and synonymous substitutions, respectively. Hence, α (the amino acid substitutions brought about by positive selection) is $\alpha = 1 - (D_s P_n)/(D_n P_s)$. By using this method, 45% of the amino acid substitutions in some *Drosophila* species appeared to be adaptive.

Parallel and convergent changes in different lineages indicate adaptive evolution. It can be studied experimentally by morphology or by comparative genomics. ▶fitness, ▶mutation beneficial, ▶mutation neutral, ▶genomics; Smith NGC, Eyre-Walker A 2002 Nature [Lond] 415:1022; Cooper TF et al 2003 Proc Natl Acad Sci USA 100:1072.

Adaptive Immunity: Develops in response to an antigen. ▶acquired immunity, ▶innate immunity

Adaptive Landscape: Represents the frequency distribution of alleles corresponding to fitness of the genotypes, e.g., *Aabb* and *aaBB* means the fixation (*peak*) of the allelic pairs (see Fig. A27).

Figure A27. Adaptive landscape. (Modified after Mohay, J. 1996 Genetika)

The *pits* of fitness may mean the fixation of *AABB* or *aabb*, and the *saddle* usually corresponds to the polymorphic condition *AaBb*. A two-dimensional model of the allelic topography may represent the allelic constitutions with the corresponding fitness in a third dimension showing “mountain ranges” and “valleys.”

Figure A28. Adaptive topography (From Smith TB., Girman DJ 2000 In: Mousseau TA et al (eds) Adaptive Genetic Variation in the Wild. © Oxford Univ Press, New York p 139)

A

The landscape may be subject to evolutionary change due to change in allelic frequencies and the environment. The landscape may become complex if several allelic pairs are considered. The (+) and (−) signs indicate high and low fitness, respectively. The adaptive landscape may be represented also in three-dimensional plot (see Fig. A28). The term is the same as adaptive topography. The adaptive landscape of molecules can also be determined by engineered replacements at, e.g., coenzyme attachment sites of metabolic enzymes (Lunzer M et al 2005 Science 310:499). ▶fitness, figs., ▶mutational landscape models; Rokyta DR et al 2005 Nature Genet 37:441.

Adaptive Mutation: Occurs at higher frequency in response to conditions of selection although the mutation is not induced by the conditions of selection. A relevant assumption is that the gene number increase under the specific conditions facilitated “amplification mutagenesis.” The phenomenon is not non-darwinian as it may appear. It takes place in three steps, e.g., (i) growth limitation favors the propagation of a subpopulation with an amplification of the *lac* gene, (ii) then *lac*⁺ revertant cells are favored, (iii) eventually a stable *lac*⁺ revertant allele arises and overgrows the colony (Hendrickson H et al 2002 Proc Natl Acad Sci USA 99:2164). The selective conditions do not increase the mutation rate but instead favor the growth of rare cells with a duplication of leaky *lac* alleles. A further increase in copy number (amplification) improves growth and increases the likelihood of a sequence change by adding more mutational targets to the clone (Kugelberg E et al 2006 Proc Natl Acad Sci USA 103:17319). Similar amplification of gene number can occur in various eukaryotes.

The increased frequency of mutation under some specific selection regimes may be attributed to the differences in genetic repair. Caution is warranted in calculating the mutation rate. If, e.g., 10 mutations are observed under both the selective and non-selective conditions but the number of survivors is 50 and 100, respectively, the apparent mutation rate is double in the first lot but it is caused only by the method of assessment, 10/50 and 10/100. It is customary to calculate the rate based on survivors but it remains unknown how many of the dead individuals were mutant. If it is assessed because of the input cells, the rate may be the same under the two conditions. ▶directed mutation, ▶adaptive amplification, ▶neofunctionalization; Foster PL 1999 Annu Rev Genet 33:57; Hall BG 2001 Mol Biol Evol 18:1389.

Adaptive Peak: The highest value(s) of fitness in an adaptive landscape. ▶adaptive landscape

Adaptive Radiation: Phyletic lines spread over a variety of different ecological niches resulting in a rapid adaptation to these locales and appearing in strikingly different forms. Competition for limited resources may form a basis for adaptive radiation (Chow SS et al 2004 Science 305:84). Adaptive mutation may account also for adaptive radiation as in sequential steps—as environmental changes take place—and the adaptive mutation is selectively reinforced. ▶phylogeny, ▶niche, ▶diversity [Shannon—Weaver index], ▶frequency-dependent selection; Francino MP 2005 Nature Genet 37:573.

Adaptive Response: Induction of (bacterial) repair enzymes, which activate glycosylases or O⁶-methylguanine methyltransferase and thereby mutated DNA is repaired. The name comes from the property of adaptation to higher doses of mutagens after an initial shorter exposure; it is mediated by the *Ada* gene product (37-kDa) of *E. coli*. ▶alkylating agent, ▶chemical mutagens, ▶DNA repair, ▶glycosylases, ▶methylation of DNA

Adaptive Value: ▶fitness

Adaptor: tRNA is called an adaptor in older literature as it adapts the genetic information in DNA through mRNA to protein synthesis. ▶tRNA, ▶aminoacyl-tRNA synthetase, ▶protein synthesis; Ibba M et al 2000 Trends Biochem Sci 25:311.

Adaptor Ligation PCR: Determines the flanking sequences of a DNA sequence by the use of nested promoters and DNA adaptor in order to amplify an entire stretch of the chromosome.

Adaptor Proteins (AP): Adaptor proteins play key roles in cellular signaling such as phosphorylation, dephosphorylation, signal transduction, organization of the cytoskeleton, cell adhesion, regulation of gene expression, all distinct yet interacting systems. Proteins equipped with the Rous sarcoma oncogen (Src) homology domains SH2 and SH3 mediate the interactions between the phosphotyrosine kinase receptors of mitogenic signals and the RAS-like G proteins. The SH2 domain selects the phospho-Tyr-Glu-Glu-Ile sequences. Phospholipase C (PLC-γ1) and the protein-tyrosine phosphatase (PTPase) recognize several hydrophobic residues following pTyr on the ligand-binding molecule. The SHC homology proteins and the insulin-receptor substrate (IRS-1) recognize somewhat different sequences: Asn-Pro-X-pTyr. The SH3 binding sites involve about 10 proline-rich amino residues. The SH3-binding peptides can bind either in NH₂→COOH or in the reverse orientation. The SOS (son of sevenless) adaptor protein

binds to Grb2 (growth factor receptor-bound protein) is attached in C→N orientation. The pleckstrin domains are widespread in occurrence (serine/threonine and tyrosine kinases, and their substrates, phospholipases, small GTPases, dynamin, cytoskeletal proteins, etc.). Pleckstrin domains occur in cytoplasmic and membrane signaling molecules. The LIM domains facilitate binding of signaling molecules, transcription factors as well as the units of the cytoskeleton. These adaptor proteins may form partnerships with a variety of proteins and thus generate complex networks of signaling. (See separate entries mentioned; Hübener C et al 2001 *Immunogenetics* 53:337; Beer S et al 2001 *Biochim Biophys Acta* 1520:89).

Adaptors: ► [linker](#)

ADAR (adenosine deaminase of acting on RNA, ADAR1, ADAR2, ADAR3): ADAR2 edits the pre-mRNA of the glutamate-sensitive ion channel receptor B subunit and adenine is converted to inosine that behaves in coding as guanine. Thus, glutamine is replaced by arginine in the protein with over 99% efficiency. ADAR1 functions overlap with ADAR2 and ADAR3. ADAR3 is specific to the brain. The enzymes contain a double-strand-binding domain and a catalytic deaminase domain. Thus alternative forms of the protein appear. At the NH₂ terminus, it includes domain Z α , responsible for the high-affinity binding to Z DNA. Point mutations in AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionate) receptor may compensate for lethality in ADAR2-deficient mice. ADAR2 is concentrated in the nucleolus but can shuttle to the nucleoplasm and increasing editing of the endogenous substrate (Sansam CL et al 2003 *Proc Natl Acad Sci USA* 100:14018). Inositol hexakisphosphate (IP₆) bound to ADAR2 core is required for RNA editing (Macbeth MR et al 2005 *Science* 309:1534). ► [mRNA](#), ► [Z DNA](#), ► [Z RNA](#), ► [RNA editing](#), ► [adenosine deaminase](#), ► [DRADA](#), ► [IP₅/IP₆](#); Wang Q et al 2000 *Science* 290:1765; Bass BL 2002 *Annu Rev Biochem* 71:817; Levanon EY et al 2005 *Nucleic Acids Res* 33:1162.

AddAB: An enzyme complex involved in double-strand DNA repair in Gram-positive bacteria in a manner similar to RecBCD in Gram-negative bacteria. In the Gram-negative α -proteobacteria, however the AddAB system can function. ► [Gram-positive](#), ► [RecBCD](#); Zuniga-Castillo J et al 2004 *J Bacteriol* 186:7905.

ADCC (antibody-dependent cell cytotoxicity): Mediates some of the immune responses. ► [antibody](#), ► [immune system](#); Hinterberger-Fischer M, Hinterberger W 2001 *Expert Opin Biol Ther* 1:1029.

Addiction: A complex phenotype relative to the abuse of drugs, alcohol, smoking or habituation to other non-natural behavior. It is generally controlled by multiple genes, deeply influenced by several social conditions, and commonly associated with antisocial behavior. It is assumed that the long-term abuse of these substances causes molecular changes in the neuronal signaling. The adaptation may modify the autonomic somatic functions causing dependence and when the agent is withdrawn, result in withdrawal anomalies. The agent may alter the motivational control system resulting in craving. Chronic use of morphine upregulates components of the cAMP signal transduction pathway. In mice, with a deletion of the CREB α element the withdrawal symptoms were reduced indicating that CREB-dependent gene transcription is a factor of opiate dependence. The major receptor for opiates (morphine, heroine) is the trimeric G protein-linked μ . Long-term opiate use decreases the μ -opiate receptor signaling without reducing the number of receptors and leading to tolerance and dependence. In non-addicted individuals, the opiate receptor opens an outward rectifying K⁺ channel and reduces the phosphorylated state of a Na⁺ channel. In an addicted individual the K⁺ channel is shut off, however, and the G protein—adenylate cyclase activates a protein kinase (PKA) and the phosphorylated Na⁺ channel moves sodium inward the locus ceruleus, a pigmented structure at the floor of the brain. As a consequence, the cyclic AMP response element (CRE) binding proteins (CREB) stimulate the transcription of RNA required for adaptation to the addictive drug. The psychoactive effects of cocaine can be superseded in rats by active immunization using a cocaine conjugate, GNC-KLH (a hapten and keyhole limpet hemocyanin). Addictive agents usually raise the dopamine level in the nucleus accumbens of the brain. Recently the glutamate receptors gained attention for their role in addiction and for their chemical blocking for a cure. The glutamate receptor seems to control the Δ FosB transcription factor and enhances the sensitivity to cocaine. The genetic component of various addictions (alcohol, opiates, cocaine, etc.) may exceed 50%. The genetic bases of addiction are generally polygenic and may be studied by the methods of quantitative genetics although the specific genetic factors responsible are hard to identify and few genetic tools exist for the identification of the determination. Heritability of response to addictive agents is generally determined based on comparison of monozygotic and dizygotic twins. Heritability of addiction to smoking and alcohol abuse may exceed 0.5; heritability to opiates and cocaine is even higher. Serotonin, nicotinic cholinergic, dopamine, cannabinoid-like receptors, neuropeptides may affect responses to various drugs. Addiction may

A

occur also in rats (Deroche-Gamonet V et al 2004 Science 305:1014; Vanderschuren LJMJ, Everitt BJ *ibid* p. 1017). ▶ion channels, ▶G protein, ▶cAMP, ▶adenylate cyclase, ▶CRE, ▶CREB, ▶behavioral genetics, ▶keyhole-limpet hemocyanin, ▶dopamine, ▶glutamate receptors, ▶neurotransmitters, ▶alcoholism, ▶smoking, ▶bulimia, ▶heritability, ▶twinning; Nestler EF, Landsman D 2001 Nature [Lond] 409:834; Goldman D et al 2005 Nature Rev Genet 6:521.

Addiction Module: Represents a prokaryotic system with resemblance to apoptosis in eukaryotes. The module includes the products of two genes: one is long lasting and toxic, the other is short lived and protects against the toxic effect. The “addiction” is a dependence on the antagonist of the toxin. This system is usually controlled by plasmid elements. In the *hok-sok* module of the R1 plasmid the *sok* gene product is an antisense RNA, subject to degradation by a nuclease. Homologs of this plasmid system have been found also in the main bacterial chromosome. Encoded by the bacterial *rel* operon the MazE antitoxin protein is subject to degradation by the *clpPA* serine protease. It protects from the toxic effects of MazF toxin protein. MazE-MazF are regulated by the level of ppGpp which itself is toxic to the cells. MazE-MazF expression is regulated also by 3',5'-bispyrophosphate, synthesized by the RelA protein under amino acid starvation. ▶apoptosis, ▶partitioning; Engelberg-Kulka H, Glaser G 1999 Annu Rev Microbiol 53:43.

Addison Disease (adrenocortical hypofunction, Xq28): An autosomal dominant defect of the kidneys cortical layer resulting in excess potassium and sodium in the urine, decreased levels of cortisol and hyperpigmentation of the skin. Some forms indicate autoimmune phenotype. ▶adrenoleukodystrophy, ▶pigmentation defects, ▶kidney diseases, ▶cortisol

Addison-Schilder Disease: An Xq28-chromosome-linked adrenocortical (kidney outer layer) atrophy and diffuse cerebral sclerosis (hardening). The cerebral lesions resemble the symptoms of multiple sclerosis. ▶multiple sclerosis

Addition Lines: Carry an extra chromosome(s) coming from another genome. ▶alien addition, ▶*Haynaldia villosa* for photomicrograph

Additive Effects: Genes' additive effects means that each allele contributes quantitatively to the phenotype of an individual that carries it, i.e., there is no dominance. ▶polygenic inheritance

Additive Genes: Each allele has a definite quantitative contribution to the phenotype without dominance within a locus and without epistasis between loci or overdominance between alleles. ▶additive variance,

▶quantitative genetics, ▶heritability, ▶epistasis, ▶overdominance

Additive Variance: Each allele contributes a special value (quantity) to the phenotype and there is no interallelic (overdominance) or interlocus (epistasis) effects on the variance. ▶genetic variance, ▶heritability, ▶QTL

Additivity of Genetic Maps: Ideally means that the distance between genes A–C is equal to the sum of the distance between A–B and B–C if the order of genes is A B C. To this generally valid rule exceptions exist because of genetic interference. ▶mapping genetic, ▶recombination frequency, ▶interference, ▶coincidence

Adducin: A membrane protein mediating the binding of spectrin to actin. ▶spectrin, ▶actin

Adduct: As a verb means to draw to the median plane or axial line. As a chemical it stands for the complex of two or more components such as the cyclobutane ring of pyrimidine dimers, benzo(a)pyrene-guanine, and other alkyl groups of mutagens added to nucleic acid bases. Lipid peroxidation generates various DNA adducts with mutagenic effects similar to that caused by exogenous carcinogens. This may be the cause by the “spontaneous” cases of carcinogenicity by high-fat diet. ▶pyridine dimers, ▶ethyl-methane sulfonate, ▶benzo(a)pyrene, ▶excision repair, ▶ABC excinuclease, ▶malondialdehyde, ▶pyrimidopurines

Adelphogamy: Sib-pollination of vegetatively propagated individual plants. ▶sibling

Adenine: A purine base in either DNA or RNA. purines.

Adenine Phosphoribosyltransferase (APRT, 16q24.3): Recessive deficiency of APRT may lead to dihydroxyadenine accumulation in the urine and kidney disease. APRT may repair cyclobutane pyrimidine dimers. ▶cyclobutane dimer

Adeno-Associated Virus (AAV): A simple, icosahedral, non-enveloped, 22 nm, non-pathogenic, single-stranded DNA (4,681 nucleotides) virus that infects a wide range of cell types in various species and integrates preferentially into human chromosomal site AAVS1 at 19q13.2-qter most frequently as an inverted repeat (←---|---→). Some forms such as episomal and multimeric circular AAV are known. Several serotypes exist. Its loading capacity is ~4.7 kb. It has only two internally situated genes, *rep* (replication) and *cap* (capsid) encoding 4 replication (Rep78, Rep68, Rep52, Rep40) and 3 viral coat proteins (VP1, VP2, VP3) using different promoters and alternative splicing. AAV has two ~145-nucleotide inverted terminal repeats (ITR), which

form double-strand structure. During replication, the ss-DNA is the template for the new strand. In vector plasmids carrying AAV its DNA is double-stranded (see Fig. A29).

Figure A29. Adeno-associated virus

Cis-acting functions required for replication (*rrs*) and binding to the human chromosome site (Sp1, 19q13.3-qter), helicase, site-specific and strand-specific endonuclease activity, packaging, integration, excision, and initiator (*inr*) of transcription site for RNA are encoded within the ITR. AAV has been used as vector for gene therapy. The AAV vectors usually cannot carry more than 4.5 kb but because of the small size of the particles, they can penetrate easier small targets (e.g., skeletal muscles, neurons). The estimates of the frequency of integration of AAV vectors into chromosomal sites are not unanimous. Some vectors carry AAV concatamers, which have ~9 kb capacity. These vectors greatly benefit by the presence of adenovirus (AV) or herpes virus helper. In the presence of adenovirus helper, it may produce more than 100,000 particles per cell. AAV vectors transfect non-dividing cells or dividing cells and because of concatamer formation, they express transgenes for long periods and do not suffer immune rejection. The recombinant AAV molecule with deletions within the viral *rep* gene is called rAAV. The *rep* guides the integration into the host chromosome and facilitates non-homologous recombination. AAV vectors can target homologous mammalian chromosomal locations and alter ~1% of the cells without additional mutations. AAV may protect the cells against human melanoma or cervical carcinoma due to the product of the *rep* gene transcribed from the open reading frame beginning at map position of promoter p5. The *rep*-minus strains do not integrate to preferential sites. For infection, AAV requires a helper function provided by adenovirus or herpes virus. In the absence of a helper, AAV becomes latent but can be rescued. The AAV based vectors frequently used as a two-plasmid co-transfection system by relying on the complementary ITR-promoter-transgene and ITR-rep-cap packaging system. Unlike the adenoviral vector, AAV vectors remain in the cell. The host immune system usually does not react much to the AAV vectors beyond the initial stage of introduction. AAV vectors appear safe for the subjects and the environment (do not cause diseases) although in

some instances unexpected tumors and chromosomal defects were observed. Tumor formation in mouse occurred at the chromosome 12 integration site that corresponds to human chromosome 14 (Donsante A et al 2007 Science 317:477). AAV can be targeted to specific cells either by the use of bispecific antibodies on the capsid that recognize AAV and the target. The tropism can be engineered also by specific amino acid insertions into the capsid for recognition of specific cell receptors. Although generally no serious immunological reaction against AAV occurs, the immune system may neutralize the passenger DNA. In the latter cases, immunosuppressive treatment may be beneficial. AAV has great potentials in gene therapy for different hereditary conditions. ►gene therapy, ►adenoma, ►herpes, ►viral vectors, ►parvoviruses, ►autonomous parvovirus, ►concatamer; Russel DW, Kay MA 1999 Blood 94:864; Miller DG et al 2002 Nature Genet 30:147; Nakai H et al 2003 Nature Genet 34:297; McCarty DM et al 2004 Annu Rev Genet 38:819.

Adenocarcinoma: Cancer of glandular tissues.
►pancreatic adenocarcinoma

Adenoma: Usually benign gland-shape epithelial tumor. The deficit of E-cadherin-mediated cell adhesion is one of the control steps in the change from adenoma to carcinoma. ►endocrine neoplasia, ►carcinoma, ►cadherins; Sieber OM et al 2002 Proc Natl Acad Sci USA 99:2954.

Adenomatosis, Endocrine, Multiple (MEN): The autosomal dominant MEN I (human chromosome 11q13) pancreatic adenomas are prevalent, in MEN II pheochromocytoma and thyroid carcinoma (10q11) and in MEN III cancers of the nerve tissues are most common although the latter two conditions appear allelic in the pericentric region of human chromosome 10q. ►pheochromocytoma, ►SHC, ►adenoma, ►cancer

Adenomatous Polyposis Coli (APC): ►Gardner syndrome, ►FAP

Adenosine: Adenine with a ribose added (see Fig. A30).
►adenine, ►nucleoside

Figure A30. Adenosine

A

Adenosine 3', 5' Cyclic Monophosphate (cAMP):

Formed from ATP by adenylate cyclase enzyme. It has important regulatory functions as “second messenger” for microbial and animal cells. ►cAMP, ►adenylate cyclase, ►G-proteins, ►signal transduction

Adenosine Deaminase (ADA): An enzyme that hydrolyzes adenosine monophosphate to inosine. Its deficiency causes severe immunodeficiency and the patient's lymphocytes are disabled to fight infections successfully. ADA is synthesized in the cells for the purpose of detoxification of excessive amounts of adenosine or its analogs; it inactivates 9-β-D-xylofuranosyl adenine, a DNA damaging chemical, and thus it can be used as a dominant selection agent in tissue culture. Its synthesis in the cells can be overproduced over ten thousand times by a strong inhibitor of ADA, 2'-deoxycytosine (dCF), and a transition-state analog for adenine nucleotide enzymes. It is encoded in human chromosome 20q13.11. RNA-specific adenosine deaminase (ADAR2, 21q22.3) is an editing enzyme. ►adenosine deaminase deficiency, ►SCID, ►severe combined immunodeficiency, ►mosaic, ►immunodeficiency, ►transition state, ►ADAR

Adenosine Deaminase Deficiency (ADA deficiency):

Also known as severe combined immunodeficiency disease (SCID). ADA deficiency may be treated with gene therapy or bone marrow transplantation or by enzyme replacement with polyethylene glycol adenosine deaminase (Peg-ADA). In case of the defect, deoxyadenosine (dAdo) or deoxyadenosine triphosphate reaches toxic levels. Into T lymphocytes isolated from the patients, retroviral vectors introduce the normally functional human ADA gene and the lymphocytes are injected into the afflicted children. Upon periodically renewed treatment, symptoms of the disease (chronic infections, diarrhea and muscle weakness) usually recede. Post-exercise cramping of the muscles may be caused by inadequate level of this enzyme. The ADA gene was located to human chromosome 20q13 area. ►adenosine deaminase, ►SCID, ►Lesch-Nyhan syndrome, ►gout, ►gene therapy, ►immunodeficiency, ►viral vectors, ►lymphocytes, ►deamination, ►dyschromatosis symmetrica hereditaria

Adenosine Diphosphate: ►ADP**Adenosine Monophosphate Deaminase (AMPD1,**

1p21-p13): Recessive deficiency of AMPD1 leads to cramps, myopathy and weakness after exercising. Most commonly, the enzyme in the skeletal muscles is affected and therefore it is called myoadenylate deaminase deficiency.

Adenosine Receptors: Mediate the activities of diverse cell types (neurons, platelets, lymphocytes, muscle cells) in response to adenosine released by the degradation of ATP. The four types of receptors are A₁, A_{2a}, A_{2b} and A₃. aggressiveness.

Adenovirus: A large mammalian (1.8×10^8 Da), icosahedral, (diameter about 80 nm) double-stranded DNA virus with ca. 36-kbp genetic material. The most commonly used serotypes for gene therapy are Ad2 and Ad5 although about 50 serotypes are known. The human adenovirus DNA has a 55-kDa protein covalently bond to both 5'-ends. The initiation of replication depends on a viral 80-kDa protein reacting with the first deoxycytidylic residue and its 3'-OH group serves as the starting point. The complementary DNA strand is a template. After replication, the 80-kDa protein is cleaved off but the 55-kDa protein stays on. The replication does not require the synthesis of Okazaki fragments because first, one of the strands is completed with the aid of the protein-dCTP primer, then the other strand is replicated. Replication can start at either end because of protein primer is used. Both strands of the DNA are transcribed into overlapping transcripts. The integrated viral DNA is generally smaller than the genome of adenoviruses. After lytic infection, a cell may release about 100,000 virus particles. Upon infection, it may produce a flu-type ailment, and can cause cancer upon integration into the genome. In humans, adenovirus is not carcinogenic and because it stays episomal it does not induce insertional mutation. The adenoviruses have broad host range and this makes them suitable for veterinary vaccine production. The adenovirus oncoprotein E1A induces progression of the cycle by binding to a protein complex p300/CBP. A histone acetylase (P/CAF) competes in this with E1A and inhibits its mitogenic activity. The main function of E1A is to disrupt the association between p300/CBP and the histone acetylase. The viral E1B gene encoded 55-kDa protein inactivates the p53 tumor suppressor gene and the cancerous proliferation begins. However, a mutant form of adenovirus (dl1520) that cannot express this 55 K protein can still replicate in cells that are defective in the p53 suppressor and consequently can lyse these defective cells. This finding offers a promise for the destruction of p53-deficient cancer cells by injection with dl1520 mutants. Normally wild type p53 (apoptosis) is a requisite for the productive infection (destruction of the cells) by wild type adenovirus. Adenoviruses have been used as vectors for genetic transformation after some regulatory sequences have been deleted and replaced. For the production of adenoviral vectors most commonly, cell line 293 is used.

This line carries the E1 viral gene in trans and thus enables replication of the vector that is deleted for it. Homologous recombination between the cell's chromosome and the vector should be avoided to prevent the formation of replication-competent adenovirus.

The maximal carrying capacity is about 6–8 kbp. Since adenovirus preferentially infects the respiratory tract, it may be used for somatic gene therapy of, for e.g., cystic fibrosis. It has also been used to transfer genes to skeletal muscles (see Fig. A31).

Figure A31. The general design of an adenoviral vector. ITR = inverted terminal repeat, Ψ = packaging signal, E1 is replaced by the transgene and E3 is deleted in the majority of vectors. The removal of E1 is important to prevent the infectivity of the viral DNA. For the lost E1 function the host cells may provide complementation in trans. Recombination, however, may give a chance for regeneration of replication competent virus.

The cell can take up adenovirus vector and its load DNA by a specific virus receptor, e.g., CAR1, and the $\alpha_v\beta_3$ or $\alpha_v\beta_5$ surface integrins. In mice incubated in vitro with a Cre-expressing adenovirus vector, Cre-mediated recombination occurred at an efficiency of 49–76%, and the infected spermatogonial stem cells could reinitiate spermatogenesis after transplantation into seminiferous tubules of infertile recipient testes. No evidence of germ-line integration of adenovirus vector could be found in offspring but this possibility cannot be ruled out because there is no known mechanism that would prevent it (Takehashi M et al 2007 Proc Natl Acad Sci USA 104:2596). Usually the adenoviral vector, taken up by non-dividing or dividing cells, is not integrated into the human genome and thus does not lead to permanent genetic change and they have to be reapplied periodically (in days, weeks or months). The adenovirus proteins evoke rapid immune responses and that may be the cause of the short duration of the transformation effects. In addition, the current vectors may cause inflammation because of antivector cellular immunity. Immunosuppressive drugs (cyclosporin A, cyclophosphamide) may mitigate the immune response but may cause undesirable side effects.

The immunogenic property of the adenoviral vectors may eventually be exploited for immunological destruction of the targeted cancer cells. An advantage of this vector is that it can be used in very high titers (10^{11} to 10^{13} particles/mL). Adenovirus is not known to induce human cancer. Adenoviral vector-mediated interleukin-12 gene therapy seems to protect mice with metastatic colon carcinoma.

Construction of improved vectors is of major interest. *Gutless* or *fully deleted* adenoviral vectors are *helper-dependent* because most of the viral genome is removed to reduce the risk of adverse immune reaction and increase the duration of expression. ▶icosahedral, ▶Okazaki fragment, ▶replication, ▶cancer, ▶viral vectors, ▶CAR1, ▶titer, ▶gene therapy, ▶p53, ▶cystic fibrosis, ▶antivector cellular immunity, ▶adeno-associated virus, ▶tumor vaccination, ▶seroswitch vector, ▶targeting vector; Benihoud K et al 1999 Curr Opin Biotechnol 10:440; Frisch SM, Mymryk JS 2002 Nature Rev Mol Cell Biol 3:441.

Adenylylate: Salt of adenylic acid.

Adenylylate Cyclase (adenylyl cyclase): An integral membrane enzyme with an active site facing the cytosol, generating cAMP (cyclic AMP) from ATP and releases inorganic pyrophosphate (two phosphates). G_{sa} subunit-bound GTP activates this enzyme. The enzyme has a weak GTPase activity that eventually breaks the G_{sa} —GTP links and thus turns off the cyclase function. The activation of the cyclase function is initiated by the hormone epinephrine, which binds to a membrane receptor and activates the G_s proteins. cAMP itself is degraded by cyclic nucleotide phosphodiesterase. The cellular level of Ca^{2+} regulates oscillation of its level. The type I enzyme is stimulated by neurotransmitters which elevate the level of Ca^{2+} . The Type II enzyme requires stimulation by G_{as} in the presence of the $G_{\beta\gamma}$ subunits of the G protein. ▶adenosine 3',5'▶cyclic monophosphate, G_s , ▶G-protein, ▶GTP-ase, ▶GTPase activating protein, ▶cyclic AMP-dependent protein kinase, ▶animal hormones, ▶epinephrine, ▶calcium ion channel, ▶anthrax, ▶junction of cellular network; Jaiswal BS, Conti M 2001 J Biol Chem 276:31698; Onda T et al 2001 J Biol Chem 276:47785.

Adenylylate Kinase Deficiency (AK1): Dominant in human chromosome 9q34.1, it causes hemolytic problems. Several AKI alleles were named. Adenylylate kinases catalyze the reversible transfer of the γ -phosphate from ATP to AMP and regulate adenine nucleotide metabolism and intracellular ATP levels. By 2005, six AK enzymes have been characterized (Ren H et al 2005 Proc Natl Acad Sci USA 102:303). ▶hemolysis, ▶hemolytic diseases

Adenylyc Acid: It is a phosphorylated adenosine.

Adenylyl Cyclase: ▶adenylylate cyclase

Adenylosuccinase Deficiency (adenylosuccinate lyase, ADSL, 22q13.1): Normally the enzyme catalyzes the reaction: succinylaminoimidazole carboxamide ribotide → aminoimidazole carboxamide ribotide and

A

the removal of fumarate from adenylosuccinate to yield adenosine monophosphate. Homozygosity for the recessive mutations may cause autism, mental and psychomotor retardations. ►autism

Adenylylation: Addition of adenine to an amino acid near the active site in a protein (by the enzyme adenylyl transferase); it may regulate the activity of the target.

ADEPT (antibody-directed prodrug therapy): A prodrug is supplied to an organism afflicted by cancer. The prodrug itself is not toxic until it is enzymatically activated. Care should be taken that the enzymes of the body would not convert the prodrug automatically into a toxin. An antibody, specific for the cancer, is conjugated with an activating enzyme. The conjugate seeks up the cancer cells and by generating locally high concentration of the toxin it is expected to kill the cancer cells. It would be desirable that the toxin would not diffuse from the tumor into normal cells. Enzymes of potential use with prodrug→toxin:

Pseudomonas carboxypeptidase/glutamic acid derivatives→benzoic acid mustards, *E. coli* β-lactamase/cephalosporin derivatives→nitrogen mustards, yeast cytosine deaminase/5-fluoro-cytosine→5-fluorouracil, almond β-glucosidase/amygdalin→hydrogen cyanide, etc. ►magic bullet, ►vascular targeting; Xu G, McLeod HL 2001 Clin Cancer Res 7:3314.

ADH (antidiuretic hormone): A short peptide (vasopressin). antidiuretic hormone.

ADH (alcohol dehydrogenase): An enzyme catalyzing the reversible reaction: acetaldehyde + NADH + H⁺ ⇌ ethanol + NAD⁺

The ADH subunits (α, β, γ) are encoded in human chromosome 4q21. ►adh⁻, ►acetaldehyde dehydrogenase, ►mutant isolation, ►ethanol, ►allyl alcohol

adh⁻: A mutant with a defective ADH enzyme. ►acrylaldehyde, ►mutation detection

Adhalin: ►muscular dystrophy

ADHD: ►attention-deficit hyperactivity

Adherence Reaction: The binding of molecules to the complement receptors of cell surface or agglutination of antibody and antigen complexes. ►antibody, ►complement, ►complement fixation

Adherens Junction: The cell surface where actin filaments attach. AJ is regulating cell adhesions, mediated by Rap1 GTPase. β-catenin, ►RAP1A, ►Knox, ►formin; AL, Brown NH 2002 Science 295:1285; Tepass U 2002 BioEssays 24:690.

Adherin: Chromosomal proteins that are similar in function to cohesin. ►sister chromatid cohesion

Adhesion: Sticking together, e.g., water molecules clinging to various surfaces. ►integrins, ►selectins, ►cadherins, ►plakoglobin, ►vinculin, ►talin, ►adherens junction

Adhesion Belt: Adherens belt connects neighboring cells. ►adherens junction

Adhesion Plaque (focal contact): The spot where a cell is anchored to the extracellular matrix by transmembrane proteins.

Adipocere (grave wax): Hydrolyzation product of body fats after death; its formation may help the preservation of DNA of the brain in some ancient animal/human remains. ►ancient DNA

Adipocyte: Fat storage cell; it is used as a depository of excess caloric intake or reserve when expenditure exceeds intake of calories. The white adipose stores energy as triglycerides, the brown adipose tissue is involved in thermogenesis (see Fig. A32). Membrane-associated metalloproteinase, MT1-MMP modulates pericellular collagenase and subsequently the growth of white adipose tissue cells (Chun T-H et al 2006 Cell 125:577). Adipocyte differentiation is regulated by the CCAAT/enhancer-binding proteins, adipocyte differentiation determinant (ADD1)/sterol response element-binding protein (SREBP1), and the peroxisome proliferator-activated receptors (PPAR). Sequential phosphorylation of CCAAT enhancer-binding protein by MAPK and GSK3β in vitro leads to DNA-binding function and clonal expansion of adipocytes (Tang Q-Q et al 2005 Proc Natl Acad Sci USA 102:9766). In addition retinoic acid, vitamin D₃, thyroid hormone receptors are involved. The retinoic receptors (RXR) are indispensable for the viability of mice. Adipocytes secrete leptin, adiponectin, resistin, TNF-α IL-6 and visfatin (Fukuhara A et al 2005 Science 307:426). ►retinoic acid, ►PPAR, ►vitamin D, ►animal hormones, obesity, ►resistin, ►brown fat, ►mesenchyma, ►MAPK, ►GSK3β; Gregoire FM et al 1998 Physiological Revs 78:783; Rosen ED, Spiegelman BM 2000 Annu Rev Cell Dev Biol 16:145; Zhang J-W et al 2004 Proc Natl Acad Sci USA 101:43; regulation of energy balance by adipocytes; Rosen ED, Spiegelman BM 2006 Nature [Lond] 444:847.

Figure A32. Adipocyte

Adiponectin: A cytokine produced by adipocytes in response to metabolic or extracellular signals. It

lowers blood glucose level and reduces the level of triglycerides in the muscles and the production of fat. It may be exploited for treatment of insulin-resistant diabetes. ▶cytokines, ▶triglyceride, diabetes, ▶osmotin, ▶resistin, ▶obesity; Yamauchi T et al 2001 *Nature Med* 7:887; Berg AH et al *ibid.* p. 947.

Adipose: Related to fat, e.g., adipose tissue = fat tissue.

Adjacent Disjunction: Neighboring members of translocation rings or chains move to the same pole; adjacent-1 when centromeres are non-homologous, adjacent-2 when centromeres are homologous (non-disjunctional) at the poles. ▶translocation chromosomal

Adjacent Distribution: ▶adjacent disjunction

Adjuvant, Immunological: If the immune response to an antigen is unsatisfactory because of the small amount present, the immune reaction may be enhanced by protecting the antigen from degradation and promoting slow release and increase its uptake by macrophages. For this purpose mineral oils, alum (a hydrated aluminium oxide), charcoal, Freund adjuvant, specific nucleotide sequences, CD154, etc. can be used. ▶immune response, ▶immunization genetic, ▶antigen, ▶Freund adjuvant, ▶vaccine, ▶CD154

Ad Libitum (ad lib.): As much as wanted; for e.g., feeding animals at level they wish to eat.

ADM (automated digital microscopy): ▶ACIS, ▶FAST, ▶microscopy

Admissibility Criteria: Legal concepts concerning the appropriateness whether a certain type of evidence, scientific method or logical arguments would be helpful for the jury to determine the facts in the court. Regarding scientific evidence, the judge decides, whether the methodology and techniques have been validated by peer reviews and publication in respected publications, whether the techniques have an acceptable error rate, and the methodology is generally acceptable by the scientific community (*Daubert factors*). The scientific methods generally improve with time and so the admissibility criteria is also subject to change within the above guiding principles. ▶forensic genetics

Admixture in Populations: May take place when two potentially interbreeding populations share a habitat for a period. When the frequency of about 50 or more markers is analyzed, statistical information may be derived on the extent and time of the admixture (admixture mapping: Patterson N et al 2004 *Am J Hum Genet* 74:979). Availability of SNP markers may permit association studies between disease genes and SNPs even when this approach may not yield much information on the molecular associations.

Using nine autosomal markers (and mtDNA), ten populations of African descent were analyzed by sampling different regions of the U.S. for European admixture. In Jamaica 6.8% and in New Orleans 22.5% appeared introgressive. The gene flow from Europeans was sex-biased, the male contribution was substantially higher than that by females (Parra EJ et al 1998 *Am J Hum Genet* 63:1839). ▶introgression, ▶linkage disequilibrium; Chikhi L et al 2001 *Genetics* 158:1347; Zhu X et al 2005 *Nature Genet* 37:177.

Admixture Mapping: Chromosomal blocks can remain intact in linkage disequilibrium after admixture of different populations. These blocks eventually decay because of recombination yet, based on the linkage disequilibrium, gene loci can be mapped. (Chakraborty R, Weiss KM 1988 *Proc Natl Acad Sci USA* 85:9119)

aDNA: ancient DNA. ▶ancient DNA

Adnfile: ▶epilepsy

AdoMet: S-adenosyl-L-methionine (current abbreviation is SAM) is a methyl donor for the enzymes guanosine 7-methyl transferase and the 2'-O-methyl transferase enzymes in the cap of pre-mRNAs and for other methylation reactions. ▶SAM, ▶cap, ▶methylase, ▶methylation of DNA, ▶methylation of RNA, homocystinuria, ▶methionine adenosyl transferase; LeGros L et al 2001 *J Biol Chem* 276:24918.

Adopted Children: Frequently used in human genetics to determine the relative effects of genes and environment. These studies are sometimes hampered, however, because either the families do not have biological children or the biological parents of the adopted children are not available for examination. According to civil law, adopted children may lose any legal ties to and identity with the natural parents. This loss of identity may carry some genetic caveats because of chances of inbreeding due to lack of information about descent. These problems are similar to the ones encountered by artificial insemination using anonymous sperm donors. ▶twinning, ▶artificial insemination

Adoptive Cellular Therapy (adoptive transfer): Infusion of immune effector cells (NK cells, macrophages, $\gamma\delta$ T cells, $\alpha\beta$ T cells, B cells, etc.) for the treatment or prevention of disease (lymphoma, leukemia, myeloma). Although this may appear an attractive alternative to chemotherapy or radiation, the allogeneic cells may induce graft-versus-host disease (immune rejection). To avoid these complications herpes simplex virus thymidine kinase gene (HStk) may be targeted to the malignant cells by a Moloney murine leukemia retroviral vector. This vector selectively seeks

A

up dividing cells. Since cancer cells divide more frequently than normal cells, the vector does not usually hit normal cells. The cells are then infused by ganciclovir, which when metabolized to ganciclovir triphosphate it is incorporated into DNA and RNA resulting in selective termination of replication in the HStk⁺ cells by this suicide technique. More differentiated tumor-specific CD8⁺ T cells were less effective than naïve ones for in vivo tumor treatment. The possible causes may be down-regulation of lymphoid homing and co-stimulatory molecules, inability to produce IL-2 and access homeostatic cytokines and entry into a pro-apoptotic and senescent state (Gattinoni L et al. 2005 J Clin Invest 115:1616). ▶cell therapy, ▶gene therapy, ▶ganciclovir, ▶TK, ▶Moloney mouse leukemia oncogene, ▶viral vectors, ▶suicide vector, ▶stem cells, ▶diabetes; Link CJ et al 2000 Stem Cells 18:220.

ADP: Adenosine 5'-diphosphate, a phosphate group acceptor in various cellular processes. It is produced by hydrolysis of ATP; it can also regenerate ATP by oxidative phosphorylation.

ADP-Ribosylation Factor: ▶ARF

Adr: A positive regulator protein of transcription.

Adrenal: Adjacent or pertinent to the kidney.

Adrenal Hyperplasia, Congenital (CAH): Occurs in both X-linked and autosomal forms and apparently controlled by several loci. Cortisol deficiency is involved. The X-linked form is attributed to gonadotropin deficiency. The steroid hormone overproduction indicates a defect in steroid 21-hydroxylase, encoded within the boundary of the HLA complex in human chromosome 6p21.3. The affected female babies are masculinized. Masculinization is preventable by the administration of dexamethasone but side effects may occur. It may be associated with Addison disease (hypotension, anorexia, weakness and pigmentation). One form of the disease is accompanied by difficulties in salt retention in the newborns. The prevalence is about 7×10^{-5} . The 17- α -hydroxylase deficiency is encoded at 10q24.3 and it involves an excessive amount of corticosterones and hypertension and hypokalemic alkalosis (increase of bases [e.g., K⁺] yet lower pH). An autosomal form in chromosome 8q21 is deficient in 11- β -hydroxylase and/or corticosteroid methyl oxidase II (HSD11B1, 1p13.1) occurs at a frequency of 1×10^{-5} . Masculinization may be caused by several other genetic anomalies and by various medications administered to the mother or maternal androgen-producing tumors. Prenatal diagnosis may use allele-specific PCR on DNA from chorionic villi. ▶HLA, ▶hermaphroditism, ▶genital anomaly syndromes, ▶adrenal hypoplasia, ▶Addison disease,

▶STAR, ▶dexamethasone, ▶PCR, ▶chorionic villi, ▶congenital adrenal hyperplasia

Adrenal Hypoplasia, Congenital (AHC): Characterized by abnormal underdevelopment (hypoplasia) of the genitalia and the gonads, insufficient function of the kidneys, hypoglycemia (reduced blood sugar), seizures, etc. Several forms of the disease (hypoadrenocorticism, polyglandular autoimmune syndrome, Addison disease) were reported with autosomal recessive inheritance. The X-chromosome-linked DAX1/AHC (Xp21.3-p21.2) locus encodes a dominant negative regulator of transcription, a nuclear hormone receptor protein with a DNA-binding domain. The DAX-1 transcription is mediated by the retinoic acid receptor. AHC may modify male determination by SRY and it seems to regulate also the steroidogenic factor Sf-1 but it does not affect ovarian development. ▶hypogonadism, ▶Kallmann syndrome, ▶adrenal hyperplasia, ▶epilepsy, ▶retinoic acid, ▶RAR, ▶dominant negative, ▶transcriptional activator, ▶SRY, ▶Sf-1, ▶Addison disease

Adrenaline: ▶epinephrine, ▶animal hormones

Adrenergic Receptors: Occur in the forms of α_1 , α_2 , β_1 , β_2 distinguished on the basis of their responses to agonists and antagonists and tissue-specificity. They all respond to the adrenal hormones, epinephrine and norepinephrine. ▶epinephrine, ▶membrane proteins, ▶receptors, ▶agonist, ▶antagonist, ▶arrestin, ▶hypotension, ▶GRK2

Adrenocortical: Pertains to the cortex (the outer layer) of the kidney.

Adrenocorticotropin (ACTH): A pituitary peptide hormone that controls the secretion of steroid hormones of the kidney in response to cAMP. ACTH unresponsiveness (familial glucocorticoid deficiency) is recessive autosomal defect of resistance to ACTH, causing hypoglycemia and childhood infections. Mutations in ACTH receptor (melanocortin 2 receptor) cause familial glucocorticoid deficiency (FGD 2) in chromosome 21q22.1. The mutation in FGD 2 involves the melanocortin 2 receptor accessory protein (Metherell LA et al 2005 Nature Genet 37:166). ▶cAMP, ▶glucocorticoids, ▶cortisol, ▶ACTH, ▶POMC, ▶melanocortin

Adrenodoxin: An electron carrier iron-sulphur protein in the mitochondria of the kidney cortex and assist cholesterol biosynthesis. ▶cerebral cholesterinosis

Adrenoleukodystrophy (ALD, Addison disease, Xq28): The X-linked neonatal form is a defect in peroxisome assembly. The disease is associated with very long chain fatty acid (VLCFA) acyl coenzyme A synthase

defects. Neural degeneration and blindness are the consequences of the disease. Autosomal forms encoding different peroxins and peroxin receptors are at 2p15, 12p13.3, 7q21-q22. ▶microbodies, ▶Zellweger syndrome, ▶Refsum disease, ▶peroxins

Adrenomedullin: A 22-amino acid vasodilator, a calcitonin-related peptide. In its absence hydrops fetalis may develop. ▶hydrops fetalis

Adriamycin: ▶doxorubicin

Adrogenital Syndrome: A complex genetic disorder based on anomalies of steroid biosynthesis and adrenal hyperplasia. Gene frequencies vary a great deal in different populations from 0.026 of Alaskan Eskimos to 0.004 in Maryland, USA. ▶adrenal hyperplasia, ▶allelic frequency, ▶steroid hormones

Adsorption: The tendency of molecules to adhere to a surface (different from absorption that is uptake through a membrane).

Adsorption Chromatography: ▶column chromatography, ▶thin layer chromatography

Adsorptive Endocytosis: ▶receptor-mediated endocytosis

Advantage of Heterozygotes: Indicates that fitness (the reproductive value) of the heterozygotes exceeds that of both types of homozygotes in a population and this may lead to balanced polymorphism. ▶balanced polymorphism, ▶polymorphism, ▶fitness

Advantageous Mutations: Favored by a particular environment and they are expected to propagate under steady-state conditions by a rate per generation: $v = \sigma\sqrt{2s}$ where σ is the standard deviation caused by diffusion (migration) and s = selective advantage in the absence of dominance. E.g., if $\sigma = 10$ km, and $s = 0.02$ then the advance per generation in kilometers will be $10\sqrt{2 \times 0.02} = 2$ then it would take 250 generations to advance 500 km. (▶mutation, ▶mutation beneficial, ▶migration, ▶selection coefficient; Cavalli-Sforza LL, Bodmer WF 1971 The Genetics Of Human Populations, Freeman, San Francisco, California.

Adventitia: The outer coating of organs by loose connective tissues composed mainly of fibrillin and elastin.

Adventive Embryos: Adventive Embryos develop from the diploid tissues of the plant nucellus (without fertilization); they occur commonly in citrus. ▶apomixis, ▶nucellus

AE Genes: Annotated expressed genes. ▶annotation, ▶ANE genes, ▶NAE genes

Aecidiospore: A dikaryon of plant rust fungi formed through a sexual process that did not involve nuclear

fusion; the aecidiospores are products of the aecidium, a group of sporangia. ▶aecidium, ▶dikaryon, ▶sporangium, ▶fungal life cycle

Aecidium or aecium: A fruiting structure of fungi (Basidiomycetes-Uredinales) such as *Puccinia graminis tritici*. Aecidia are formed only on the intermediate host, barberry, but the spores infect only wheat.

Aedes aegypti: The mosquito, which transmits yellow fever and dengue fever viruses. (See Rai KS, Black WC 1999 Adv Genet 41:1). The draft sequence of its genome has been determined as ~1376 million base pairs and it is about 5 times the size of the genome of the malaria vector *Anopheles gambiae*. Nearly 50% of the *Ae. aegypti* genome consists of transposable elements (Nene V et al 2007 Science 316:1718). ▶Anopheles mosquito, ▶malaria

Aegilops caudata: A diploid representative of the *Triticum* genus ($2n = 14$) carrying the 7-chromosome C genome (current name *Triticum dichasians*). *Aegilops cylindrica*: an allotetraploid of the wheat genus containing the CD genomes (C from *T. dichasians* and D from *T. tauschii*). Current name *Triticum cylindricum*. *Aegilops squarrosa*: *Triticum tauschii* by current name, is a diploid species in the wheat genus with the D genome (see Fig. A33).

Figure A33. Glume of *T. peregrinum*. (Courtesy of Drs. Gordon Kimber and Moshe Feldman)

Aegilops umbellulata, by current name *Triticum umbellulatum*, a diploid species of the wheat genus with the C^u genome. *Aegilops variabilis*, currently *Triticum peregrinum*, a species of the wheat genus; occurs in nature both as tetraploid (DM) and hexaploid (DDM) genomic constitution. ▶*Triticum*

Aegricorpus: A genetic-physiological complex determined by the host-pathogen interaction; the phenotype of the disease in plants. ▶host-pathogen relations, ▶Flor's model

Aequorin (GFP): Luminescent protein (green fluorescent protein of 238 amino acids) from jellyfish (*Aequorea victoria*); its activation is dependent on the level of the available Ca²⁺ and on this basis minute quantities and differences in this ion can be measured

A

by optical means within the range of 0.5–10 mM. This may be of major importance because calcium may play regulatory functions in all eukaryotic cells. The chromophore results from the cyclization and oxidation of the Ser⁶⁵ (Thr⁶⁵)Tyr⁶⁶ Gly⁶⁷ amino acid sequence in the central helix of the 11-stranded β barrel. Aequorin has also the advantage that is non-invasive and non-destructive label in various organisms. Its excitation peaks are at 395 and 475 nm, and the emission peak of the pure GFP is at 470 nm. Mutant proteins with higher absorption peaks and different colors (red, yellow) exist. By the use of fluorescence resonance energy transfer (FRET), linking GFP reversibly to peptide spacers result in conformational changes and altered light emission (color). GFP is sensitive to pH, temperature, and prior illumination. Excitation by 488 nm light increases fluorescence 100 folds and remains stable for days (Patterson GH, Lippincott-Schwartz J 2002, Science 297:1873). The gene has been cloned and sequenced and has been widely used in animals and plants, in various modified forms, as a reporter gene. GFP is a strong immunogen. ►calmodulin, ►Renilla GFP, ►BFP, ►EGFP, ►FRET, ►drFP583, ►barrel; Methods in Enzymology, vol 302, 1999; Tsien RY 1998 Annu Rev Biochem 67:509; Labas YA et al 2002 Proc Natl Acad Sci USA 99:4256; van Roessel P, Brand AH 2002 Nature Cell Biol 4:E15; <http://www.conncoll.edu/ccacad/zimmer/GFP-ww/GFP-1.htm>.

AER: Apical ectodermal ridge.

Aerobe: An organism that uses oxygen as the terminal electron acceptor in respiration. ►electron acceptor, ►respiration

Aerobic: A reaction (or organism) requires or takes place in the presence of oxygen.

AF (activation function protein): Activates and recruits co-activators of gene expression.

a/ α -Factors: ►mating type determination in yeast

Affected Individual: Expresses a particular (disease) trait.

Affected-Relative-Pair Method: Similar to ASP, but other relative pairs are used.

Affected-Sib-Pair Method: (ASP): A non-parametric method for linkage analysis of susceptibility genes. For this purpose the risk ratio (λ_s) is determined, that is the risk of a sib of an affected proband compared to the average prevalence in the population. For e.g., diabetes has a prevalence of 0.004 in the general population but its incidence among sibs of affected individuals is 0.06, hence $\lambda_s = 0.06/0.004 = 15$. This λ_s is for all loci responsible for the phenotype. The

larger λ_s the higher is the genetic contribution. It is also affected by the interaction (can be multiplicative or additive) of the various factors contributing to the phenotype. The strength of the proof for linkage depends on the so-called *maximal lod score* (MLS) symbolized by T and means the log odds in favor of linkage. Usually, the estimation is carried out in steps by selecting at each step linkage with markers increasing from $T > 1.0$. Statistically valid linkage is expected when the T score reaches or exceeds 3. The T value may also increase by the use of larger populations. Recombination decreases MLS and the use of multiple loci increases the estimate. Another advantage of this approach is that both recessive and dominant alleles can be studied. It is applicable also for quantitative traits. This procedure may not necessarily be applicable only to sibs but cousins or other close relatives (uncles, aunts) may also be included. ►recombination, ►frequency, ►maximum likelihood method applied to recombination, ►lod score, ►non-parametric tests, ►allele sharing, ►GSMA; Dupuis J, Van Eerdewegh P 2000 Am J Hum Genet 67:462.

Affective Disorders: Psychological illnesses, psychoses. manic depression, ►autism, ►hyperactivity [ADHD], ►Tourette's syndrome, ►neurodegenerative diseases, ►bipolar mood, ►unipolar depression, ►schizophrenia, ►paranoia, ►obsessive-compulsive behavior, ►addiction; Evans KL et al 2001 Trends Genet 17:35.

Afferent: Conducting or transferring toward the middle.

Affibody: Engineered binding protein using the 58 amino acid Z domain of *Staphylococcus aureus* Protein A (SPA). SPA strongly binds the Fc domain of immunoglobulins. ►antibody, ►receptin; Wahlberg E et al 2003 Proc Natl Acad Sci USA 100:3185.

Affine Gap Cost: Expresses the “penalty” for gaps in a sequence alignment also according to the length of a gap. ►genome projects, ►contig

Affinity (Michie D, Wallace ME 1953 Nature [Lond] 171: 26): Unlinked genes segregate to the same gamete more frequently (quasi-linkage, Robinson, R. 1971) or less frequently (reverse linkage) than expected on the basis of randomness (Bailey NTJ 1961 Introduction to the mathematical theory of genetic linkage, Oxford, Clarendon Press, England). (►translocation chromosomal) In immunogenetics: the intensity of interaction between a particular antigen receptor and its epitope. ►epitope

Affinity Capture: ►acesims

Affinity Chromatography: Polyadenylated mRNA can be separated from other RNAs by adsorption on oligo T (thymine) cellulose or sepharose columns by virtue of the complementarity of the A and T bases. Similar

procedures are used for the purification of antibodies on immobilized antigen media (antibody purification) and DNA-binding proteins can be isolated and enriched by a factor of 10^4 with the aid of affinity chromatography. ►gel retardation assay, ►cDNA library screening, ►immunoprecipitation

Affinity Labeling: Most commonly a photo-affinity hapten is used (i.e., one that is activated only upon illumination). The affinity label is bound to the antigen-binding site amino acids of the antibody and thus reveals the site on the antibody where the attachment is taking place. ►hapten, ►antigen, ►antibody

Affinity Maturation: Selection of cells with high affinity for the antigen as clonal selection progresses. It takes place by accumulation of mutations in the *germinal center* of a lymphoid follicle in the paracortex of a lymphoid node and combinatorial assembly of the variable, joining and diversity sequences of the immunoglobulin genes. These alterations take place in response to the antigens arriving there through small capillary veins on the surface of the antigen-presenting cells and helper T cells. Immunoglobulin G (IgG) usually responds well after the second immunization. Affinity maturation is also a process for the selection of memory cells. TRAF and CD40 regulate the affinity maturation. ►clonal selection, ►antibody, ►antigen-presenting cell, ►immune response, ►repertoire shift, ►immunoglobulins, ►hapten, ►memory immunological, ►lymphoid organ, ►TRAF, ►CD40, ►vaccine; Ahonen CL et al 2002 Nature Immunol 3:451; Meffre E et al 2001 J Exp Med 194:375.

Affinity Purification: Required unless the antibody reacts with more than one antigen. If this is not the case, an affinity chromatography column is prepared by using pure antigen. Alternatively, monoclonal antibody must be used or the immunoglobulin library must be carefully analyzed for true or false positive immune reactions. ►antibody, ►antigen, ►monoclonal antibody, ►TAP

Affinity Tag: A short peptide or protein domain is fused to all members of a set of proteins. The tag facilitates the selective binding of these proteins to specific resins and thereby isolation, purification and elution under conditions that retain their activity (Nilsson J et al 1997 Protein Exp Purif 11:1).

Affinity-Directed Mass Spectrometry: Detects interaction between proteins, receptors-ligands, proteins-nucleotides, etc. ►mass spectrum, ►TAP

AFI: amaurotic familial idiocy, now called Tay-Sachs disease (TSD). ►Tay-Sachs disease

Afibrinogenemia: 4q28 recessive deficiency of fibrinogen (blood coagulation factor I). The afflicted individuals bleed very heavily after injury. Periodic blood accumulation under the skin (ecchymosis), nose bleeding (epistaxes), bloody tumors (hematomas), bloody cough (hemoptysis) or stomach-intestinal or genitourinary bleeding occur. Characteristically, for longer periods no symptoms appear. Therapy is intravenous injection of concentrated human fibrinogen. ►antihemophilic factors, ►hemophilia, ►dysfibrinogenemia, ►fibrin-stabilizing factor

Aflatoxins: Group of heterocyclic mycotoxins produced under appropriate conditions by the *Aspergillus flavus* and *Aspergillus parasiticus* fungi (see Fig. A34). The aflatoxins are extremely carcinogenic because they affect DNA synthesis. The LD₅₀ of aflatoxins orally administered to monkeys may be as low as (1750) µg per kg. Aflatoxin may be a contaminant on grains, peanuts, dry chili pepper, and on many other material humans and animals eat or are exposed to. Aflatoxins frequently cause mutations in *p53* tumor suppressant at codon 249 (AGG→AGT) resulting in hepatocarcinomas. The 8,9-oxide of aflatoxin B forms a mutagenic adduct in the DNA at N⁷-guanine. ►environmental mutagens, ►p53, ►toxins, ►mycotoxins, ►adduct; Smela ME et al 2001 Carcinogenesis 22:535; Cary JW et al 2002 Biochim Biophys Acta 1576:316.

Figure A34. Aflatoxin

AFLP (anonymous fragment length polymorphism, amplified fragment length polymorphism): DNA fingerprinting technique involving restriction enzyme digestion and amplification of special fragments by PCR. It can be used for mapping genes or for the estimation of nucleotide diversity in populations. ►DNA fingerprinting, ►PCR, ►restriction enzymes, ►anonymous DNA segment, ►VNTR; Vos PR et al 1995 Nucleic Acids Res 23:4407; Saunders JA et al Crop Sci 2001 41:1596; Breyne P et al 2002 Proc Natl Acad Sci USA 99:14825.

African Green Monkey (*Cercopithecus aethiops*): Kidney cells are the best laboratory host for the propagation of SV40 (Simian virus 40). ►SV40, ►cos, ►Cercopithecidae

AFS: ►affected-sib-pair method

After Morning Pill: ►hormone receptors [RU-486]

A

Agameon: A species without sexual reproduction.

Agamic: A species reproducing asexually (without gametes).

Agammaglobulinemia: Occurs as an X-chromosomal (congenital) and autosomal defect in the synthesis of γ -globulin, a component of the heavy chain of antibodies. The X-chromosome-linked (Xq21.33) is frequently called Bruton's agammaglobulinemia (XLA). The protein responsible is tyrosine kinase of 659 amino acids, encoded by 19 exons. The manifestation of XLA may differ in different families, indicating the involvement of several genes. It is conceivable that the defect is caused by rearrangement of the genes involved. Some of the individuals have truncated V regions of the antibody. In the afflicted persons the IgG and IgM content is generally no more than 1% of the normal. The absence of plasma cells from the lymph nodes, spleen, intestine and bone marrow is also a basic defect. The patients are very susceptible to pyogenic infectious bacteria (staphylococci, pneumococci, streptococci, and *Hemophilus influenzae*). Pus-forming inflammation of the sinuses, pneumonia, meningitis (inflammation of the brain), furunculosis (boils) are common but can be prevented by the use of antibiotics or raising the γ -globulin levels by regular injections. Without treatment, these infections may become fatal. The afflicted children are not more susceptible to viral, enterococcal, gram-negative bacteria, protozoan or the majority of fungal infections. Another X-chromosome linked or autosomal agammaglobulinemia causes susceptibility to bacterial, fungal and viral infections and leukemia. This is generally accompanied by lymphopenia (decrease of lymphocytes in the blood). This disease is generally detected after the discontinuation of breast-feeding of the babies or near the end of the first year of life. Agammaglobulinemia may occur also as an acquired disorder with onset at different ages, generally as a follow-up to other diseases. The prevalence is about 0.5 to 1×10^{-5} . ▶[gammaglobulin](#), ▶[immunoglobulins](#), ▶[immune system](#), ▶[antibody](#), ▶[hypogammaglobulinemia/common variable immunodeficiency](#), ▶[immunodeficiencies](#), ▶[achondroplasia](#), ▶[cancer](#), ▶[BTK](#)

Agamospecies: Reproduces by non-sexual means, e.g., parthenogenesis, apomixia. ▶[species](#), ▶[parthenogenesis](#), ▶[apomixia](#), ▶[asexual reproduction](#)

Agamospermy: Seed production without fertilization, ▶[apomixis](#), ▶[parthenogenesis](#), ▶[diplospory](#), ▶[apospory](#), ▶[adventitious embryos](#), ▶[apomixis](#)

Aganglionosis: Congenital lack of intestinal ganglions. ▶[Hirschsprung disease](#)

Agar: Gelling agent produced from marine algae with various degrees of purification (bacteriological agar,

noble agar) and used for microbial and plant cell culture media. ▶[gellan gum](#), ▶[agarose](#)

Agarose: A purified linear galactan hydrocolloid isolated from marine algae. In the crude form, it is generally contaminated with salts and other substances, polysaccharides, proteins. Some commercial products are highly purified. It is used for electrophoretic separation of oligo and polynucleotides from 0.1- to 60-kb range, depending on the concentration of this matrix. The higher concentration (2%) separates the smallest molecules whereas the lowest concentration (0.3%) permits the separation of the largest fragments. 0.9–1.2% are the most commonly used concentration ranges separating 0.4- to 7-kb fragments. Contaminations of the agarose may interfere with further enzymatic handling of the eluted DNA. ▶[electrophoresis](#), ▶[gel electrophoresis](#)

Agave (sisal): Basic chromosome number $x = 30$ and the various plant species may be diploid, triploid or pentaploid. The plant has been used for medicinal purposes as laxative; and its juice may cause abortion.

Advanced-glycation end product (AGE): A sugar-derived carbonyl group added to a free amine that forms an adduct after rearrangement producing AGEs. Age may cross-link amino groups in macromolecules and thus may promote aging, accelerate diabetes and may participate in other reactions. The cross-links may be broken by *N*-phenacylthiazolium bromide and may have therapeutic application. ▶[Alzheimer disease](#), ▶[aging](#), ▶[diabetes](#), ▶[adduct](#); Pushkarsky T et al 1997 Mol Med 3:740.

Age: The time since the birth of an individual. Prenatal age is more difficult to determine. Ultrasonic measurements are frequently compared with tables obtained by empirical data.

Age and Mutation in Human Populations: Expressed by the formula $\mu_t = \alpha t + \mu_0$ where mutation rate at a given time is μ_t , α is the mutation rate per cell divisions and μ_0 the initial frequency of mutation. It is expected that mutation rate increases as the number of cell divisions increases in the spermatogonia and oogonia. The available data indicate that chondrodystrophy (achondroplasia, a dominant dwarfness) and acrocephalosyndactyly (Apert's syndrome, pointed top of the head and syndactyly [webbing in between or attachment of the fingers and toes]) increases at birth by about 2–4 fold with paternal age from 25 to 45 years. Other dominant mutations show similar tendencies but with much less clear differences. The human eggs may be different because new egg cells are not formed in the female babies after birth; the oogenesis is almost complete in the newborn. Nevertheless, some age differences are still expected.

Chromosomal aberrations (trisomy) in the eggs may increase, however, from 1/2300 at age 20 to 1/46 after 45, probably because of the prolonged meiotic dictyotene stage (diakinesis). Some of the eggs complete meiosis before each ovulation, a period extending over 30–40 years. Trisomy in sperm is much less common, partly because it is the product of new divisions, partly because the disomic sperm may be at a disadvantage in competition for fertilization. A normal human ejaculate may contain 25–40 million sperm cells. The increase of mitochondrial mutation rate by aging is equivocal. Accumulation of mutations by aging is organ-specific in mice. ▶mutation rate, ▶gonads, ▶Apert syndrome, ▶syndactyly, ▶gametogenesis, ▶trisomy, ▶longevity; Dollé MET et al 2002 Nucleic Acids Res 30:545.

Age Correlation between Mates: Much higher in consanguineous marriages than in unrelated mates. On an average, age correlation makes first-cousin marriages about twice, second cousin marriages about 1.7 times and third cousin marriages about 1.4 times as frequent as if there would be no correlation between the ages at marriage. Since some of the human hereditary diseases have late onset, the greater the age at marriage may reduce the reproduction of genes with late manifestation also the afflicted persons may not marry or chose not to have children if they marry. ▶consanguinity

Age of Onset of Disease: The probability can be calculated: $(1 - \varphi_1)(1 - \varphi_2) \dots (1 - \varphi_{x-1})$ where φ_x = the probability of onset between ages x and $x + 1$ the probability of surviving to age x before onset is $l_x = (1 - q_1)(1 - q_2) \dots (1 - q_{x-1})$ where q_x = the probability of dying at age x before the onset of the condition. ▶aging

Age of Parents and Secondary Sex Ratio: Slightly decreasing from 0.517 to 0.516 at parental age group 15–19 to 0.512–0.511 at parental age 45–49. Based on very large samples examined, the age gap between parents does not affect significantly the sex ratio. ▶sex ratio

Age-Specific Birth and Death Rates: The probability that an individual of a certain age dies (or gives birth) within the following year is determined by population projection matrices. The numbers of giving birth and death rates in a time interval can be determined by 1-B/N for birth per women extracted from available census figures. One such study in (1966) found that among women in the age group of 15–30 and 30–45 the mean number of children born per women was 1.37 and 0.465, respectively. The studies found that the average survival of age groups 0–15, 15–30 and 30–45 were 0.992, 0.988, and 0.964, respectively. Thus, if one takes a sample of 30 woman of age group

0–15 they will give birth to $30 \times 1.37 = 41.1$ children. In the age group 30–45, dealing with 20 human females, the prediction will be $20 \times 0.465 = 9.3$, etc. Similarly, the survivors expected in the age group 0–15 will be $40 \times 0.992 = 39.68$, in the age group 15–30 the expectation is $30 \times 0.988 = 29.64$, by the end of the respective periods, etc. The natural logarithm of the annual growth rate is called the *intrinsic rate of natural increase of the population*, and it means that once a stable equilibrium is reached for the various age groups it will increase by this intrinsic rate per year. Example: if the population growth at equilibrium at 15 years cycles is 1.307 then the annual $r = \ln(1.307)^{1/15} \cong 0.0178$. The age-specific birth and death rates and r must be determined for each population because considerable variations may exist from time to time even in the same group, depending on cultural and economic conditions. A statistical survey indicates that women with later onset of menopause live longer. At the present period the estimated maximal human life span is about 120 years. ▶human population growth, ▶menopause, ▶longevity, ▶mortality; Bongaarts J, Feeney G 2003 Proc Natl Acad Sci USA 100:13127.

Agent Orange ($\text{Cl}_3\text{C}_6\text{H}_2\text{OCH}_2\text{COOH}$): Herbicide containing mainly the synthetic auxin 2,4,5-trichlorophenoxy acetic acid (2,4,5-T). It had been used as a defoliating agent and brush killer. The LD_{50} of 2,4,5-T for mammals is 500 mg/kg, however, there are reports of much lower doses of high toxicity particularly at subcutaneous injection. It is frequently contaminated by dioxin, a carcinogen. The symptoms of Agent Orange exposure can be anorexia, hepatotoxicity, chloracne, gastric ulcers, porphyrinuria, porphyria, teratogenesis, leukemia, etc. Genes in the plasmids derived from *Pseudomonas ceparia* may degrade 2,4,5-T. ▶ LD_{50} , ▶anorexia, ▶hepatotoxicity, ▶acne, ▶chloracne, ▶ulcer, ▶porphyria, ▶teratogenesis; Ngo AD et al 2006 Int J Epidemiol 35:1220.

AGGA Box: An upstream transcriptional regulatory site. ▶transcription factors, ▶promoter

Agglutination: Also known as clumping occurs when two different blood types are mixed or when bacteria are exposed to specific antisera. The basis of this phenomenon is a component of the complement on the antibody (C1_q) protein that binds to the Fc region of the IgG heavy chain and that is followed by a change in conformation of the antibody. The binding of the epitope to the antibody triggers this process. ▶immunoglobulins, ▶antibody, ▶epitope, ▶complement

Agglutinin: An antibody that causes agglutination of cognate antigen. ▶abrin

A

Aggrecan: A chondroitin sulfate proteoglycan of the cartilage (Schwartz NB et al 1999 *Progr Nucleic Acid Res Mol Biol* 62:177).

Aggrecanase: ►arthritis

Aggregation: Aggregation of proteins/fragments of proteins may impair the ubiquitin-proteasome degradatory system. ►ubiquitin

Aggregation Chimera: Produced in vitro by the assembly of genotypically different early (8-cell) embryonic cells. ►chimera, ►allophenic, ►multiparental

Aggregation, Familial: The increased incidence of genetically determined traits among relatives, e.g., among natural children and parents compared with unrelated adoptive children. ►heritability, ►recurrence risk

Aggregulon: A protein complex involved in activation and repression of genes; the term re-glomerate was used in the same sense.

Aggresome: An aggregate sink of insoluble misfolded proteins in the endoplasmic reticulum or close to the microtubule organizing center (MTOC) containing chaperones, proteasome and proteasome activator complexes. Some viruses generate aggresomes-like structures for replication. These virus factories are assembled in the vicinity of MTOCs and recruit vimentin, chaperones, ubiquitin and mitochondria similarly to regular aggresomes. Some viruses form nuclear aggresomes others replicate in cytoplasmic aggresomes. Cells with aggresomes can undergo normal mitosis. The aggregated proteins are asymmetrically distributed to one of the eukaryotic daughter cells, leaving the other daughter (the one that divides further) free of accumulated protein damage (Rujano MA et al 2006 *PloS Biol* 4:e417). ►endoplasmic reticulum, ►proteasome, ►chaperone, ►ataxin, ►virioplasm, ►autophagy; Kopito RR 2000 *Trends Cell Biol* 10:524; Kolodziejaska KE et al 2005 *Proc Natl Acad Sci USA* 102:4854; Wileman T 2006 *Science* 312:875.

Aggression: A behavioral trait with great variance in animal and human populations; it may be an expression of innate self-assertion, frustration or a response to antisocial behavior encountered. It may be the consequence of affective disorders and mental illness (paranoia). Evolutionists attribute aggression to the means of survival in the struggle for life, and it is observable among the majority of animals. Accordingly, in subhuman beings it is instinctive and largely depends on the species concerned. Among humans, it has an animal component but it is determined also by the ethical and cultural factors of the individual and the standards of the population. While animals are not credited with conscientious value judgments, in human societies, the moral, ethical, religious and cultural

principles may predominate. All normal human ethnic groups appear to have a condemning attitude toward violence. Yet mainly humans display violent aggression within species. It has been suggested that the human species lack the ability of submission, a widely common ability among other mammals. In the male, vole antidiuretic hormone (vasopressin) may be responsible for aggression. The genetic basis of aggressive behavior is generally not understood although it is known that a deficiency, e.g., in hypoxanthine-guanine phosphoribosyl transferase may result in hostile and self-mutilating behavior. The major problem is concerned with the large non-biological but cultural component of aggression. Unfortunately, human societies treat the cultural problem with double standards: killing and violent behavior is condemned yet major religions approve patriotic or holy wars with the weapons of mass destruction. The questions remain unsettled whether capital punishment is appropriate for killers, is induced abortion an act of aggression, is euthanasia a merciful act or just another form of taking life? To what extent are criminals predestined by their genetic endowment to aggression and how much is the role of the social environment, and the free will? Obviously, some of the answers are beyond the scope of genetics. Mice deficient in α -calcium-calmodulin kinase II displayed reduced levels of serotonin and aggressive behavior. Mice with knocked-out adenosine receptor ($A_{2a}R$) display high blood pressure and aggressiveness. ►behavior genetics, ►submission signal, ►ethics, ►morality, ►instinct, ►Lesch-Nyhan syndrome, ►nitric oxide, ►calmodulin, ►serotonin, ►behavior in humans, ►personality, ►mental illness, ►paranoia, ►adenosine receptors, ►antidiuretic hormone.

Aggressiveness: Aggressiveness of a plant pathogen is measured by the evocation of a disease phenotype, depending on the genotype of the pathogen, that of the host and environmental factors.

Aging: An exponential increase in mortality as a function of time or cell divisions. Some type of irreversible alterations in the DNA may determine aging. In older cells, the chromosomal telomeres are shortened. Cloning by nuclear transfer can reverse this cellular aging (Hayflick limit), yet the aging pattern of the nuclear donor cell lines is genetically determined and it is conserved by nuclear transfer (Clark AJ et al 2003 *Nature Cell Biol* 5:535). In skeletal muscle stem cells, regeneration is impaired due to loss of Notch signaling. In liver cells, the decline is due to a complex of C/EBP and Brahma (chromatin remodeling factor). In aged mouse progenitor cells young serum restored the aforementioned functions (Conboy IM et al 2005 *Nature [Lond]* 433:760). In the aging heart tissue of the mouse there is a stochastic down-regulation of

gene expression compared to young hearts (Bahar R et al 2006 Nature [Lond] 441:1011).

The frequency of nondisjunction dramatically increases by age, e.g., the incidence of Down syndrome may increase 200 fold in the offspring of just pre-menopausal mothers. The autosomal recessive Werner syndrome (gene frequency 1 to 5×10^{-3}) involves premature aging (graying of hair, atrophy of skin, osteoporosis, decreased libido, and increased risk of cancer) is characterized also by non-ketotic hyperglycinemia. Progeria (Hutchinson-Gilford syndrome), another autosomal recessive trait, also causes very early senescence. The Rothmund-Thomson, Cockayne, and Down syndromes, trichothiodystrophy and ataxia telangiectasia, all involved with defects in maintaining DNA integrity, display progeroid symptoms (Hasty P et al 2003 Science 299:1355). Severe mutation in the xeroderma pigmentosum F gene (*XPF*) can lead to profound crosslinking sensitivity and progeroid symptoms. This gene encodes an endonuclease, similar to that encoded by RAD1 in yeast. Expression data from XPF-ERCC1-deficient mice indicate increased cell death and anti-oxidant defenses, a shift towards anabolism and reduced growth hormone/insulin-like growth factor 1 (IGF1) signaling (Niedernhofer LJ et al 2006 Nature [Lond] 444:1038).

Aging has been attributed to defects of the immune system and to diminished activity of superoxide dismutase, an enzyme normally destroying the highly reactive radicals that arise due to irradiation and aerobic metabolism. During aging of healthy individuals, the rate of loss or organ function is variable but with some exceptions (endocrine, thermoregulatory and gastrointestinal systems, which lose faster) it is generally between 0 to 2% annually (Sehl ME, Yates FE 2001 J Geront A Biol Sci Med Sci 56:B198). Aging increases the potentials for cancer by some partly understood processes (Finkel T et al 2007 Nature [Lond] 448:767).

It has been suggested that aging is the result of degenerative changes in the mitochondria, the formation of aberrant DNA circles. Recent information fails to support increased point mutation rate in the control region of cultured fibroblast mitochondrial DNA among normal individuals or persons with neurodegenerative diseases (Chinnery PF et al 2001 Am J Hum Genet 68:529). Defective mitochondrial DNA polymerase γ results in premature aging in mice (Trifunovic A et al 2004 Nature [Lond] 429:417). It seems that premature aging in mutable mtDNA is caused by the mutator activity without affecting the production of ROS, reactive oxygen species (Trifunovic A et al 2005 Proc Natl Acad Sci USA 102:17993). Aging mitochondria frequently show deletions (Bodyak N et al 2001 Hum Mol Biol 10:17).

Some genes are silenced by methylation and others are activated by demethylation during aging. By-products of oxidative phosphorylation, hydrogen peroxide and superoxide may accumulate during senescence. Over-expression of catalase in the mitochondria of transgenic mice extended life span (Schriner SE et al 2005 Science 308:1909). Aging causes primarily functional losses in the neurons rather than large-scale losses of the neurons. Atrophy, decrease of receptors, accumulation of fluorescent pigments and cytoskeletal abnormalities in the brain occur in aging mammals (see Fig. A35).

Figure A35. Progeria. (From Bergsma, D. ed. 1973 Birth Defects. Atlas and Compendium. By permission of the March of Dimes Foundation)

Microarray hybridization of aging neocortex and cerebellar tissues of mouse, involving (6347) genes, indicated inflammatory responses, oxidative stress and reduced neurotrophic support. Caloric limitations retarded some of the symptoms by decreasing glucose and insulin-like growth factor level in the plasma (Longo VD, Finch CE 2003 Science 299:1342). Caloric restriction limits aging, probably by reducing oxidative stress and promotes proliferation of mitochondria through a peroxisome proliferation-activated receptor coactivator 1α signaling (López-Lluch G et al 2006 Proc Natl Acad Sci USA 103:1768). Reduced body temperature in mice also increased life span (Conti B et al 2006 Science 314:825). Insulin/insulin-like growth factor signaling promotes growth, energy storage and shorten life cycle. Transcription factor FOXO (regulator of pro-apoptotic and cell cycle genes) and June-N-terminal kinase (JNK, a stress factor) may prolong life span (Wang MC et al 2005 Cell 121:115). Mouse with 5-adenylylcyclase knocked out (*AC5* KO) is resistant to cardiac stress and have increased median lifespan of 30%. *AC5* KO mice are protected from reduced bone density and susceptibility to fractures of aging. Old *AC5* KO mice are also protected from aging-induced cardiomyopathy, e.g., hypertrophy, apoptosis, fibrosis, and reduced cardiac function. Significant activation of the Raf/MEK/ERK

A

signaling pathway and upregulation of cell protective molecules, including superoxide dismutase were detected. Fibroblasts isolated from *AC5* KO mice exhibited ERK-dependent resistance to oxidative stress (Yan L et al 2007 Cell 130:247).

An analysis of gene expression of humans indicates that a set of genes display reduced expression after age 40. These genes involve synaptic plasticity, vesicular transport and mitochondrial function. In contrast, genes concerned with stress response, anti-oxidation and DNA repair are induced. The promoters are damaged in the aged cortex of the brain due to reduced DNA base excision (Lu T et al 2004 Nature [Lond] 429:883). Aging is not caused by the activation of specific genes rather it is the consequence of decline in maintenance factors and the accumulation of damage (Kirkwood BL 2005 Cell 120:437). Mutations in genes affecting endocrine signaling, stress responses, metabolism and telomeres can increase the life span as well as changes delaying age-related disease pathways (Kenyon C 2005 Cell 120:449). In *Caenorhabditis* superoxide dismutase and catalase reduced aging significantly. This causes delays in mitochondrial replication. The slow replication leaves unprotected the D loop of mtDNA, possibly increasing the chances for deletions and mutations (see Fig. A36).

During normal aging the same lamin A cryptic splice site and histone modifications take place as in Hutchinson-Gilford progeria (Scaffidi P, Misteli T 2006 Science 312:1059). Anticonvulsant drugs (ethosuximide) prolonged life of *Caenorhabditis* (Evason K et al 2005 Science 307:258). Misregulation of mitosis caused by gradual defects in cell cycle control proteins, chromosomal movement, etc. may also be players in aging. Voltage-activated Ca^{2+} influx into the brain neurons is accelerated during aging.

Hereditary premature aging is also known in animals. The mouse autosomal recessive gene *klotho*—encoding β -glucuronidase (Chang Q et al 2005 Science 310:490)—seems to be a regulator of several symptoms of aging and represses insulin-like growth factor (IGF) signaling (Kurosu H et al 2005 Science 307:1829). A *klotho* allele in humans, KL-VS (13q12) potentially increases the susceptibility to coronary artery disease (Arking DE et al 2003 Am J Hum Genet 72:1154). *Klotho* regulates the transient receptor potential ion channel (TRPV5) by hydrolyzing extracellular sugar residues on TRPV5 and regulates calcium concentration in the blood. Calcium deposits can cause arterial disease. *Klotho* converts the fibroblast growth factor to a kidney special FGF23 receptor (Urakawa I et al 2006 Nature [Lond] 444:770).

The product of this gene shares sequence similarities with β -glucosidase proteins. In *klotho*^{-/-} mouse

the level of μ -calpain is specifically activated and it leads to degradation of the cytoskeletal protein α -spectrin (Manya H et al 2002 J Biol Chem 277:35503). In *Caenorhabditis*, mutations are known that in combination may extend the life of the nematodes through two different pathways up to five fold. Mutation in succinate dehydrogenase cytochrome b causes oxidative stress and premature aging in the nematodes. In *Drosophila* the *mth* (*methuselah*) mutant line, encoding apparently a protein with homology to GTP-binding proteins with seven-transmembrane domain receptors, extends the life by about 1/3.

In yeast, activated GTPase (RAS), inactivation of the *LAG1* gene (encoding a membrane-spanning protein) and the *SIR* silencing complex extend life span (Hekimi S, Guarente L 2003 Science 299:1351). Aging in mammals seems to be associated with aging of the lymphocytes and their function. DNA microarrays can detect gene expression changes during development/aging and it seems that the processes show great similarities between *Caenorhabditis* and *Drosophila* (McCarroll SA et al 2004 Nature Genet 36:197). The telomerase enzyme has also been implicated in aging. Since aging usually occurs after the reproductive period, it is no longer the object of natural selection (antagonistic pleiotropy). Population geneticists entertain two genetic mechanisms for aging: the accumulation of deleterious mutations and increase in antagonistic pleiotropy among gene loci. Some population display *altruistic aging*, i.e., aging becomes beneficial for the younger groups of individuals. In rodents, calorie restricted (CR) diet has substantial anti-aging effect. In yeast, the replicative lifespan is increased by deleting *TOR*, *SCH9* (limiting caloric uptake) and deletion of *FOB1* genes (limiting ribosomal DNA replication). Several other deletions are also increasing lifespan of yeast (Kaeberlein M et al 2005 Science 310:1193). Mammalian cell survival is promoted by caloric restriction through the induction of the SIRT1 deacetylase. SIRT1 (Sir2) deacetylates the repair factor Ku70, which moves away the pro-apoptotic Bax protein from the mitochondria and thus inhibits apoptosis, which is associated with aging. Mitochondrial mutations due to proof-reading deficiency of DNA polymerase γ caused various mutations in mouse mitochondria but only an increase in apoptotic markers furthered aging (Kujoth GC et al 2005 Science 309:481).

Insulin and insulin-like growth factor attenuate the SIRT effect (Cohen HY et al 2004 Science 305:390). Aging has been attributed also to the gradual loss of the telomeric DNA repeats. It has been suggested that the secretion of inflammatory cytokines may be a contributing factor. The life expectancy in years in the USA changed from 47 to 76 from (1900) to 2000.

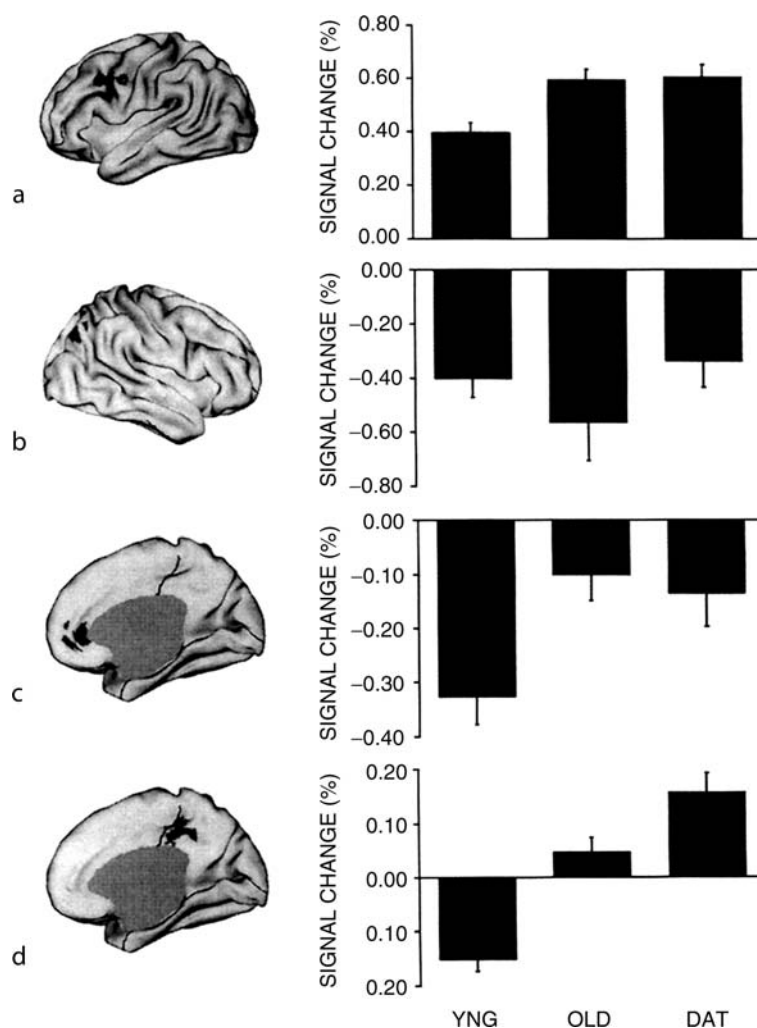

Figure A36. Brain activity in aging and Alzheimer disease. The brain was scanned by magnetic resonance imaging in four angles of the cortex. (a) left frontal, (b) right lateral parietal, (c) medial frontal and (d) medial parietal/posterior cingulate. The relative activity in each region is shown by bars and standard error for young adults (yng), healthy old (old) and older adults with early-stage alzheimer type dementia (dat). Noteworthy is that young adults deactivate specific brain regions during active task performance. The deactivated regions overlap with those that show reduced resting metabolic activity in aging and dementia. The most critical difference between healthy and alzheimer dementia is shown at (d). (Courtesy of Lustig C et al 2003 Proc Natl Acad Sci USA 100:14504 by permission. Copyright National Academy of Sciences USA, 2003). In mice the metaproteinase Zmpste24 is essential for lamin A of the nuclear envelope and its deficiency results in senescence by activation of p53 (Varela I et al 2005 Nature [Lond] 437:564)

In Sweden, the maximum life expectancy increase between (1861) and (1999) was 0.44 year per decade. The heritability of aging based on twins of humans is about or less than 0.35. The evidence for the role of mitochondria in aging has been questioned. Age-associated decline of cognitive abilities seem to be correlated to neuronal atrophy in the subcortical regions of the brain and the process may be prevented by neurotrophin or neurotrophin gene therapy. Somatic transfer of CREB gene into the hippocampal region of the brain of 15 months old rats reduced

memory loss (Mouravlev A et al 2006 Proc Natl Acad Sci USA 103:4750). ▶senescence, ▶Hayflick's limit, ▶longevity, ▶killer plasmids, ▶chromosome breakage, ▶DNA repair, ▶Werner syndrome, ▶progeria, ▶Hutchinson-Gilford syndrome, ▶Cockayne syndrome, ▶Bloom syndrome, ▶Alzheimer disease, ▶xeroderma pigmentosum, ▶ERCC, ▶longevity, ▶superoxide dismutase, ▶ion channels, ▶RAS, ▶lymphocytes, ▶telomere, ▶telomerase, ▶cytokines, ▶selection, ▶silencer, ▶RAS, ▶mating type determination in yeast, ▶mortality, ▶apoptosis,

Aglycon: Protein or lipid linked to a polysaccharide.

α-1,4-Glucosidase Deficiency: ►acid maltase

Agonadism, Familial: Absence of gonadal tissue; usually part of a syndrome. ►azoospermia

Agonescence: Telomere-shortening dependent cell senescence and may be abrogated by telomerase. ►senescence

Agonist: Activates a receptor. *Inverse agonists* are antagonists of overexpressed receptors.

Agonistic Behavior: Combative behavior. ►aggression

Agoraphobia: A psychological disorder of fear from certain conditions or venues.

Agouti: Alternating light and dark bands on individual hairs of the fur in mammals such as mouse, rat, rabbit (see Fig. A37). The genes *agouti* and *extension* determine the relative amounts of eumelanin (brown-black) and pheomelanin (yellow-red) pigments. *Extension* encodes the receptor of the melanocyte-stimulating hormone (MSH) and *agouti* is a signal sequence in the hair follicle, inhibiting eumelanin production and the melanocortin receptor, an MSH receptor. Agouti has been cloned and sequenced; it contains 5 exons but two of them are not translated. The secreted protein products have 131 amino acid residues. The alleles that produce increased amounts of pheomelanin makes the mice more prone to late-onset obesity and diabetes. An agouti-related protein (AGRP), a neuropeptide, may increase several fold in obese mice. A^y and A^{vy} increase the liability to neoplasias and others cause embryonic lethality. ►pigmentation of animals, melanin, ►melanocyte-stimulating hormone, ►melanocortin, ►ghrelin; Dinulescu D, Cone RD 2000 J Biol Chem 275:6695.

Figure A37. Agouti hair pattern

Agrelope: The part of an antigen that interacts with a deselope (antigen-binding site) of a MHC (major histocompatibility) molecule. ►deselope, ►epitope, ►histotop, ►antigen

Agricultural Measures: ►measurement units

1 hectare (ha) = 10 m⁴ = 2.47109 acres; 1 acre = 0.40469 hectare; 1 square kilometer = 100 hectares; 1 square mile = 640 acres = 259 ha.

1 bushel (bu) = 35.2393 liters = [approximate values]; *wheat* = 60 lb = 27.215 kg, *paddy rice* = 45 lb = 20.412 kg, *corn* (maize) = 56 lb = 25.401 kg, *soybeans* = 60 lb = 27.215 kg, *rye* = 56 lb = 25.401 kg, *sorghum* = 56 lb = 25.401 kg, *barley* = 48 lb = 21.772 kg, *potatoes* = 60 lb = 27.215 kg, *oats* = 32 lb = 14.515 kg, *apples* = 48 lb = 21.772 kg.

1 box of oranges (California, Arizona) = 77 lb = 34.926 kg, (Florida, Texas, Louisiana) = 90 lb = 40.823 kg, 1 box of *lemons* = 79 lb = 35.843 kg.

1 bale of cotton (U.S.) = 480 lb = 217.723 kg.

100 kg per hectare = 1.49 bushel (60 lb) per acre; 1 bushel (60 lb) per acre = 67.3 kg per hectare.

1 metric ton = 0.98421 long tons = 1.10231 short tons = 10 metric quintals.

Agricultural Productivity: Affected by genetic improvement of plants and animals and improved husbanding and cultural practices. Between the years (1951) and (1980) the overall plant productivity in the USA increased 166% and that of animals to 144%. The yield of maize after the introduction of hybrids increased to about 500%. ►heterosis, ►QTL

Agrin: A natural glycoprotein (200 kDa) causing the aggregation of acetylcholine receptors on muscle cells in vitro and in vivo is used for the formation of neuromuscular junctions and the T lymphocytes. The process also requires a muscle-specific protein kinase (MuSK). $\alpha 3Na^+/K^+$ -ATPase is the neural receptor for agrin (Hilgenberg, LGW et al. 2006 Cell 125:359). Agrin deficient mutant mouse is inviable. Agrin may restore function in muscular dystrophies caused by mutation in laminin. ►acetylcholine receptors, ►laminin, ►neuregulins; Trautmann A, Vivier E 2001 Science 292:1667; Moll J et al 2001 Nature [Lond] 413:302; Misgeld T et al 2005 Proc Natl Acad Sci USA 102:11088.

Agrobacterial Vectors: ►cointegrate vectors, ►binary vectors, ►transcriptional gene fusion vector, ►translational gene fusion vectors

Agrobacterium Mini-Plasmid: Carries the T-DNA, including its borders, but it is free of other segments, including the *vir* genes. *Agrobacterium tumefaciens*, ►T-DNA

Agrobacterium rhizogenes: A bacterium closely related to *A. tumefaciens*. It induces hairy roots rather than crown gall on the host plants. The genes responsible for the formation of hairy roots reside in the *Ri* plasmid. The hairy root tissues, unlike crown gall, readily regenerate into plants. The *Ri* plasmid has been used similarly to the *Ti* plasmid to construct plant transformation vectors. In *Nicotiana glauca* DNA sequences (*Ngrol*) homologous to the left segment of the T-DNA of the *Ri* plasmid have been detected. This observation indicates horizontal interspecific gene transfer. (►*Agrobacterium tumefaciens*, ►*Ri* ►plasmid, ►crown gall Moriguchi K et al 2001 J Mol Biol 307:771).

Agrobacterium tumefaciens: A soil born plant pathogenic microorganism of the family of *Rhizobiaceae*. It is responsible for the crown gall disease (tumor) of the majority of wounded dicotyledonous plants and it also infects a few monocots (*Liliaceae*, *Amaryllidaceae*). Several of its characteristics are similar to *Rhizobium*, *Bradyrhizobium* and *Phyllobacterium* species (see Fig. A38). The pathogenicity is coded in genes within the T-DNA of its *Ti* (tumor-inducing plasmid). T-DNA containing plasmids are the most important transformation vectors of plants. The T-DNA (transferred DNA) is an about 21 kb segment of the *Ti* plasmid with two direct repeat flanks bordering the oncogenes (responsible for tumorigenesis in the wild type plasmids), and some of the opine genes. Molecular biologists most widely use the *Agrobacterium* strains A6 and C58, containing octopine and nopaline encoding *Ti* plasmids, respectively. Certain *Agrobacteria* strains have *limited host range* (LHR) caused by an altered *virA* gene in the *Ti* plasmid. The *supervirulent* strains on the other hand overproduce the *VirG* protein. The infection of some species of plants is limited. Inhibition of purine synthesis leads to supersensitivity to infection in yeast, *Arabidopsis*, tobacco and *Ageratum* plants (Roberts RL et al 2003 Proc Natl Acad Sci USA 100:6634).

Figure A38. Crown gall

For the transfer of the T-DNA to other cells, including plant cells, requires the formation of a conjugation tube (pilus) controlled by virulence genes *virA*, *virG*, *virB1* to *virB11*. Altogether about 12 genes are involved in the transfer. *Agrobacterium tumefaciens* C58 has one ~2.1-Mb linear chromosome and three circular DNA plasmids (~2.8 Mb, ~0.54 Mb, ~0.21 Mb). Its total genome is ~5.67 Mb. The total number of assigned protein-coding genes is 1286, 1715, 333 and 141, respectively. The T-DNA is located in the 0.21 Mb plasmid. *Agrobacteria* can transfer DNA also to yeast and some other fungi. The T-DNA can integrate from binary vectors also into human HeLa cells (Kunik T et al 2001 Proc Natl Acad Sci USA 98:1871). Transferring the T-DNA into plant symbiotic bacteria such as *Rhizobia* enables these bacteria to transfer genes into plants (Broothaerts W et al 2005 Nature [Lond] 433:629). (►*Ti* plasmid, ►T-DNA, ►virulence genes of *Agrobacterium*, ►transformation [plants], ►host-pathogen relation, ►BIBAC, ►transformation genetic; Koncz C et al 1992 Methods in Arabidopsis Research, In: Koncz C et al (eds) World Scientific Publ. Co., Singapore, p. 284; Tzfira T et al 2000 Annu Rev Microbiol 54:187; Kunik T et al 2001 Proc Natl Acad Sci USA 98:1871; Wood DW et al 2001 Science 294:2317).

Agrocin 84: The non-plant-pathogenic *Agrobacterium radiobacter* synthesizes this compound and it is taken up by *A. tumefaciens* carrying agrocinopine. Agrocin associated with a toxin moiety is toxic to *A. tumefaciens* because it inhibits leucyl-tRNA synthetase. ►*Agrobacterium tumefaciens*, ►crown gall; Reader JS et al 2005 Science 309:1533; Kim J-G et al 2006 Proc Natl Acad Sci USA 103:8846.

Agrocinopine: A phosphorylated sugar, an opine, produced in octopine plasmids from mannopine by the enzyme agrocinopine synthase. ►*Agrobacterium*, ►opines, ►octopine

Agroinfection: A method of plant transformation. More than one genome of the double-stranded DNA of Cauliflower Mosaic Virus is inserted in tandem within the T-DNA of *Agrobacterium tumefaciens*. Such a construction permits the escape of the viral DNA from the bacterial plasmid once it was introduced into plants. Gemini viruses can be introduced into plants in a similar way. ►cauliflower mosaic virus, ►gemini-viruses, ►transformation genetic; Grimsley N et al 1989 Mol Gen Genet 217:309.

Agropine: Bicyclic phosphorylated sugar derivative of glutamic acid; it is synthesized by *Agrobacterium* strain Ach5. opines.

A

Agropyron ($x = 7$): A genus of grasses; their chromosomes are homoeologous to that of several species within the genus of wheat and can be substituted to introduce agronomically useful genes (e.g., disease resistance). Some hybrids are known as perennial wheat, a forage crop. ▶[chromosome substitution](#), ▶[alien transfer](#), ▶[homoeologous chromosomes](#)

α GT (glucosyltransferase uridine 5'-diphosphate galactose β -D galactosyl-1,4-*N*-acetyl-D-glucosaminide α (1-3)galactosyltransferase, E.C.2.4.1.151): Synthesizes the carbohydrate epitope Gal α 1-3Gal β 1-4GlcNAc-R, which reacts with natural antibodies forming a barrier to xenotransplantation. Murine bone marrow cells transgenic for α GT may overcome the production of xenoreactive antibodies. This principle may facilitate the development of techniques to facilitate organ transfer between animals and humans. ▶[epitope](#), ▶[xenograft](#), ▶[transgenic](#), ▶[antibodies](#), ▶[epitope](#)

AGRP (agouti-related protein): ▶[agouti](#), ▶[obesity](#)

α -Helix: A secondary structure of polypeptides with maximal intrachain hydrogen bonding. A most common conformation, when after 5.4 Å high, five right turns of an amino acid chain, every 18th amino acids occupy the same line as the first. ▶[pitch](#), ▶[protein structure](#)

Ahonen Blood Group: A rare type, distinct from ABO, MNS, P, Rh, Duffy, Kidd and Dembrock. ▶[blood groups](#)

AHR: ▶[arylhydrocarbon receptor](#)

AIB: A steroid receptor implicated in breast cancer. ▶[breast cancer](#), ▶[steroid hormones](#); Anzick SL et al 1997 Science 277:965.

Aicardi-Goutières Syndrome (AGS1 3p21; AGS2 13q14.3, AGS3 11q13.2, AGS4 19p13.13): A heterogeneous disease, a progressive encephalopathy with calcification of the basal ganglia, excessive number of lymphocytes in the cerebrospinal fluid (lymphocytosis), brain atrophy and early death after birth. Elevated level of interferon α in the brain fluids—in the absence of infection—is a marker for the disorder. AGS1 is caused by mutation of TREX1, a DNA repair exonuclease. AGS2 is due to mutation of endoribonuclease H β -subunit. AGS3 involves mutation in the C subunit of ribonuclease H and AGS4 is mutant in ribonuclease H A subunit. ▶[ribonuclease H](#); Crow YJ et al 2000 Am J Hum Genet 67:213; Crow YH et al 2006 Nature Genet 38:910.

AICD: ▶[memory immunological](#)

AID: Artificial insemination by donor. artificial insemination, ▶[AIH](#), ▶[ART](#), ▶[acquired immunodeficiency](#)

AID (activation-induced deaminase): The main cause of somatic hypermutation (10^{-3} to 10^{-4} per base) and its deficiency obliterates somatic hypermutation and class switching in the development of the secondary repertoire of antibody molecules, the last step in the generation of functional antibodies. The main targets of AID are cytidines in single-stranded DNA or in double-stranded DNA during transcription. It erases methyl marks during development. Although immunoglobulins are the main targets of AID, other genes and bases besides C are also affected primarily in a binding motif of the enhancer/promoter region (Kotani A et al 2005 Proc Natl Acad Sci USA 102:4506). Protein kinase A (PKA) mediated phosphorylation is a critical factor in B cell antibody diversification (Basu U et al 2005 Nature [Lond] 438:508). ▶[immunoglobulins](#), ▶[antibody](#), ▶[antibody gene switching](#), ▶[class switching](#), ▶[immune system](#), ▶[epigenetics](#), ▶[APOBEC](#), ▶[UNG](#); Martin A et al 2002 Nature [Lond] 415:802; Conticello SG et al 2005 Mol Biol Evol 22:367)

AIDS: ▶[acquired immunodeficiency syndrome](#)

AIF (apoptosis-inducing factor): A mammalian mitochondrial flavoprotein (M_r 57K) with homology to prokaryotic oxidoreductases. The encoding gene was located to human chromosome Xq25-q26. From purified mitochondria AIF liberates—by increasing membrane permeability—cytochrome-c and caspase-9 and when injected into the nuclei it causes DNA breakage and thus promotes apoptosis. ▶[apoptosis](#), ▶[APAF](#), ▶[mitochondrial diseases in humans](#), ▶[mtPTP](#), ▶[CAD](#), ▶[ACINUS](#), ▶[L-DNase II](#); Wang X et al 2002 Science 298:1587.

AIG (anchorage independent growth): Normal mammalian cells grow in monolayer anchored to a solid surface. Tumor cells grow independently of anchorage. ▶[anchorage](#), ▶[tumor](#), ▶[cancer](#), ▶[CATR1](#), ▶[onco-genes](#)

AIH: Artificial insemination by husband. AID, ▶[artificial insemination](#), ▶[ART](#)

AIMS: *Arabidopsis* information database at Michigan State University. ▶[Arabidopsis thaliana](#)

AIR: Mitotic kinase acting on histone.

AIRE: An autoimmune regulatory protein of ~545 amino acids; when defective it is responsible for the autoimmune polyendocrine syndrome. ▶[APECED](#), ▶[autoimmune disease](#), ▶[autoimmune polyendocrinopathy](#)

Air Pollution: A probable cause of alterations in the genetic material. It appears that expansion of tandem repeats in the DNA increased about twofold by particulate material in the air compared to the gaseous material (Somers CM et al 2004 Science 304:1008). ▶environmental mutagens, ▶tandem repeat, ▶unequal crossing-over

AKAPs (A kinase anchoring protein): Cytoplasmic proteins, binding to cyclic adenosine 3',5' monophosphate (cAMP-dependent protein kinase PKA, calcineurin [phosphatase 2B]) and protein kinase C [PKC] and appears to have a regulatory role as a scaffold for the cellular signaling system. signal transduction, ▶T cell, ▶condensin; Colledge M, Scott JD 1999 Trends Cell Biol 9:216.

AKI: Adenylate kinase.

A-Kinases: cAMP-dependent protein phosphorylating enzymes; the phosphorylation is dependent on sufficiently high level of cAMP. ▶cAMP

Akinesia (akinesia): Lack of movement or poor movement or paralysis. Several types of fetal akinesia are parts of several syndromes. ▶Pena-Shokeir syndrome

AKR Mice: A long-inbred albino, specially selected strain of the animals containing the genes *Akv-1* and *Akv-2* that code for ecotropic retroviruses causing thymic lymphosarcoma (leukemia). Ecotropic viruses replicate only in cells from what they have been isolated originally. AKR strains have relatively short life span, are sensitive to ionizing radiation and highly susceptible to the carcinogenic effect, but resistant to the teratogenic effect of ethylnitrosourea. ▶replicase, ▶ecotropic retrovirus, ▶ENU

AKT Oncogene (PKB, serine/threonine protein kinase B): Isolated from thymomas (cancer of the thymus) of AKR mice transformed by an ecotropic virus. In the mouse genome, it is located in chromosome 12. A homolog of it is found in human chromosome 14q32.3 and it is frequently associated with chromosomal breakage. The Akt protein is a threonine/serine protein kinase (protein kinase B/PKB) and targeted by PI3-kinase-generated signals. Akt is involved in the regulation of cellular proliferation/apoptosis, glycogen synthase kinase (GSK3), endothelial nitric oxide synthase and protein synthesis. The interplay of Akt and Tor is frequently observed in cancer progression (Hay N 2005 Cancer Cell 8:179). AKT is activated by loss of PTEN in several types of tumors. Akt is regulated also by an insulin-like growth factor (IGF) and the nerve growth factor (NGF). AKT2 defect results in insulin resistance and diabetes (George S et al 2004 Science 304:1325). Akt is often called a cell survival kinase, activated by phosphoinositide kinase,

PIK and down-regulated by the RAS oncoprotein or by a phosphatase. Akt reduces apoptosis by phosphorylating protein BAD and inhibiting Bcl and caspase-9 in human cells. AKT inhibits cytochrome C release from mitochondria and thus inhibits apoptosis even when BAX and BAK are inactive (Majewski N et al. 2004 Mol Cell 16:819). The level of Akt1 was found 68% lower in schizophrenia than in normal tissues (Emamian ES et al 2004 Nature Genet 36:131). Akt regulates NF-κB that promotes the expression of anti-apoptotic genes. When Akt phosphorylates Raf the Raf-MEK-ERK signaling pathway is inhibited and cellular proliferation is initiated. The antiapoptotic PDGF also seems to be under Akt influence. TNF-α may or may not be involved through IKK in the regulation of NF-κB. The apoptotic FAS protein synthesis is apparently limited through blocking the FKK protein by Akt. *Akt1* governs mammary epithelial tumor cell (MEC) polarity, migratory directionality and breast cancer onset induced by ErbB2 in vivo (Ju X et al 2007 Proc Natl Acad Sci USA 104:7438). ▶AKR, ▶insulin-like growth factor, ▶nerve growth factor, ▶PKB, ▶phosphoinositides, ▶ecotropic retrovirus, ▶apoptosis, ▶glycogen, ▶hexokinase, ▶GSK3, ▶mice, ▶oncogenes, ▶nitric oxide, ▶BAD, ▶Bcl, ▶BAX, ▶BAK, ▶caspase, ▶NK-κB, ▶PDGF, ▶IKK, ▶FKK, ▶PDK, ▶ERBB1, ▶signal transduction, ▶TOR, ▶epiloia, ▶prostate cancer, ▶PML, ▶Parkinson disease; Datta SR et al 1999 Genes and Development 13:2905; Madrid LV et al 2001 J Biol Chem 276:18934).

ALA: Aminolevulinic acid, a first compound in the synthesis of porphyrins from glycine and succinyl CoA. ▶heme

α-Lactose: Milk sugar is converted into allolactose by the β-galactosidase gene of the *Lac* operon of *E. coli* and the latter then becomes the inducer of the operon. ▶Lac operon

Aladin (AAAS, triple-A syndrome): A neurological disorder resulting in alacrima (lack of tears), achalasia (failure of the smooth muscles to relax), and adrenal insufficiency because of defect in a WD-repeat family of regulatory proteins encoded at 12q13.1. ▶WD-40

Alagille Syndrome: Autosomal dominant (human chromosome 20p11.2) involving obstruction of the bile duct (cholestasis) and jaundice, lung anomalies (pulmonary stenosis), deformed vertebrae, arterial narrowness, deformed iris, altered eye pigmentation, facial anomalies (see Fig. A38), etc. The biochemical defect is in the Notch-ligand, Jagged-1. In some cases translocations or deletions of the region accompany it.

A

Figure A39. Alagille syndrome. By adulthood prominent chin develops in Alagille syndrome

The multiplicity of the symptoms has been considered as a contiguous gene syndrome. The incidence is $\sim 4 \times 10^{-4}$. ▶contiguous gene syndrome, ▶face/heart defects, ▶cholestasis, ▶Byler disease, ▶BRIC, ▶Fallot's tetralogy, ▶Notch; Spinner NB et al 2001 Hum Mutat 17:18.

Aland Island Eye Disease: ▶albinism ocular

Alanine: L-alanine [$\text{CH}_3\text{CH}(\text{NH}_2)\text{COOH}$] is a non-essential amino acid for mammals. The enantiomorph D-alanine may not be metabolized by some organisms and may even inhibit their growth. β -Alanine [$\text{CH}_3\text{CH}_2\text{CH}_2\text{CO}_2\text{COOH}$] is synthesized by several microorganisms from aspartate but it occurs only in trace amounts in animal tissues, possibly through the action of intestinal microorganisms; γ -butyric acid [$\text{H}_2\text{NCH}_2\text{CH}_2\text{CH}_2\text{COOH}$] is structurally related. Its dipeptides with histidine are carnosine, homocarnosine and anserine. ▶alaninuria, ▶alanine aminotransferase, ▶carnosinemia

Alanine Aminotransferase (glutamate-pyruvate transaminase, GPT): Autosomal dominant gene (8q24.2-qter) encodes the enzyme that catalyzes the reversible transamination of pyruvate and α -ketoglutarate to alanine. This enzyme exists in cytosolic and mitochondrial forms. ▶amino acid metabolism, alaninuria, ▶glutamate pyruvate transaminase, ▶alanine

Alanine-Scanning Mutagenesis: ▶homologue-scanning mutagenesis

Alaninuria (with microcephaly, dwarfism, enamel hypoplasia and diabetes mellitus): The autosomal recessive condition is accompanied by the clinically demonstrable excessive amounts of alanine, pyruvate and lactate in the blood and urine. Both lactate and alanine are derived from pyruvate. ▶alanine aminotransferase, ▶amino acid metabolism, ▶alanine, ▶hypoplasia, ▶diabetes

Alarmones: Signal molecules (commonly modified nucleotides such as ppGpp) in response to stress. ppGpp interferes with IF2-dependent initiation

complex formation, severely inhibits initiation dipeptide formation, and blocks the initiation step of translation. IF2 has the properties of a cellular metabolic sensor and regulator that oscillates between an active GTP-bound form under conditions allowing active protein syntheses and an inactive ppGpp-bound form when there is a shortage of nutrients (Milon P et al. 2006 Proc Natl Acad. Sci USA 103:13962). ▶discriminator region, ▶IF2

Albers-Schönberg Disease: ▶osteopetrosis type II

Albinism: A pigment-free condition in plants and animals (see Fig. A40). The absence of skin and hair pigmentation in mammals is generally determined by homozygosity of recessive genes controlling melanin synthesis. Melanocytes are the cells specialized for melanin synthesis. During embryonal development melanoblasts, precursor cells of melanocytes move to surface areas. Melanin is synthesized in special cytoplasmic organelles, melanosomes.

Figure A40. Tyrosinase (Tyr, chromosome 7–44.0) alleles of mouse (left *c/c*, right *c/c<ch> p/p*). Courtesy of Dr. Paul Szauter, <http://www.informatics.jax.org/mgihome/other/citation.shtml>

The precursor of melanin is the amino acid tyrosine and the conversion is catalyzed by the aerobic oxidase, tyrosinase (polyphenol oxydase). In one type of albinism tyrosinase activity in the hair follicle is still present. Albinism may involve the entire melanocyte system of the body or it may be limited to the eye (11q14-q21). In this case, a pigment-specific integral glycoprotein product of the (oculocutaneous) OCA1 gene is specially targeted to the intracellular melanosomes. OCA2 was assigned to 15q11.2-q12. OCA3 is at 6q13-q15. Albinism of the eye may occur in a sectorial manner in females heterozygous for the Xp22.3-p22.2-linked recessive gene (OA1). Albinism of the eye may involve problems of vision, involuntary eye movements (nystagmus), and head nodding. OA2 (Xp11.4-p11–23) males may be partially color blind (protanomalous). Albinism is controlled by numerous single genes.

Figure A41. Cuna Indian Albinos (Courtesy of Dr. C Keeler)

The prevalence of albinism varies from 1/14,000 to 1/60,000 depending on the gene, and the ethnicity of the population; it is generally more frequent among negroids than among caucasoids. Ocular albinism may occur very frequently among some Indian tribes (1/150). Albinism involves hypersensitivity to light and increased susceptibility to some forms of cancer. The absence of hair pigmentation may be locally corrected by gene therapy using the normal tyrosinase gene. Albinism may be a component of complex syndromes and may be associated with deafness, neuropathy and bleeding disorders. Albina condition occurs with very high frequency in progenies of plants exposed to ionizing radiation (see Fig. A41). In plants over 100 genes can cause albinism when mutated. ▶Himalayan rabbit, ▶piebaldism,

Figure A42. Albina plant

▶pigmentation of animals, ▶Chédiak-Higashi syndrome, ▶Hermansky-Pudlak syndrome, ▶xeroderma pigmentosum, ▶light-sensitivity diseases, ▶color blindness, ▶tyrosinase, ▶eye color, ▶hair color, ▶motor proteins, ▶oculocutaneous albinism; Toyofuku K et al 2001 Biochem J 355(pt2):259.

Albino: Animals defective in melanin synthesis. More commonly in plants, *albina* is the designation of leaf-pigment-free individuals (because the Latin word *planta* is of feminine gender).

Albizzin (L-2-amino-ureidopropionic acid): A glutamine analog. ▶asparagine synthetase

Albomaculata (or status albomaculatus): A green-yellow-white variegation caused by mutation in extranuclear genes in plants. ▶chloroplast genetics

Albright Hereditary Osteodystrophy (pseudohypoparathyroidism, PHP1A, PHP1B, 20q13.2): Autosomal recessive pseudoparathyroidism is based on a defect in a G-protein mutation. The locus actually encodes two G protein subunits, Gs and XL α_s . Gs is expressed from both parents, XL α_s is expressed only from the paternal chromosome. There is a third maternal transcript of the gene that encodes the neurosecretory NESP55 protein. The three transcripts share exons 2 to 11 but have different first exons. The NESP55 coding region is within exon 1 and the rest of the exons remain untranslated. An X-linked dominant form is based on a defect in the parathormone-adenylate cyclase-G $_s$ -protein complex. It displays imprinting. ▶hyperparathyroidism, ▶parathormone, ▶G-protein, ▶McCune-Albright syndrome, ▶imprinting, ▶epigenesis; Bastepe M et al 2005 Nature Genet 37:25.

Albumins: Include different proteins soluble in water and in dilute salt solutions, such as bovine serum albumin (BSA) used in chemical analyses. In the fetal serum of mammals, the predominant protein is the albumin α -fetoprotein, transcribed from two genes in humans, and they have about 35% homology and are immunologically cross-reactive despite their substantial divergence. Both serum albumin and α -fetoprotein, products of the same gene family, are synthesized in the liver and gut. After birth, the production of the latter drops dramatically whereas the former is produced throughout life. Their tissue-specificity of expression resides within 150 bp from the beginning of transcription. The α -fetoprotein gene carries three enhancer elements 6.5, 5 and 2.5 kbp upstream that may increase the level of transcription up to 50-fold. The liver-specificity for the serum albumin gene is controlled by the PE (proximal element), which is most important for promoter activity. It is located between the TATA and CCAAT

A

boxes. The distal element (DE I [around -100 base from the initiation of translation] is most important for liver-specificity. There are also DE II [around -116], DE III around about -158]). The PE element (5'-GTTAATGATCTAC-3') is quite similar to sequences in the promoters of other liver-expressed genes. The PE binding protein is HNF-1 (88 kDa) is also shared by other liver genes, including the hepatitis virus promoter. The binding proteins associated with the DEs do not appear liver-specific inasmuch as they are used by a variety of other genes of ubiquitous expression, or the specificity is modified by so far unknown co-factors. ►serum, ►fetoprotein, ►transcription, ►enhancer, ►promoter, ►TATA box, ►CCAAT box, ►HNF

Alcaptonuria: ►alkaptonuria

Alcohol: An organic molecule formed from hydrocarbons by substituting -OH for H. The simplest representative is ethanol (ethylalcohol, $\text{CH}_3\text{—CH}_2\text{—OH}$, MW 46.07, boiling point 78.3°C). Ethanol usually contains 5% water; the absolute ethanol is very hygroscopic; for disinfection the 60–80% solutions are most effective. Moderate alcohol consumption may protect against ischemic heart disease. This protection was attributed to modulation of blood lipoproteins, reduced activation of platelets and thrombosis. Protein kinase C(ϵ) signals may also be involved in the protection at physiological levels of blood alcohol (>10mM). ►ischemia, ►thrombosis, ►protein kinases, ►ethanol

Alcohol Dehydrogenase: ►ADH, ►mutation detection

Alcohol Fermentation: The conversion of sugar into alcohol in the absence of air by glycolysis. ►glycolysis

Alcoholism: A chronic and addictive use of the chemical is a behavioral trait with some hereditary component of the manifestation. Alcoholism may involve fatal or very serious consequences in certain diseases, in pregnancy, and when certain types of medicines or drugs are used. The *fetal alcohol syndrome* includes microcephaly (small head), folded skin at the side of the nose, defective eyelids, upturned nose, etc. In adults, it may cause cirrhosis of the liver leading to further (fatal) complications. The maternal alcohol blocks in the fetus the NMDA glutamate receptors and activates the GABA_A receptors resulting in long-lasting process of neurodegeneration. Unfortunately, no association between alcoholism and any particular gene or chromosomal segment has been firmly established; it is apparently under polygenic control. Alcohol abuse during pregnancy may expose the fetus and the newborn to serious developmental harm (fetal alcohol syndrome, FAS) including physical and

mental retardation that may seriously affect lifelong the health and function of the individuals. FAS is an increasingly serious social problem along with other abuses of drugs. About 0.001–0.002 fraction of the children are suffering from it. In mice, the higher alcohol consumption appeared to be associated with defects in the 5-HT_{1b} serotonin receptor and genetic variations (Lys487Glu) of the aldehyde dehydrogenase 1 locus. The (ADH1 and 2) aldehyde dehydrogenases are present in some far-East human populations and may increase the proclivity to alcohol consumption by a factor of 5 to 10. In some other populations low in ADH1 the alcohol consumption is moderate because of the poor tolerance. ADH actually has a protective effect against alcoholism. In *Caenorhabditis*, the neuropeptide Y receptor-like protein allelic variants can account for variations in alcohol tolerance (Davies AG et al 2004 Neuron 42:731). In *Drosophila*, a single inebriation by alcohol may start the development of alcohol tolerance. The tolerance requires the catecholamine octopamine (functional analog of noradrenaline of mammals (see Fig. A43)), and a nuclearly encoded (*Hang*) DNA-binding zinc-finger protein (Scholz H et al 2005 Nature [Lond] 436:845).

Figure A43. Octopamine

In mice the *Alp1* locus may be responsible for 14% and the *Alcp2* for 18% of the total alcohol preference. Interestingly the former gene is acting only in males and the latter only in females. Other loci-controlling alcohol withdrawal sensitivity (chromosome 1), alcohol-induced hypothermia and amphetamine-induced hyperthermia, and other hyperthermia loci seem to be in chromosome 9 of mouse. These loci do not appear to be controlling general tendencies for substance abuse. Alcohol preference appears to be a quantitative trait with ~0.39 heritability and ~60% concordance between monozygotic twins. Sensitivity to the effects of alcohol may be affected by a GABA_A type receptor and mediated by protein kinase C ϵ . Synuclein- α gene seems to be expressed at more than 2-fold rate in the brain of rats, which prefer alcohol compared to those which do not care for the substance (Liang T et al 2003 Proc Natl Acad Sci USA 100:4690). Moderate alcohol consumption may be beneficial to some individuals but alcohol

consumption in general is undesirable for health and social consequences (Pearson H 2004 Nature [Lond] 428:598). ▶**Dubowitz syndrome**, ▶**polygenic inheritance**, ▶**teratogenesis**, ▶**serotonin**, ▶**neurotransmitter**, ▶**substance abuse**, ▶**mortality**, ▶**QTL**, ▶**behavior in humans**, ▶**aldehyde dehydrogenase**, ▶**Flynn**, ▶**NMDA**, ▶**GABA**, ▶**glutamate receptor**, ▶**protein kinases**, ▶**addiction**, ▶**synuclein**, ▶**rheumatic fever**; Almasry L 2001 Am J Hum Genet 68:128; Sillaber I et al 2002 Science 296:931; Weiss F, Porrino LJ 2002 J Neurosci 22:3332; Yao L et al 2002 Cell 109:733.

Aldehyde Dehydrogenase (ALDH, acetaldehyde dehydrogenase): Form ALDH1 is encoded in human chromosome 9q21. Low level of this form of the enzyme is responsible for poor alcohol tolerance. An ALDH2 functions in the liver and it is encoded in 12q24.2 and ALDH3 is coded in human chromosome 17. Oxidizes also cyclophosphamide-derivative aldophosphamide to non-toxic carboxyphosphamide (see Fig. A44). ▶**alcohol dehydrogenase**, ▶**cyclophosphamide**

Figure A44. Aldehyde

Aldolase-1 (fructose-1,6-bisphosphate aldolase): The ALDOA isozyme has been mapped to human chromosome 16q22-q24, ALDOB (fructose intolerance) in chromosome 9q22, ALDOC in human chromosome 17cen-q12. There is also a deoxyribose-5-phosphate aldolase but its deficiency is apparently harmless. ALDOA deficiency may be involved in a form of hemolytic anemia (γ-glutamylcysteine synthetase deficiency). ▶**fructose intolerance**, ▶**anemia**

Aldose: A sugar that ends with a carbonyl group (=C=O).

Aldosterone (18-aldosterone): The main electrolyte-regulating steroid hormone of the kidney cortex. It activates a sodium channel I ATP-dependent manner. steroid hormones, ▶**aldosteronism**, ▶**ion channel**; Gorelik J et al 2005 Proc Natl Acad Sci USA 102:15000.

Aldosteronism (hyperaldosteronism, glucocorticoid-remediable aldosteronism [GRA]): Aldosteronism is controlled by two autosomal dominant genes. It is due to the excessive activity of aldosterone synthase (ADOS) and steroid 11β-hydroxylase (CYP11B2), coded in human chromosome 8q21. These two genes are quite similar in structure and also frequently form somatic recombinants. Their activity results in increased aldosterone production and hypertension.

This hyperaldosteronism is suppressible by glucocorticoids and dexamethasone. The chimeric genes are under adrenocorticotrophic hormone control. Consequently, aldosterone is secreted and causes water and salt reabsorption and high blood pressure. ▶**hypertension**, ▶**aldosterone**, ▶**glucocorticoid**, ▶**dexamethasone**, ▶**hypoaldosteronism**, ▶**pseudo-hypoaldosteronism**, ▶**mineral corticoid syndrome**

Aleurone: A protein-rich outer layer of the endosperm of monocotyledonous kernels. There is only a one-cell-thick layer of aleurone in wheat and maize, three-cell-thick layer in barley, and a layer of variable cell-thickness in rice. There are about 250,000 cells in the aleurone in maize and about 100,000 in barley. Aleurone color genes have proven to be very useful chromosomal markers (such as loci *A*, *C*, *R*, *Bz*, *B* in maize and some of the functional homologs in other cereals). The dominant alleles can be identified already in the seeds of the heterozygotes, and in case of maize, they can be classified on the cob in immobilized condition and in large numbers. ▶**maize**

Alexander's Disease: An autosomal recessive anomaly of lipid metabolism accompanied by a megaencephaly (synonym: macroencephaly), a pathological enlargement of the brain. Astrocyte fibers and small heat-shock proteins may be involved. Defects in NDUFV may be responsible for the symptoms. ▶**NDUFV**; Brenner M et al 2001 Nature Genet 27:117.)

Alfalfa (*Medicago sativa*): A leguminous forage plant (see Fig. A45). Its closest wild relatives are *M. coerulea* (2n = 16) and the somewhat more distant *M. falcata* (2n = 16). *M. sativa* is autotetraploid (2n = 4x = 32). *M. truncatula* (~454–526 bp) has only about half the genome size of *M. sativa*; it is also diploid and its circular chloroplast genome is 124,039 bp. Alfalfa is also called lucerne. By antisense technology, the lignin content of the plant tissue has been reduced and its digestibility improved (Srinivasa Reddy MS et al 2005 Proc Natl Acad Sci USA 102:16573). ▶**gene index**; *M. truncatula* database <http://www.tigr.org/tldb/e2k1/mta1/>.

Figure A45. *Medicago sativa*

A

Alfalfa Mosaic Virus: The genetic material of this virus consists of four RNAs of 1.3, 1.0, 0.7 and 0.34×10^6 Da.

Alga: Alga can be prokaryotic such as blue-green algae, or eukaryotic such as *Chlamydomonas reinhardtii*, *Ch. eugametos*, *Euglena gracilis*, seaweeds etc.; they are photosynthetic microorganisms. The unicellular red alga *Cyanidioschyzon merolae* has 16,520,305 base pairs in its 20 chromosomes, with at least 5,331 genes. The single mitochondrion is 32,211 bp with 34 protein genes. The single plastid is 149,987 bp encoding 208 intron-less protein genes. (Matsuzaki M et al 2004 Nature [Lond] 428:653). ▶ *Chlamydomonas*, ▶ *Euglena*

Algeny: The genetic alteration of an organism by non-natural means such as ▶ *genetic engineering*, ▶ *gene therapy*, ▶ *genetic surgery*, and ▶ *transformation*

Algesia: Increased sensitivity to pain.

Alginate: A polymer of mannuronic acid and guluronate; it is found in the cell wall of brown algae. ▶ *biofilm*; Wong TY et al 2000 Annu Rev Microbiol 54:289.

Algol (algorithmic oriented language): A computer language set by international procedure. ▶ *algorithm*

Algorithm: A set of rules and procedures for solving problems in a finite number of sets; usually the repetitive calculation aims to find the greatest common divisor for two members. Computer programs include algorithms.

Algorithm, Genetic: Genetic algorithm uses a computational program to interpret evolutionary changes of mutation, recombination, and selection. ▶ *algorithm*, ▶ *darwinism*

Alien Addition: Addition of the chromosome(s) of another species to the genome of polyploids without seriously disturbing genic balance, in contrast to the case with diploids, where even small duplications or deletions may become quite deleterious. The procedure of addition involves crossing the higher chromosome number species as pistillate parent with the lower chromosome number pollen donor (see Fig. A46). The F_1 is generally sterile but by doubling their number (with colchicine) may result in a fertile amphiploid. Upon the recurrent back crossing of the amphiploid with the recipient parent, monosomy results for the donor's chromosomes. The F_1 is generally sterile but doubling their number (with colchicine) may result in a fertile amphiploid. After repeated backcrossing in large populations, one may obtain plants with single monosomes for all chromosomes of the donor. These are called single monosomic addition lines. Disomic additions are obtained by selfing such monosomics. These carry an

extra pair of chromosomes. The purpose of addition is that occasionally the added chromosome, containing agronomically useful genes, may get substituted for its homoeolog and lead to a substitution line. ▶ *addition line*, ▶ *pistillate*, ▶ *pollen*, ▶ *amphidiploid*, ▶ *monosome*, ▶ *disomic*, ▶ *homoeologue*, ▶ *substitution line*, ▶ *transchromosomic*; Sears ER 1953 Am J Bot 40:168.

Figure A46. The general scheme for the generation of alien addition lines in wheat. The same procedure is applicable to other polyploid plant species

Alien Substitution: Alien Substitution takes place when chromosome(s) of another species replace the own chromosome(s) of a species. Alien substitutions may be obtained from alien addition lines. However, monosomic lines are used most commonly. Monosomic lines can be maintained without too many difficulties in polyploids, because the genomes are better balanced. Monosomic plants produce some eggs that are nullisomic. These recipients are then crossed with a donor species. In the F_1 the chromosome absent in the parent nullisomic will appear as a monosome of

the donor. These monosomic individuals are repeatedly backcrossed (6–8 times) with the recipient, until in some individuals all the chromosomes of the donor are eliminated, except that particular monosome. Selfing this monosomic substitution line results in a disomic substitution that has the same chromosome number as the euploid line from which the nullisomic arose, but one pair of the chromosomes will represent the donor. ►alien addition, ►monosomic, ►nullisomic, ►back-cross, ►selfing, ►euploid, ►alien transfer lines, ►chromosome substitution; Sears ER 1972 Stadler Symp 4:23.

Alien Transfer Lines: Alien substitution lines are interesting to the geneticist, but the plant-breeder is rarely satisfied with the substitution of an entire chromosome because the new chromosome may contain, in addition to the desirable gene(s), some that are undesirable. Homologous pairing and crossing over, on the other hand can borrow short segments or even single genes from the alien chromosome. This goal can also be achieved by induced translocations, and the resulting line is called a transfer line. ►alien ►substitution, ►alien transfer, ►transchromosomic, ►translocation; Sears ER 1956 Brookhaven Symp Biol 9:1.

AlifoldZ: Consensus structures of aligned sequences can be useful measures in detecting functional RNAs. One method is to test multiple sequence alignments for the existence of an unusually structured and conserved fold. An energy score consisting of free energy and a covariation term significantly improves sensitivity, as compared to a single sequence prediction (Washietl S, Hofacker IL 2004 J Mol Biol 342:19). ►RNAz, ►EvoFold, ►RNA structural

Alignment: Alignment finds nucleotide and amino acid linear sequence matches in nucleic acids and polypeptides, respectively. High alignment scores indicate great similarity between sequences. Free downloads of aligning software are available on the internet. Alignment scores estimates similarities versus dissimilarities in sequences, as well as gaps in the sequence of macromolecules. homology, CLUSTAL W, also BLAST, genomics, PFAM, human–mouse genomes: Schwartz S et al 2003 Genome Res 13:103; Higgins GD et al 2005 Proc Natl Acad Sci USA 102:104511, pairwise sequence alignment: <http://genome.cs.mtu.edu/align/align.html>, protein sequence alignment: <http://compbio.mds.qmw.ac.uk/S4.html>, genome alignment, annotation: <http://www.bx.psu.edu/>, multiple alignment of structure: <http://bioinformatics.albany.edu/~dmaps/>, binding motif alignment: <http://www.benoslab.pitt.edu/stamp/>, multiple sequence alignment with medical and microbial relevance: <http://genome.lbl.gov/vista/>

index.shtml, multiple sequence alignment: <http://prodata.swmed.edu/compass/compass.php>.

AlignACE: AlignACE is a computer program that locates upstream regions of regulons. It helps identify genes in a functional pathway, or genes homologous to known regulons, or a group of genes derived from conserved operons. ►regulon; McGuire AM et al 2000 Genome Res 10:744.

Aliphatic Molecules: The carbon atoms occur in an open chain (non-aromatic) that is bound by single or multiple bonds.

ALK: ►anaplastic lymphoma

Alkaline Chromatography: Is used for the rapid separation of less than 150 bases long DNA probes on Sepharose CL-4B (a beaded [60–14 mm pore size], cross-linked agarose). ►Sepharose

Alkaline Lysis: Alkaline Lysis is a procedure to extract plasmid DNA from bacterial cells, using 0.2 N NaOH and 1% SDS. The plasmids may be further purified by CsCl-ethidium bromide gradient ultracentrifugation, or by polyethylene glycol precipitation at 10,000 rpm. ►SDS

Alkaline Phosphatase: Alkaline Phosphatase cleaves phosphates at a pH optimum about 9; it is present in microorganisms and animal cells but absent from plant tissues. The alkaline phosphatase of *E. coli* is 86-kDA and contains 2 subunits. The human intestinal alkaline phosphatase (ALP1) is encoded in chromosome 2q37, as are the placental enzymes (ALPPP/PLAP); the liver enzyme is coded by ALPL in chromosome 1p36.1-p34. Enzyme levels that are higher or lower than normal may have deleterious consequences. Hypophosphatasia for ALP may be dangerous or even lethal for infants. ►acrodermatitis enteropathica, ►acid phosphatase

Alkaloids: Alkaloids are diverse (more than 2500), mainly heterocyclic, organic compounds containing nitrogen. They are generally alkalic in nature and are secondary metabolites of plants; frequently effecting strong biological activity at higher concentrations (examples are nicotine, caffeine, cocaine, morphine, strychnine, quinine, papaverine, atropine, hyosciamine, scopolamine codeine, capsaicine, lupinin, etc.). Of particular interest is colchicine (obtained from the lily, *Colchicum autumnale*) that blocks the microtubules of cells, causing the doubling of the chromosome number. Vincristine and vinblastine (from *Vinca rosea*) are antineoplastic drugs. The “animal alkaloid,” ptomaine, found in decomposing cadavers, is actually a microbial product. ►nicotine, ►caffeine, ►Datura ►alkaloids, ►cocaine, ►morphine,

A

►capsaicine, ►lupine, ►colchicine, ►vinblastine; Facchini PJ 2001 Annu Rev Plant Physiol Mol Biol 52:29.

Alkalosis: Alkalosis is the diminished buffering capacity of tissues that leads to higher pH.

Alkane: An alkane is a aliphatic molecule joined by a single covalent bond, e.g., $\text{CH}_3\text{—CH}_3$. ►alkene

Alkaptonuria (alcaptonuria, AKU): Alkaptonuria is a recessive metabolic disorder (prevalence about 1/40,000) in which a defect in the enzyme homogentisate 1,2-deoxygenase prevents homogentisic acid from being metabolized into maleyl- and fumaryl-acetoacetic acids. The degradation of the aromatic amino acids normally follows the pathway (see Fig. A47):

Figure A47. Alkaptonuria

The accumulated homogentisic acid in AKU is excreted in urine and is readily oxidized into a dark compound (see on the cornea: see Fig. A48), alkapton, staining dark already the diapers of affected newborns. Alkapton also causes dark pigmented spots in the connective tissues and bones, and with the ageing of the patient may lead too arthritis. This human hereditary biochemical defect was first recognized in 1859 and its genetic control identified by Sir Archibald Garrod in 1902. The gene (AKU) was located inhuman chromosome 3q21-q23. ►tyrosine, ►phenylketonuria, ►amino acid metabolism, ►tyrosinemia

Alkene: Alkenes are hydrocarbons with one or more double bonds, e.g., $\text{H}_2\text{C=CH}_2$. ►alkane

Alkylating Agent: An alkylating agent alkylates other molecules; many chemical mutagens and carcinogens are alkylating agents. The mutationally most effective alkylation site in DNA is the O^6 site of guanine. O^6 -alkylguanine can pair with either cytosine, or thymine, resulting in a substitution mutation in case of the latter. The alkyl may be removed from the DNA

in *E. coli* by an alkyltransferase enzyme. The acceptor may be a cysteine residue of that protein.

The natural compounds yatakemycin and duocarmycin SA (see Fig. A50) can alkylate nucleosomal DNA in the highly shielded minor groove and are potentially effective anti-tumor agents (Trzupek JD et al 2006 Nature Chem Biol 2:79).

►mutagens-carcinogens, ►mutagenic potency, ►environmental mutagens, ►carcinogen, ►chemical mutagens, ►alkyltransferase; see Fig. A49.

Alkylation: Alkylation is the addition of a CH_3 group (or other member of the alkane series) to a molecule. Alkylation of DNA bases may lead to mutation through mispairing and base substitution. Also, alkylation may lead to disruption of the sugar-phosphate backbone of the DNA through depurination by AP nucleases. Thymine is alkylated at the O^4 position and adenine at the N3 position. ►base pairing, ►hydrogen pairing, ►tautomeric shift, ►AP endonuclease, ►chemical mutagens, ►alkyltransferases, ►methyltransferase; Bautz E, Freese E 1960 Proc Natl Acad Sci USA 46:1585.

Alkyltransferases: Alkyltransferases protect the DNA against alkyl adducts by transferring the methyl or ethyl (alkyl) groups to cysteine and repairing the damage. These enzymes, present in different organisms, display an active site consensus V(I)PCHRV(I). If the level of these enzymes is reduced either by inhibitors, e.g., O^6 -benzylguanine, or by mutation, the efficiency of alkylating agents for treatment of cancer increases. DNA repair; Reese JS et al 2001 Oncogene 20:5258.

Allantois: The allantois is a tubular part of the hindgut, later forming the umbilical cord of the fetus and it fuses with the chorion. It also participates in the formation of the placenta. amnion, ►chorion

Allegro: Allegro is a computer program for multipoint linkage, free at allegro@decode.is.

Allele: Alleles are alternative states of a gene (e.g., a^1 and a^2). Hybrids of a^1/a^2 are commonly of mutant phenotype, although they may show incomplete (allelic) complementation. Two alleles are identical if their base sequences are identical, even though one or both of these may be different from the sequence of the wild type. *Non-identical alleles* are still in the same gene (and are non-complementary) yet their expression may be distinguishable. *Homoalleles* are effected in the same codon but a different nucleotide occurs at the same site in each, and therefore the alleles cannot be separated by recombination in a

Figure A48. Degradation of aromatic amino acids

Figure A49. Most common reactions of the alkylating agent, ethylmethane sulfonate with guanine

Figure A50. Duocarmycin

heterozygote for the locus. The differences between *heteroalleles* are located at non-identical sites within the codon, or in another codon altogether, and the alleles can therefore be separated by recombination. *Isoalleles* convey wild phenotype, yet under special circumstances can be recognized by appearance. *Multiple alleles* are more than two alternative alleles

of the same locus. *Super alleles* are additional mutations in cis to an allele within a gene that reinforces their expression. *Codominant alleles* both are expressed in the heterozygotes. In some organisms alleles of the *a1* locus are symbolized as *a1-1*, *a1-2*, etc. Molecular geneticists involved in physical mapping of the DNA use this term for any DNA difference (e.g., restriction fragment) that displays Mendelian inheritance and occupies the same chromosomal site (see Fig. A51). Allelic variation is widespread within a species and knowledge of the nature of these alleles is not just important in biology, but may also be relevant in applied fields such as disease susceptibility, forensic identifications, etc. In yeast, by hybridizing two different strains and through conduction microarray analysis, the frequency of such variation (single-feature polymorphism) can be ~1% (Winzeler EA et al 1998

A

Science 281:1194; Gresham D et al 2006 Science 311:1932). ▶gene symbols, ▶RFLP, ▶RAPD, ▶Mendelian ▶segregation, ▶coalescent, ▶mutation ▶age ▶of, ▶SNIPS; Slatkin M, Rannala B 2000 Annu Rev Genomics Hum Genet 1:225.

Figure A51. Mutation in a gene results in an allelic change from A (adenine) to G (guanine). Nucleotide substitution is identified by sequencing of the PCR amplified segment of the DNA. In the heterozygote for the site reduced amounts of both A and G is shown. (Courtesy of Amersham Biosciences, GE Healthcare Biodirectory 2005, p. 310.)

Allele Calling: Allele calling refers to the identification of an allele on the basis of chemical/molecular information.

Allele Dropout: When small DNA samples are multiplied too many times during forensic or ancient DNA analysis, certain alleles of a heterozygous individual may be lost to the process. ▶forensic ▶genetics, ▶DNA ▶fingerprinting; Gill P et al 2000 Forensic Sci Int 112:17.

Allele-Sharing Methods: Allele-sharing methods detect linkage by examining pedigrees for whether a particular genetic locus (chromosomal fragment) is more common among individuals in a pedigree than expected by random segregation. It is basically a non-parametric method. The probability of allele-sharing may be denoted by Y and the probability that R alleles are shared among $2N = \binom{2N}{R} Y^R (1-Y)^{2N-R}$. For R shared alleles the maximum lod score = $R \log_{10} R + (2N-R) \log_{10} (2N-R) - 2N \log_{10} N$.

An allele-sharing study of 1,592 DZ twin pairs from two independent Australian cohorts, of which 1,561 pairs were informative for linkage on chromosome 6, and 336 DZ twin pairs from the Netherlands, showed no evidence of excess allele sharing, either at the HLA locus or in the rest of the genome. One Australian group indicated a small yet significant deficit of allele-sharing (Montgomery GW et al 2006 Amer J Hum Genet 79:1052). ▶non-▶parametric ▶tests, ▶lod ▶score; Nyholt DR 2000 Am J Hum Genet 67:282.

Allele-Specific Probe For Mutation (ASP): In principle, this would detect single base change mutations because under very high stringency of hybridization oligonucleotide probes (ASO) would hybridize only to that sequence, which is exactly matching but not to another that has one base pair substitution. This would also identify heterozygotes because they would hybridize to both types of probes, mutant and normal. This procedure requires high skills but can be semi-automated. ▶hybridization, ▶mutation ▶detection, ▶probe, ▶SNIP, ▶ASO; Prince JA et al 2001 Genome Res 11:152.

Allelic Association: ▶linkage, ▶disequilibrium

Allelic Combinations: Allelic combinations in gametes (at independent loci) can be predicted by $2n$ where n is the number of different allelic pairs, and it produces $4n$ gametic combinations and $3n$ genotypes. If the number of loci is n and each has a number of alleles, the number of zygotic genotypes at one locus can be calculated as $[a \times (a + 1)]/2$ and for n loci: $\left[\frac{a \times (a+1)}{2} \right]^n$

Thus e.g., for 100 loci, each with three alleles $[(3 \times 4)/2]^{100} \geq 6.53 \times 10^{77}$ zygotic genotypes are

possible. ▶multiple alleles, ▶gametic array, ▶Mendelian segregation

Allelic Complementation: Allelic complementation is partial or incomplete complementation among mutant alleles of a gene, representing different cistrons (see Fig. A52).

Figure A52. Allelic complementation of py^5 (top row), py^4 (bottom row) temperature-sensitive mutants requiring 2-methyl-4-amino-5-aminomethyl-pyrimidine grown in test tubes. their hybrids are in the middle. (From SL Li and GP Rédei, unpublished)

If the alleles are defective when homozygous, they do not contribute to the synthesis of functional proteins. Each of the two alleles in a heterozygote has another non-overlapping defective polypeptide product. The correct polypeptide chains in the cytoplasm may combine in the heterodimeric or heteropolymeric proteins, and due to right assembly, the function of these proteins may be restored. Since the available correct polypeptide chains are reduced in number relative to that in the wild type, only a reduced number of good protein molecules can be formed. Therefore, allelic complementation is incomplete. The beneficial effect from the non-defective peptide chains may be brought about also by conformation correction, i.e., the conformation of defective chains is brought into line as an effect of the other polypeptide chain, as long as there is no defect at the active site. The extent of allelic complementation can be best determined by in vitro enzyme assays when regulatory genes cannot modify the functions by higher intensity or prolonged transcription of the relevant cistrons. ▶step allelomorphism, ▶conformation, ▶complementation mapping, ▶allelism test, ▶non-allelic, ▶non-complementation; Li SL, Rédei GP 1969 Genetics 62:281.

Allelic Dropout: Allelic dropout occurs during amplification (by PCR) when a microsatellite locus is not replicated by the DNA polymerase. ▶PCR; Miller CR et al 2002 Genetics 160:357.

Allelic Exclusion: Allelic exclusion refers to the phenomenon when only one of the two alleles at a locus is expressed or only one type of chain rearrangement is functional. Such conditions are found in immunoglobulins, various receptors, interleukin-2, and imprinted genes. Protein kinase C (PKC) modulates both differentiation and allelic exclusion during thymocyte differentiation. ▶immunoglobulins, ▶monoallelic ▶expression, ▶interleukin, ▶imprinting, ▶PKC, ▶thymocytes; Michie AM et al 2001 Proc Natl Acad Sci USA 98:609; Borst P 2002 Cell 109:5; Mostovslavsky R et al 2004 Cell 118:539.

Allelic Fixation: Allelic fixation takes place in a random mating population when one allele completely replaces another. The process depends on the coefficient of selection and the size of the populations (see Fig. A53). The time that has elapsed since the fixation of a beneficial allele is estimated on the basis of nucleotide variation at linked loci. (Przeworski M 2003 Genetics 164:1667).

Allelic Frequencies: Allelic frequencies can be determined on the basis of the Hardy-Weinberg theorem, according to which, the genotypic composition of a random mating population is $p^2 + 2pq + q^2$, where p^2 and q^2 are the frequencies of the homozygous dominants and recessives, respectively. Thus, if we consider a single allelic pair, A and a , and diploidy, the frequency of the A allele = double the number of homozygous dominants plus the number of heterozygotes. The frequency of the a allele = double the number of homozygotes plus the heterozygotes, because the homozygotes have two copies of the same allele whereas the heterozygotes have only one of each kind (see Fig. A53).

The frequency of the recessive alleles in an equilibrium population is simply $1 - p$ ($= q$). The heterozygotes may not be directly recognized in case of dominance, therefore this equation may not be applicable there. However, in case the population is at equilibrium and the mating is at random, the frequency of the recessive alleles is $q = \sqrt{q^2}$. If the size of the homozygous recessive class is very small, the vast majority of recessive alleles occur in the heterozygotes. In case of sex-linkage, the male carries one dose (XY) whereas the female is XX. Thus, males display recessive traits more frequently than do females, who express it only when homozygous. Therefore, if the expression of an X-linked recessive allele is 0.10 in males, in females it is expected to show up at $(0.10)^2 = 0.01$. The frequency of alleles in a population may change by selection, mutation, random drift, and migration. At random mating the total variance of allelic frequency with two alleles of $2n$ genes is computed from the Weir

A

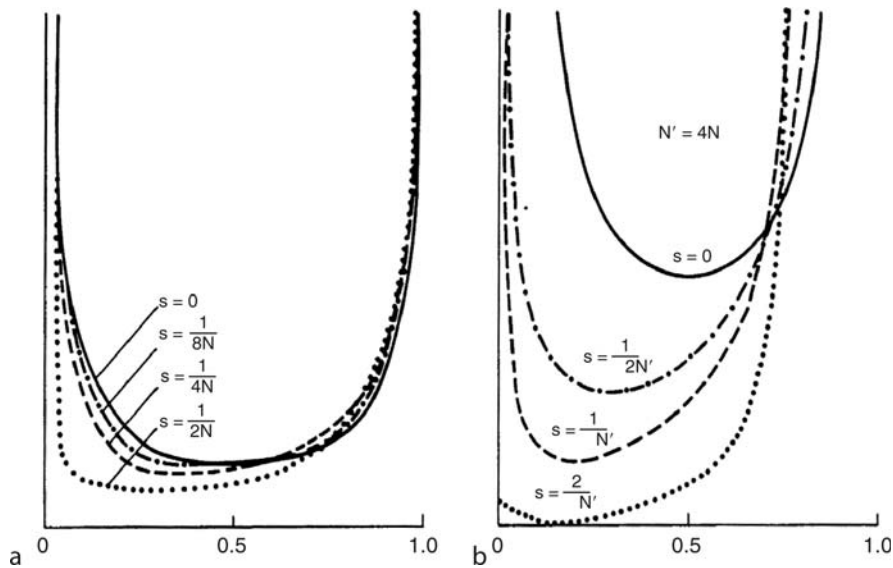

Figure A53. In very small populations only high selection coefficients can bring about changes in allelic distribution (a). When the size of the population increases fourfold, relatively small selection coefficients effectively modify the direction of fixation (b). The ordinate represents allelic densities, the abscissa shows allelic frequencies from loss, (0) to complete fixation (1.0); s = selection coefficient, N = population size. (From Wright S 1931 Genetics 16:97)

formula: $V(p) = \frac{p(1-p)}{2n} [F_{ST}(2n-1) + 1]$ and $F_{ST} = \frac{\sigma^2 - 1}{2n-1}$. ▶Hardy - Weinberg theorem, ▶selection, ▶mutation, ▶random genetic drift; Hung S-P, Weir BS 2001 Genetics 159:1365, <http://info.med.yale.edu/genetics/kkidd>; <http://alfred.med.yale.edu/alfred/AboutALFRED.asp>.

Allelic Interaction: ▶overdominance

Allelic Recombination: Allelic recombination takes place between the same sites of the homologous chromosomes. ▶ectopic recombination, ▶homologous recombination

Allelic Rescue: Allelic rescue is a procedure for cloning a mutant allele. A vector carrying the wild type allele, which has, however, an internal deletion overlapping the mutant site, transforms the mutant cell. When the cellular (gap) repair system fills in the deleted sequences using the mutant template, the plasmid vector carrying a copy of the mutant gene can be isolated, and along with it the gene itself. ▶DNA repair, ▶transformation, ▶marker rescue

Allelism Test: An allelism test is carried out by a complementation test. If two recessive genes are allelic, they fail to complement each other in the F_1 hybrids (i.e., the hybrid is of mutant phenotype). In case the hybrid of two recessive individuals is of wild phenotype (i.e., they complement each other) the two genes are not allelic. Thus, the number of

complementation groups reveal the number of different loci. In practice, the term complementation groups is understood as different complementation groups. However, allelic genes at the same multicistronic locus may show partial or allelic complementation. allelic complementation, non-allelic non-complementation; Demerec M, Ozeki H 1959 Genetics 44:269.

Allelomorph: Allelomorph is a historical term for an allele. ▶allele

Allelopathy: Allelopathy refers to the release of repellent or toxic compounds by plants to suppress neighboring species or to defend against insects or other parasites. (See Pickett JA et al 2003 Biochem Soc Trans 31 [1]:123)

Allelotyping: Allelotyping is the determination of the spectrum and frequency of allelic variations in a population. Polymorphism may be determined by restriction fragment length, SNIPS, LOH, PCR, etc. genotyping, ▶RFLP, ▶SNIPS, ▶PCR, ▶LOH; Girard L et al 2000 Cancer Res 60:4894; Yan H et al 2002 Science 297:1143.

Allergen: An allergen is any substance that causes an allergy. ▶allergy, allergenicity assessment: <http://bioinformatics.bmc.uu.se/evaler.html>.

Allergy: Sensitivity to a particular antigen(s); an allergy is the evidence of an immunological reaction. Common forms are the hay fever after exposure to

pollen (ragweed), drug, food, bacteria, cold, etc. The allergic reaction may be a hereditary property (atopy). In asthma, hay fever, and various other allergic reactions the regulatory *Re* gene is implicated in the decrease of immunoglobulin E level, and in *re/re* individuals it seems to be higher. The frequency of the *re* gene is estimated to be about 0.49. The IgE response in about 60% of the atopy cases is assigned to chromosome 11q13-q12, the site of the high-affinity IgE receptor (FcεRI-β) gene. The IgE response is apparently controlled by IgE receptor (FcεRI) and regulated by interleukin 4 (IL-4). It also appears that the IgG Fc receptor, FcγRIII, affects FcεRI assembly. Ragweed sensitivity is assigned to the HLA complex in human chromosome 6. Elevated levels of immunoglobulin E, controlled by an autosomal dominant gene with incomplete penetrance, have been detected in the neutrophil chemotaxis defect, characterized by chronic eczema, repeated infections by staphylococci and eosinophilia (cytological structures readily stained with eosin stains). Asthma and other allergies are apparently under the control of multiple genetic loci. Allergies may be alleviated by desensitization, which involves exposure to increasing amounts of the allergen in order to regulate IgE production. DNA immunization may stimulate Th1 immunity, either by producing IgG2a and IFN-γ, or by Th2 response along with the production of IgE and IgG and an increase in interleukins (IL-4, -5, -10). Actually Th1 cells antagonize the inflammatory reaction whereas Th2 cells, with the aid of IL-3, IL-5 and GM-CSF, stimulate eosinophils through IL-3, IL-4, IL-6 and IL-9 and regulate mast cells and inflammation. Dendritic cells negatively regulate Th2 cells with the aid of IL-12, and Th2 cells in turn, helped by IL-10, lower the response of dendritic cells to allergens. Bacteria and viruses promote the production of IL-12 and thus stimulate Th1 cells. Th1 cells boost the body's defense against intracellular pathogens (bacteria and viruses) by increased production of IFN-γ and synthesis IgG2a. Th2 cells, IgE, and IgG1 mediate defense against larger extracellular pathogens. The allergens of fungi and other parasites boost the level of Th2 cells and elevate IgE level in the serum. IL-4 and IL-13 enhance IgE production by B-lymphocytes and thus evoke inflammatory responses. The CD23 receptor of IgE may promote or hinder antibody presentation depending on the circumstances. In grass hay fever, CD4⁺CD30⁺ Th2 cells react to the allergen. Glucocorticoids and IL-4 enhance Th2 activity, whereas dihydroepiandrosterol favors Th1 cells. IFNα, IL-12 and TGF-β expand Th1, while IL-10, IL-6 and IL-4 skew the balance toward Th2. Allergen recognition through MHC class II peptides, organ localization, and response to allergens

all have clear genetic components. Environmental factors play very important roles as well, considering how the overall incidence of allergy and asthma is on the rise. ▶atopy, ▶ragweed, ▶HLA, ▶immunoglobulins, ▶asthma, ▶anaphylaxis, ▶eczema, ▶hypersensitive reaction, ▶γδT cell, ▶interleukin, ▶immunization ▶genetic, ▶CD4⁺, ▶CD30⁺, ▶CD23, ▶IFN, ▶TGF, ▶IL-▶10, ▶IL-3, IL-5, ▶IL-6, ▶IL-4, ▶IL-12, ▶IL-13, ▶glucocorticoid, ▶histamine, ▶interferons; Nature [Lond] 402[6760] Suppl.; oral allergy vaccine: Ma S, Jevnikar AM 2005 Proc Natl Acad Sci USA 102:17255.

<http://www.nlm.nih.gov/medlineplus/allergy.html>, allergen prediction: <http://www.imtech.res.in/raghava/allgpred/>.

Alligator (giant lizards): The two most commonly known species are *Alligator mississippiensis*, 2n = 36, *Crocodylus niloticus* 2n = 32.

Allium (onion, garlic): *Allium* is a monocot genus, 2n = 16 or 32, and is well suited for cytological analysis.

Alloantibody (isoantibody): An alloantibody is produced by an individual of a species, against alloantigens within the species. This may be due to preceding transfusions or pregnancies and may cause hyperacute rejection in case of transplantation in another individual of the same species. ▶alloantigen

Alloantigen: An alloantigen is a genetically determined antigen variant within the species. It may also be called neoantigen when the epitope appears the first time. Alloantigens are recognized within the same species by lymphocytes with different haplotype. ▶antigen, ▶epitope, ▶lymphocyte, ▶haplotype, ▶isoallogen, ▶alloantibody

Alloantisera: Alloantisera are antibodies that can recognize a certain protein in a different individual.

Allocatalasia: Allocatalasia is characterized by the condition when the catalase activity and stability is normal yet the protein is a different variant. ▶catalase

Allocation: Allocation refers to the differential distribution of cellular resources to specific structures and organs in an individual organism.

Allochronic Species: Allochronic species do not exist during the same time period in evolution.

Allocyclus: Chromosomal regions, chromosomes, or genomes may show cyclic variation in coiling and heteropycnosis. ▶heterochromatin, ▶heteropycnosis, ▶Lyonization, ▶Barr body

Allodiploid: An allodiploid is a polyploid that has chromosome sets (genomes) derived from more than

A

one ancestral organism, e.g., hexaploid bread wheat has A, B, and D genomes. ►autotetraploid, ►*Triticum*

Allodynia: Allodynia is pain hypersensitivity evoked by innocuous stimuli. ►pain sensitivity; Tsuda M et al 2003 *Nature [Lond]* 424:778.

Allogamous: Allogamous individuals do not pollinate the pistils of the same plant, crosspollinating, and are also called exogamous species.

Allogamy: Allogamy is fertilization between gametes from different individual(s). ►autogamy

Allogeneic: Antigenic difference exists between two cells (in a chimera). ►antigen, ►allograft, ►autologous, ►xenogeneic

Allogeneic Inhibition: Allogeneic inhibition is found in mice; in this condition parental cells do not accept a graft from the F1, but the reciprocal graft may be successful. grafting in medicine; Mathew JM et al 2000 *Transplantation* 70:1752.

Allogenic: ►allogeneic

Allograft: The transplantation of tissues carrying cell surface antigens not present in the recipient leads to a graft that may be rejected and destroyed, and the process itself may harm the recipient. ►HLA, ►graft, ►isograft, ►heterograft, ►complement, ►grafting in medicine, ►xenotransplantation

Allohaploid: An allohaploid is a haploid cell derived from an allodiploid. ►allodiploid

Allolactose: The inducer of the *Lac* operon; it is the intermediate product of lactose (a di-saccharide) digestion by β -galactosidase, and is further converted to galactose and glucose by the same enzyme. ►galactosidase, ►lactose, ►*Lac* operon

Allolysis: ►fratricide

Allometric Development: Allometric development refers to the different growth (development) rate of one part of the body relative to other parts.

Allometry: Allometry is the study of growth of organs in different dimensions of space and time within an individual, or populations, or during evolution (Frankino WA et al 2005 *Science* 307:718; Kodric-Brown A et al 2006 *Proc Natl Acad Sci USA* 103:8733).

Allomixis: ►cross fertilization, ►allogamy

Allomone: ►kairomones

Allopatric Speciation: Allopatric speciation is involved in geographic adaptation and sexual isolation of species living in non-identical habitats. ►speciation, ►postzygotic isolation

Allophenic: Originally, allophenic genes refer to those genes that may not be expressed in one cell type but act as gene activators in other tissues. It also refers to the expression of genes in chimeric tissues of an embryo or adult that has been produced through in vitro fusion of two or more genetically different (chimeric) blastomeres. These blastomeres develop upon the fusion of the gametes of two parents, each, and several different blastomeres can be fused, resulting in (tri-, quadri-, hexa-parental, etc.) multiparental offspring. The fused blastomeres are implanted into the uterus of pseudopregnant animals, who carry the developing mosaic embryos to term. The procedure opposite to the formation of allophenic chimeras is splitting up 8-cell embryos, in two steps, into separate blastomeres and insertion of four such cells into an empty zona pellucida. Subsequently, these “quadruplets” can be transferred into the uterus of a rhesus monkey, which has produced a viable, normal offspring by this procedure (Chan AWS et al 2000 *Science* 287:317). This type of cloning offers the means for producing progeny identical in both its nuclear and cytoplasmic hereditary components. biparental, chimera, blastomere, photo at multiparental; LoCascio NJ et al 1987 *Dev Biol* 124:291; Petters RM, Markert CL 1980 *J Hered* 71:70.

Allophycocyanin: Allophycocyanin is a fluorochrome; it is excited at wavelengths 610 and 640 nm and emits bright red light at 650 nm. It is used in flow cytometry. ►fluorochromes, ►flow cytometry, ►phycobilins

Alloplasmic: An alloplasmic cell is a cell in which the cytoplasm and the nucleus are of different origins. ►nuclear transplantation, ►cell genetics

Allopolyploid: An allopolyploid species contains two or more types of genomes from different species, e.g., *Triticum turgidum* (macaroni wheat), an allotetraploid containing the AABB genomes, *Triticum aestivum* (bread wheat), an allohexaploid with AABBDD genomes, and *Triticum crassum* (a wild grass), a hexaploid DDDMM. *Nicotiana tabacum* is an allotetraploid ($2n=48$) containing the genomes of *N. tomentosiformis* ($2n=24$) and *N. sylvestris* ($2n=24$). When *N. tabacum* is crossed with either of the parents, the F1 will have 12 bivalent (12") and 12 univalent (12') chromosomes. The degree of homology between genomes can cytologically be determined in meiosis on the basis of chromosome pairing and chiasma frequency. Allopolyploids generally acquire during evolution genes that suppress multivalent pairing of chromosomes, therefore the gene segregation pattern resembles that of diploids with more than one pairs of alleles. A duplex autotetraploid may segregate in a range between 35:1 and 19.3:1 (depending on the distance between gene and centromere), while an

allotetraploid is expected to display a 15:1 ratio and an allohexaploid a 63:1 proportion if there are 4 and 6 copies of the genes, respectively. However, some genes (which have only two alleles) in hexaploids may display a 3:1 segregation. ▶duplex, ▶sesquidiploid, ▶allopolyploid segmental, ▶autopolyploid

Allopolyploid, Segmental: Here, participating genomes have partial (segmental) homology yet are sufficiently different to cause some sterility. ▶allopolyploid

Alloproteins: Alloproteins contain non-natural amino acids. ▶genetic ▶code, ▶peptidomimetics; Kiga D et al 2002 Proc Natl Acad Sci USA 99:9715.

Allopurinol (hydroxypyrazole pyrimidine): Allopurinol is an inhibitor of de novo pyrimidine synthesis and xanthine oxidase activity (see Fig. A54). It is used as a medicine to treat gout and hyperuricemia, but can also cause severe skin disease (epidermal necrolysis). ▶xanthine, ▶gout, ▶uric acid, ▶Stevens-Johnson syndrome

Figure A54. Allopurinol

Alloreactive (allorestrictive): An alloreactive cell is a T cell that recognizes a foreign antigen and mobilizes cellular defense against it, e.g., graft rejection. ▶T cell, ▶antigen

All-Or-None Trait: Such a trait is either present or absent, and there are no intermediates.

Allospecific: Its specificity is different from the standard normal.

Allostasis: Allostasis is a stage or state of homeostasis beyond the normal range. It may be evoked by environmental stress. homeostasis.

Allostatis: Allostatis are juvenile hormone inhibitors in insects. They have highly conserved six C-terminal amino acids. juvenile hormone.

Allosteric Control: Allosteric control is the modification of the activity of an enzyme by alteration at a site different from the active site by another molecule affecting its conformation without a covalent attachment. ▶active ▶site, ▶conformation, ▶intrasteric regulation; Süel GM et al 2003 Nature Struct Biol 10:59; signal transduction models: Changeux J-P, Edelstein SJ 2005 Science 308:1424.

Allosteric Effector: An allosteric effector is a molecule that is involved in bringing about allosteric control. ▶allosteric control, ▶allostery

Allostery: Allostery is a conformational change in a protein (ribozyme) through the effect of a ligand molecule; the process is often called allosteric shift. ▶allosteric ▶control; Monod J et al 1963 J Mol Biol 6:306.

Allosyndesis: Allosyndesis is the synapsis between non-entirely homologous chromosomes in an allopolyploid. ▶homoeologous chromosomes, ▶chromosome pairing

Allotetraploid: ▶amphidiploid

Allotopic Expression: Allotopic expression takes place when a gene, which is not organellar (mitochondrial or plastidic by origin), is targeted and expressed in an organelle. ▶ectopic expression

Allotype: Allotype refers to the difference in antibody (or antigen) caused presumably by allelic substitution mutation in the same constant region genes. ▶isotype, ▶immunoglobulins, ▶antibody

Allozygote: Allozygote refers to an individual that at one or more loci possesses alleles that were not derived from the same common ancestor, i.e., are not identical by descent. ▶inbreeding, ▶coancestry, ▶autozygous

Allozymes: Allozymes are different forms of an enzyme, occurring due to allelic differences in the genes.

All-Walking Approach: All-walking approach is a program used in the physical mapping of DNA in connection with YACs. The STS (sequence-tagged sites) are derived from the ends of YAC inserts. The three main advantages of this program are: the position of the STS here is defined vis-à-vis cases where the STS is internal; the program identifies chimeric YACs; and uses end-STS YACs that tend to be larger than others. ▶YAC, ▶STS

Allyl Alcohol: Allyl alcohol is a liquid eye-irritant that permits positive selection of alcohol dehydrogenase mutations because the wild type cells (*adh*⁺) behave in a suicidal manner to convert this compound to acrylaldehyde, as a result of which, only the *adh*⁻ cells can survive. ▶mutant isolation

Almond (*Prunus amygdalus*): The basic chromosome number $x = 7$ and $2x$ to $6x$ forms are known.

Alopecia: Alopecia is hair loss or baldness caused probably by an autoimmune condition occurring in different forms. In some cases it is accompanied by psychomotor epilepsy (involuntary movements), palm and sole keratosis (callosity), nail dysfunction, and lower mental capacity. In humans it appears as autosomal dominant. A recessive mutation (ACA, [Thr]→GCA, [Ala]) in human chromosome 8p12,

A

causing total baldness (alopecia universalis), may be based on a defect in a zinc finger transcription factor. One form is caused by mutation in the Hfh11^{nu} (forkhead/winged helix) transcription factor family. In mice, asebia (rudimentary sebaceous glands) and alopecia may be caused by mutation in two genes: *Scd1* encoding stearoyl-CoA desaturase 1 and *Scd2* coding for stearoyl-CoA desaturase 2. Some cancer chemotherapies induce alopecia, which can be mitigated by topically applied inhibitors of CDK2, such as the analogs of 3-(benzylidene)indolin-2-ones, etoposides, and cyclophosphamide-doxorubicin. ▶baldness, ▶hair, ▶autoimmune disease, ▶keratosis, ▶zinc finger, ▶nude mouse, ▶connective tissue disorders, ▶hypotrichosis, ▶etoposide, ▶cyclophosphamide, ▶doxorubicin

Alpers Progressive Infantile Poliodystrophy: This condition involves degeneration of the gray matter of the brain and cirrhosis of the liver. POLG (15q25) mutations affecting the catalytic subunit of mitochondrial DNA polymerase- γ A are responsible (Nguyen KV et al 2005 Neurology 65:1493). ▶mitochondrial DNA depletion syndromes

Alpert Disease (AFP) AFP is alpha-fetoprotein deficiency, encoded at human chromosome 4q11-q13. ▶fetoprotein; Greenberg F et al 1992 Am J Obstet Gynec 167: 509.

Alpert Syndrome 10q26 Alpert Syndrome is acrocephalosyndactylia, a disease characterized by a pointed skull and fused fingers and toes. This autosomal dominant or recessive human disease involves the fibroblast growth factor receptor (FGFR2), which is defective in the Pfeiffer syndrome as well. Its estimated mutation rate is $3-4 \times 10^{-6}$. ▶Pfeiffer syndrome; Moloney DM et al 1995 Nature Genet 13:48.

Alpha Accessory Factor: The alpha accessory factor enhances the affinity of pol α and primase for the DNA template. ▶pol α , ▶primase, ▶Okazaki fragment

Alpha Complex: The translocation complex of chromosomes (see Fig. A55), it transmits only through the female, whereas the beta complex is transmitted only through the male (in *Oenothera*). ▶translocation complex, complex heterozygotes; Cleland RE 1972 *Oenothera*: Cytogenetics and Evolution. Academic Press, New York.

Alpha-Fetoprotein: ▶fetoprotein

Alpha Helix: The alpha helix is a hydrogen-bonded secondary structure of polypeptides, where the polypeptide backbone is tightly wound around the longitudinal axis of peptide bonds and the groups of amino acids protrude along this generally right-handed helical structure (see Fig. A56). Commonly, 3.6 amino acids form each turn. It is often represented as a cylinder as well. protein ▶structure, ▶pitch

Figure A56. Two representations of alpha helix

Alphameric: Alphameric symbols use alphabetical notations, and possibly other characters, such as numbers.

Alpha Parameter: The alpha parameter provides a combined estimate of the frequency of quadrivalent association (q), meiotic exchange (e), and favorable anaphase distributions (a), and from these it predicts the frequency of double reduction, i.e., the production of *aa* gametes when the parental constitution is *AAAA* (see diagram of chromosome mechanics). In a triplex the cytogenetic constitutions can be represented as shown. The letters W, X, Y and Z stand for the centromeres, the chromatids are symbolized by the gray lines, and the dominant and recessive alleles are numbered from *A1* to *A6* and *a1* to *a2*, respectively (see diagram).

(i) In the absence of recombination the association of chromatids, alleles, and centromeres are: *A1-A2*, *A3-A4*, *A5-A6*, and *a1-a2*.

(ii) In case of recombination between gene and centromere the following arrays are formed:

A1-A3, *A1-A5*, *A3-A5*. These are the possible recombinant associations of dominant alleles, which were originally attached to different centromeres.

(iii) *A1-a1*, *A3-a1*, and *A5-a1* are the three possible dominant-recessive recombinant associations, when only one chromatid originally attached to a centromere is considered in the quadrivalent.

The total frequency of the gametes is 1 and the frequency of group (i) is designated as α , and the chance of each of the 4 types of associations within this group is $\alpha/4$.

The combined frequency of recombinant group (ii) and (iii) associations is $1 - \alpha$. Since groups (ii) and (iii) have 3 representatives each, and combined 6, the frequency of each of the recombinant associations is $(1 - \alpha)/6$.

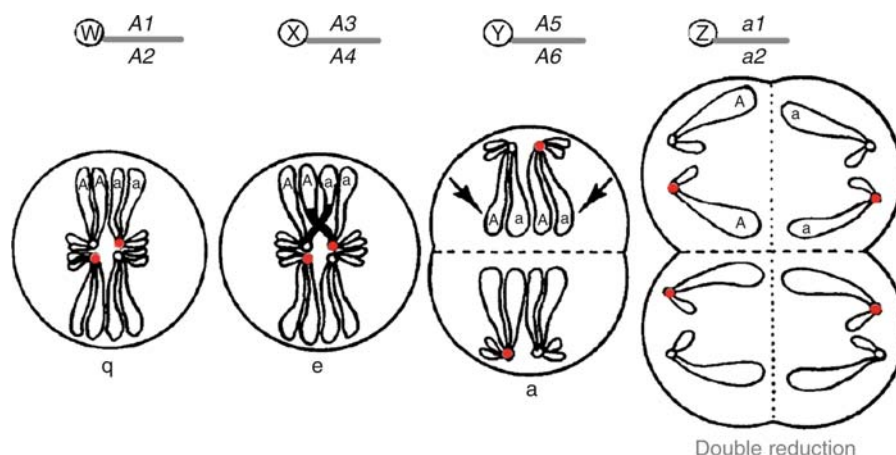

Figure A57. Chromosome mechanics (double reduction) are represented by the diagram; empty arms carry the A (dominant) allele

Group (i) has 3 double dominants ($A1-A2$, $A3-A4$, and $A5-A6$) among 4, each with a frequency of $\alpha/4$. The combined frequency of the group is $3 \times (\alpha/4)$. Group (ii) also has 3 double dominants ($A1-A3$, $A1-A5$, $A3-A5$) with individual frequencies of $(1 - \alpha)/6$ each, and a combined group frequency of $3 \times (1 - \alpha)/6$. Thus the total frequency of gametes with a dominant allele in both chromatids is $[3 \times (\alpha/4)] + [3 \times (1 - \alpha)/6] = [3\alpha/4] + [(3 - 3\alpha)/6]$. After dividing both the numerator and denominator of the second term by 1.5, we obtain the formula: $[3\alpha/4] + [(2 - 2\alpha)/4] = (2 + \alpha)/4$ = the frequency of AA gametes. The frequency of the Aa gametes is obtained similarly. Group (iii) has 3 Aa gametes with individual frequencies of $(1 - \alpha)/6$, and their combined frequency upon dividing numerator and denominator by 1.5 becomes $3 \times (1 - \alpha)/6 = (3 - 3\alpha)/6 = (2 - 2\alpha)/4$. The frequency of the double recessive gametes (aa) as shown above is $\alpha/4$. Thus the total gametic output of the triplex is $\frac{2+\alpha}{4}$ AA : $\frac{2-2\alpha}{4}$ Aa : $\alpha/4$ aa . The practical meaning of the α parameter is best illustrated by an example. Let us assume that the cytological analysis indicates the value of $q = 0.7$, $e = 0.25$, and $a = 0.333$. Thus $\alpha = 0.7 \times 0.25 \times 0.333 \times 0.5 = 0.02914$. This value can then be substituted into the formulas in the table (see Table A3).

Accordingly, for the simplex (line 3 at tetrasomy) AA becomes $\alpha/4 = 0.02914/4 = 0.007285$, Aa is obtained in frequency $2(1 - \alpha)/4 = 0.48543$, and $aa = (2 + \alpha)/4 = 0.507285$. Thus the double dominant gametes are expected to occur at a frequency below 1%, while Aa and aa at a near equal frequency of around 50%.

The proportion of the double reduction (aa gametes) indicates to some extent the relative distance of the gene from the centromere, albeit not in precise units directly convertible to map distance,

but approximating it. Theoretically, these calculations are elegant, but unfortunately the determination of the variable components of α requires great experimental skills and very favorable conditions. Therefore the analysis of segregation in polyploids is very difficult. ▶autopolyploids, ▶centromere ▶mapping; Mather K 1935 J Genet 30:53; Mather K 1936 J Genet 32:287.

Alpha Particles: Alpha particles are helium nuclei (contain 2 protons and 2 neutrons) emitted by radioactive decay. They release their excessive energy in a very short track; even in air they move only for a few centimeters. They have minimal penetration in living material, yet are very destructive (can break chromosomes) because of their short track and high ionizing energy.). Mean number of lethal lesions/per cell: α rays: 0.01, γ rays: 0.001, 10 MeVB neutrons: 0.005. ▶ionizing radiation, ▶linear energy transfer

Alpha Tocopherol (vitamin E): Tocopherols are plant products but are required in mammals for the maintenance of fertility and for the prevention of muscle degeneration. They appear to be antioxidants for unsaturated lipids. Lipid peroxidation may result in cross-linking of proteins and may cause mutation, the appearance of age pigments (lipofuscin), etc. ▶unsaturated fatty acids, ▶fatty acids

Alphavirus: An alphavirus is a single, negative-strand RNA virus with a 240 molecule basic capsid protein, surrounded by a lipid bilayer of 240 glycoprotein heteromeric envelope. It can infect a variety of cells and its genomic RNA is translated into non-structural proteins to begin the replication of the viral RNA. Although it is a cytotoxic virus it may be engineered

into a vector for transient gene therapy or used for vaccination. This group of viruses includes the Sendai virus and the Simliki forest virus. ►Sendai virus

Alphoid DNA: ► α satellite

Alport's Disease: Alport's Disease exists in different forms of which, autosomal dominant, recessive, and X-linked types are described. The phenotypes vary but most common symptoms are inflammation of the kidney(s), and deafness. Most probably the primary defect involves the basement membrane of the kidney glomerules and the Goodpasture antigen leading to kidney failure and hypertension. Bone marrow-derived stem cells may repair basement membrane defects and may prove therapeutically useful for treatment of Alport patients (Sugimoto H et al 2006 Proc Natl Acad Sci USA 103:7321). The basement membrane defect is an Xq22 coded collagen α -chain anomaly. Essentially, the Alport syndrome is the same as the Epstein syndrome. The autosomal dominant Alport syndrome with leukocyte inclusions and macrothrombocytopenia (also called Fechtner syndrome) is assigned to 22q11-q13. ►Goodpasture syndrome, ►collagen, ►basement membrane, ►kidney diseases, ►thrombocytopenia, ►May-Hegglin anomaly, ►stem cells

ALPS-1, ALPS-2 (autoimmune lymphoproliferative syndrome): ALPS-1 (10q24) is caused by malfunction (mutation in Fas or FASL [1q23]) and ALPS-2 by mutation in caspase-10 (2q33-q34). In either case the apoptotic process is interfered with, causing neurodegeneration, tumorigenesis, and other disorders. The disease is rare and occurs in childhood.

T cells accumulate but carry no CD4 or CD8 and the immune system turns against the red blood cells or the platelets. ►autoimmune ►diseases, ►FAS, ►FasL, ►apoptosis, ►CD4, ►CD8, ►T cells; Chun HJ et al 2002 Nature [Lond] 419:395.

ALS: ►amyotrophic lateral sclerosis

Alström Syndrome (ALMS, 2p13): The Alstrom Syndrome is an autosomal recessive human defect involving obesity, retinitis pigmentosa, deafness, and diabetes. Its frequency is elevated in some Louisiana and Nova Scotia populations of French origin. The ALMS1 protein contains 4,169 amino acids. ►obesity, ►Bardet-Biedl syndrome

ALT: ALT is a mechanism alternative to telomerase for the maintenance of telomere length integrity. ALT relies on recombination and depends on the Rad52 protein mediating homologous recombination. In order to prevent the restoration of telomere length during cancer therapy, perhaps both telomerase and ALT need to be targeted. ►telomerase; Grobely JV et al 2001 Hum Mol Genet 10:1953.

AlterMap: The AlterMap is a computer program replacing sections of the Kohara map of *E. coli* with the MapSearch alignments of DNA fragments. ►Kohara map

Alternate Disjunction: Alternative disjunction takes place in a translocation heterozygote when each pole receives a complete set of the genetic material, and consequently the zygote is genetically stable. ►adjacent distribution, ►translocations chromosomal, ►translocation complex

Alternate Paternity: Alternative paternity is the situation where the biological father is different from the legal father. ►paternity exclosure

Alternation of Generations: Alternation of generations refers to the cycles of haploid and diploid generations such as the gametophytic and sporophytic generations of plants. It also refers to the cycles of sexual and asexual generations that coexist in some species. ►life cycles, ►meiosis, ►mitosis, ►apomixis, ►parthenogenesis, ►fission, ►gametophyte, ►sporophyte

Alternative Splicing: Alternative splicing of mRNAs generates different protein molecules from the same genes after eliminating introns (see Fig. A58). Tissue-specific expression of many human genes is based on alternative splicing and the extent of the global operation can be studied by microarrays (Pan Q et al 2004 Mol Cell 16:929). Splicing factors such as the hnRNP and a serine-arginine protein are used to carry out these functions. hnRNP A1 normally favors a distal 5' splice site, but under the influence of p38 protein kinase signals, splicing may be switched to a proximal 5' splice site. Typically, alternative splicing occurs in immunoglobulin synthesis (among other mechanisms) and T cell receptors to generate a greater repertory of antibodies from a fewer number of genes (Wang J et al 2002 Science 297:108). A survey of 528 human genes indicated 22% alternative splicing, while others indicated 40–60% alternative splicing. (Modrek B, Lee C 2002 Nature Genet 30:13). (Estimates indicated transcripts between 2.5 and 5.4 per human gene.). The average in human chromosome 12 was 2.89 transcripts per gene but for UBC (ubiquitin C, 12q24.3) 20 transcripts were found for each gene (Scherer SE et al 2006 Nature 440:346). A study of 1% of the human genome indicated that 86% of the genes are alternatively spliced (Harrow J et al 2006 Genome Biol 7[Suppl.1]:S4.1). Also it was found that in 1% of the human genome there are tissue-specific and often unannotated set of exons outside the current boundaries of

the annotated genes (Denoeud F et al 2007 Genome Res 17:746). Alternative splicing displays great similarities between the human and mouse genomes (Modrek B, Lee CJ 2003 Nature Genet 34:177). However, Yeo GW et al 2005 (Proc Natl Acad Sci USA 102:2850) found much less correspondence in alternative splicing between humans and mice. The *Drosophila* axon guidance receptor *Dscam* (Down syndrome cell adhesion molecule) gene has the potential to generate 38,000 alternative transcripts (Schmucker D et al 2000 Cell 101:671). Thus alternative splicing requires fewer genes to carry out different functions. Alternative splicing has similar incidence in humans and other higher eukaryotes but it is rare or non-existent in unicellular eukaryotes. In general, about one-third of the alternative splice isoforms contain premature termination codons and although they may persist, eventually they are degraded by nonsense-mediated mRNA decay (Lewis BP et al 2003 Proc Natl Acad Sci USA 100:189). Aberrant alternative splicing is a common cause of human genetic disease (Cáceres JF, Kornblihtt AR 2002 Trends Genet 18:186). Exons duplicated in tandem (occurring in about 10% of eukaryotic genes) may be responsible for alternative splicing. Computational methods identified 245 mammalian genes in which, the exons in the DNA are not linear with the order in the mRNA. Exons in the RNA can be duplicated leading to a potential increase in phenotypic variations (Dixon RJ et al 2005 Nucleic Acids Res 33:5904). Alternative splicing is common in cancer and most of the cDNA sequences (~70%) in databases are derived from cancer cells. Therefore, these do not represent normal conditions (Roy M et al 2005 Nucleic Acids Res 33:5026). In vitro study indicates that in *Drosophila*, exons flanked by long introns have 90-fold higher chances of being alternatively spliced. The length of upstream introns in *Drosophila* is more influential than the length of downstream introns. In humans, the architecture has a similar consequence. (Fox-Walsh KL et al 2005 Proc Natl Acad Sci USA 102:16176). In *Arabidopsis* and rice plants, more than 21% of the genes display over 8% alternative splicing; more than half result in intron retention (Wang B-B, Brendel V 2006 Proc Natl Acad Sci USA 103:7175). ►splicing, ►spliceosome, ►introns, ►mRNA ►surveillance, ►hnRNA, ►p38, ►microarray ►hybridization, ►tissue ►specificity, ►exon ►skipping, ►K_A/K_S, ►DEGEST; Lopez AJ 1998 Annu Rev Genet 32:279; Tollervey D, Cáceres JF 2000 Cell 103:703; Standiford DM et al 2001 Genetics 157:259; Modrek B et al 2001 Nucleic Acids Res 29:2850; Hu GK et al 2001 Genome Res

Altosomes: Altosomes are structurally altered dinucleosomes composed of two histone octamers, and bear an asymmetrically located region of nuclease-accessible DNA. Altosomes can be formed on chromatin that contains the abundant mammalian linker histone H1 and has a unique micrococcal nuclease digestion footprint that helps measure the position and abundance of altosomes on any DNA sequence. Over time, altosomes spontaneously revert to structurally normal but improperly positioned nucleosomes, suggesting a novel mechanism for transcriptional attenuation as well as transcriptional memory, following human SWI/SNF action (Ulyanova NP, Schnitzler GR 2005 Mol Cell Biol 25:11156). ► **nucleosome**, ► **SWI/SNF**

Altruistic Behavior: Altruistic behavior is an evolutionary feature in animals where members of the species protect other members, especially the young, even at their own peril. Altruism (helping others without expecting benefits) is genetically controlled; however, cultural inheritance also plays an important role. Human infants as young as 18 months can already show altruism, but chimpanzees at the same development stage are much less motivated for this behavior (Warneken F, Tomasello M 2006 Science 311:1301).

Altruism can promote the survival of the population. Altruism may also be manifested in mating behavior. In a pride of animals some males may refrain from reproduction to allow more powerful kin to mate with available females. Apoptosis involves some elements of altruism of single cells that turn suicidal in order to ensure differentiation of a tissue or defend the organism against mechanical or biological injuries or attacks. ► **kin selection**, ► **inclusive fitness**, ► **apoptosis**, ► **behavior genetics**, ► **aggression**, ► **group selection**, and ► **“green beard effect”**; Agrawal AF 2001 Proc Roy Soc Lond B Biol Sci 268:1099; Abbot P et al 2001 Proc Natl Acad Sci USA 98:12068; group selection and cooperation: Traulsen A, Nowak MA 2006 Proc Natl Acad Sci USA 103:10952

Alu Family: Alu family refers to 150–300-bp long nucleotide sequence monomers associated head-to-tail, and repeated about 300,000–500,000 times or more in the primate genome. RNA polymerase III transcribes Alu sequences. These nucleotide sequences are cut by the Alu I restriction enzyme (recognition site AG↓CT) and hence the name of these gene families. Members of this family are also considered to be transposable elements, which depend on other elements for transposition. The Alu sequences are specific for the human genomes but homologs appear in other mammals. The Alu sequences appear to have evolved from the 7SL RNA genes throughout the human genome by retrotransposition, to reach the present number of more than one million copies. Several lines of evidence demonstrate that these elements modulate gene expression at the post-transcriptional level (Häsler J, Strub K 2006 Nucleic Acids Res 34:5491; corrigendum: double bond error in Fig 3 [Nucleic Acids Res 35:5491]).

Alu insertional mutations have been identified in the genes involved in antihemophilic factor IX, neurofibromatosis, Apert syndrome, adenomatous polyposis cancer, X-linked immunodeficiency, and breast cancer. It is most likely that many more such sequences will be identified in the completely sequenced human genome. Alu elements may be inserted into RNA transcripts and may convert introns into new exons by a process of *exonization* (Lev-Maor G et al 2003 Science 300:1288). Alu sequences as well as other repeats, by recombination increase the instability of the genome. Alu elements can be used to trace evolutionary paths and human migration (Salem A-H et al 2003 Proc Natl Acad Sci USA 100:12787). ► **SINE**, ► **LINE**, ► **7SL RNA**, ► **selfish DNA**, ► **Myr**, ► **see the diseases listed under separate entries**; Stenger JE et al 2001 Genome Res 11:12; Roy-Engel AM et al 2001 Genetics 159:279;

Batzer MA, Deininger PL 2002 Nature Rev Genet 3:370, Alu in the human genome: McGuire DJ et al 2006 Adv Exp Med Biol: 578:73.

Alu-Equivalent: Alu-equivalent are a group of genomic sequences similar to the Alu family. ► [Alu family](#)

Aluminum Tolerance: Aluminum tolerance can be bred into plants by expression of the transgene of *Pseudomonas aeruginosa* citrate synthase. The transgenic plants exude citrate or malate by the roots and lower the pH of the soil. Aluminum induces from the roots of tolerant plants the release of organic acids and chelate Al^{3+} into the rhizosphere; the complexes so formed are less toxic. Several plant genes (QTLs) are involved in the resistance (Hoekenga OA et al 2006 Proc Natl Acad Sci USA 103:9738). Aluminum in alkalic or neutral soil is toxic to many crop plants. The *stop1* mutation (involved in the zinc finger domain in a predicted Cys2His2-type zinc finger protein encoded in chromosome 1 of *Arabidopsis*) had no effect on cadmium, copper, lanthanum, manganese, and sodium chloride sensitivity, but it caused hypersensitivity to Al^{3+} root-toxicity (Iuchi S et al 2007 Proc Natl Acad Sci USA 104:9900). (See Ma JF et al 2001 Trends Plant Sci 6:273)

Alzheimer's Disease (AD, FAD): Is a presenile/senile dementia (loss of memory and ability of judgment as well as general physical impairment) involving the accumulation of amyloid protein plaques in the brain, and resulting in degeneration of neurons and build-up of neurofibril tangles. At an early (prodromal) stage of AD, memory loss is not yet associated with dementia. In this condition there is atrophy in the hippocampus and the region near the hippocampus (parahippocampal region) (Soub TR et al 2006 Proc Natl Acad Sci USA 103:10041). The amyloid fibers form antiparallel β -sheets in a cross arrangement and are bound together between phenylalanine rings and salt bridges that exist between charged pairs (glutamic acid–lysine). These fibers stabilize the structure of the plaques. (Makin OS et al 2005 Proc Natl Acad Sci USA 102:315). Four major genes are responsible for AD. The amyloid- β peptide ($A\beta$, of 40–42 amino acids) comes from a larger amyloid precursor protein (β APP) that is synthesized in the normal brain, is processed in a number of ways, and is encoded in chromosome 21q21.3–q22.05 as a rare early onset dominant (AD1). Duplications of 0.58 to 6.37 Mb segments involve increase in deposits of amyloid- β (Rovelet-Lecrux A et al 2006 Nature Genet 38:24). The $A\beta$ -42 fragment has more deleterious effects; its three-dimensional structure has been determined (Lührs T et al 2005 Proc Natl Acad Sci USA 102:17342). The largest protein spans the cell

membrane (AD3, 14q24.3). One of the extracellular domains is a protease inhibitor. This domain may be released in normal cells, but in diseased cells the amyloid protein is processed incorrectly. Regulation of K^+ ion channels, calcium homeostasis, and protein kinase C (PKC) gene activation (by bryostatin) promote the solubility and secretion of the amyloid protein APP α obtained from transgenic mouse brain cells. Thus, it may alleviate the human condition as well (Etcheberrygaray R et al 2004 Proc Natl Acad Sci USA 101:11141).

Synaptic acetylcholinesterase (AChE-S) seems to promote fibril formation of insoluble $A\beta$. The homologous synthetic butyrylcholinesterase (BchE) that has a tryptophan residue in the polar side of the C terminus of the enzyme, co-localizes with AChE and attenuates fibril and tangle formation of amyloids (Diamant S et al 2006 Proc Natl Acad Sci USA 103:8628).

Genes responsible for the amyloid protein synthesis have been cloned and others mapped to human chromosomes 1q31–42 encoding STM2/AD4, a seven-transmembrane integral protein [presenilin 2], and to chromosome 14q24.3 encoding protein S182/AD3 (presenilin 1), which is 67% homologous to STM2. Human chromosome 19q13.2 encodes (AD2) apolipoprotein E (APOE) that controls the late onset of Alzheimer's disease. In late-onset AD (LOAD) Bace1 protease cleaves APP to generate the N terminus of $A\beta$. This protease is more active in patients with LOAD. Some results indicate that compounds antagonizing the apoE/ $A\beta$ interaction constitute an effective therapeutic approach for AD (Sadowski MJ et al 2006 Proc Natl Acad Sci USA 103:18787). A Bace-linked leucine-rich repeat transmembrane 3 (*LRRTM3*) neuronal gene promotes APP processing by BACE1 (Majercak J et al 2006 Proc Natl Acad Sci USA 103:17967). Expression of the β -site β -amyloid precursor protein (APP) cleavage enzyme gene *BACE1* is tightly controlled at both the transcriptional and translational levels. A functional hypoxia-responsive element in the *BACE1* gene promoter up-regulates β -secretase cleavage of APP and production of amyloid- β protein, by increasing *BACE1* gene transcription and expression both in vitro and in vivo. Thus, hypoxia facilitates onset of AD (Sun X et al 2006 Proc Natl Acad Sci USA 103:18727). APP overexpression leads to postsynaptic silencing through a selective reduction of AMPA receptor-mediated currents. $A\beta$ likely mediates this effect because expression of mutant APP incapable of producing $A\beta$ was found not to depress transmission (Ting JT et al 2007 Proc Natl Acad Sci USA 104:353).

Homozygosity for the APOE-4 allele (frequency ~16%) increases the chances of onset of the disease

A

about 20 times, while a single copy of the APOE-2 (frequency ~7%) only doubles this chance. Chromosome 21q21.3-q22.05 (AD1) encodes β APP (early onset, dominant) and seems to be involved with the disease. $A\beta$ is the major component of the brain plaques and its ligand is a protein with a relative molecular weight ~50K, identical to RAGE (receptor for advanced glycation endproduct) or AGE/ β APP and for amphoterin controlling neurite outgrowth (an inflammatory process). RAGE/AGER receptor (6p21.3) mediates the interaction of $A\beta$ with endothelial cells and neurons, causing oxidative stress. Its interaction with microglia results in cytokine production, chemotaxis and binding movements. A spurious, unconfirmed interaction among AD1/APP, AD2/APOE, A2M (α -macroglobulin, encoded at 12p13.3-p12.3), and a low-density lipoprotein related protein (LRP, encoded at 12q13.1-q13.3) have been reported. The PAR-4/PRKC (prostate apoptosis response) mutations in the gene encoding 342 amino acids, that include a leucine zipper and a death domain, mediate neuronal degeneration and mitochondrial dysfunction in case of defects in presenilin 1. $A\beta$, in the mitochondria of AD patients, interacts with an alcohol dehydrogenase (ABAD). Reactive oxygen species are leaked consequently and lead to mitochondrial toxicity and impairment of hippocampal function. The latter causes memory impairment (Lustbader JW et al 2004 Science 304:448). Mutations in the control region of the brain mtDNA interfere with mitochondrial replication and transcription in AD (Coskun PE et al 2004 Proc Natl Acad Sci USA 101:10726). Sporadic AD may be associated with the very low-density lipoprotein (VLDL) receptor gene. The sortilin-related protein (SORL1; 11q23.2-q24.2) is a member of both the vacuolar sorting protein-10 domain receptor and the low-density lipoprotein receptor. Inherited variants in the SORL1 neuronal sorting receptor are associated with late-onset AD. These variants occur in at least two different clusters of intronic sequences within the *SORL1* gene (also known as *LR11* or *SORLA*) and may regulate tissue-specific expression of *SORL1*. SORL1 directs trafficking of APP into recycling pathways, and under-expression of SORL1 causes sorting of APP into $A\beta$ -generating compartments and results in AD (Rogaeva E et al 2007 Nature Genet 39:168).

AD is common among individuals with Down's syndrome (that occurs due to chromosome 21 trisomy where β APP is located). Some psychotropic drugs (drugs affecting the nervous system) may alleviate certain symptoms. The incidence of Alzheimer disease (AD) increases from 0.1% below 70 to double or may even reach 2% after age 80. The risk for first-degree relatives varies from 24 to 50% by age 90. Aberrant aggregation of $A\beta^{42}$ fragments and aging, are slowed when there is a decrease in insulin/insulin-like growth

factor-1 signaling. (Cohen E et al 2006 Science 313:1604). The concordance rate of AD among monozygotic twins is 40–50% and among dizygotic twins 10–50%. Genetic screening for the disease is not considered appropriate. In 2005, the estimated number of people afflicted was 4.5 million and by (2050) this number may increase to 11.3–16 million. The sporadic (apparently non-genetic) cases of this disease may be caused by frameshift mutation in the RNA during transcription or after transcription, in the β amyloid precursor and/or in ubiquitin-B. The identification of AD is difficult without an autopsy or biopsy detecting the brain plaques. Biopsies generally reveal shrinkage of gyri in the lobes of the brain involved in processing learning and memory, namely the temporal and the frontal. Pet scans (positron emission tomography) of living brains reveal reduced energy metabolism in these regions in case of AD (Mattson MP 2004 Nature [Lond] 430:631). The aggregation of $A\beta$ can be detected by fluorescence correlation spectroscopy, provided the polymerization is promoted by “seeding” with synthetic $A\beta$ probe in femtoliter samples of the cerebrospinal fluid and Cy2 fluorophore is used. The difference between afflicted and healthy individuals is clear and the procedure may be of potential value for diagnosis. It is highly desirable that AD be detected before the onset of clinical symptoms. Magnetic resonance imaging of the brain of a mouse into whose basal ganglia or blood stream E,E-1-fluoro-2,5-bis(3-hydroxycarbonyl-4-hydroxy)styrylbenzene (FSB) has been precisely injected, clearly labels the early deposits of amyloids (see Fig. A59). The toxicity of the procedure seems negligible although much improvement is required before it could be used clinically for humans (Higuchi M et al 2005 Nature Neurosci 8:527; this paper is also the source of the formula of FSB adopted).

Figure A59. FSB

Mice transgenic for a mutant (Val⁷¹⁷→Phe⁷¹⁷) human APP, when immunized with $A\beta^{42}$, either prevented, or reduced the neuropathological symptoms. Unfortunately this type of vaccination resulted in meningoencephalitis in some patients and clinical trials were halted. Immunotherapy for AD so far has resulted in beneficial as well as undesirable, effects (Monsonogo A, Weiner HL 2003 Science 302:834). A non-viral $A\beta$ vaccine in mice is shown to have, beneficial prophylactic effects and ~50% reduction

in amyloids after the onset of amyloid deposition, without serious side effects (Okura Y et al 2006 Proc Natl Acad Sci USA 103:9619).

Figure A60. Cyclohexanehexol

The most likely time-course of the development of AD is: mutations in the amyloid and presenilin genes → production of Aβ⁴² fragments → formation of plaques in the brain cortex → hyperphosphorylation of tau, oxidative stress, and the formation of tangled fibers → neuronal dysfunction and neuronal death → mental deterioration. Tau reduction can block Aβ- and excitotoxin-induced neuronal dysfunction and may represent an effective strategy for treating AD and related conditions (Robertson ED et al 2007 Science 316:750). There is evidence that the formation of plaques and fibrillar tangle is preceded by the appearance of 2.7 to 4.2 nm diameter soluble oligomers (see Fig. A60). The structure of the oligomers, rather than their amino acid composition, may be responsible for the toxicity (Kayed R et al 2003 Science 300:486). Early in the disease axonal swelling may occur due to deficit in microtubule-associated transport of proteins, organelles and vesicles (Stokin GB et al 2005 Science 307:1283). The hyperphosphorylation of tau, a microtubule-associated protein, is mediated by the cyclin-dependent kinase, Cdk5. Phosphorylation gets enhanced and tau binds less efficiently to microtubules, when the p35 regulatory subunit of Cdk5 is cleaved into a truncated p25 fragment. Also, Cdk5/p25 promotes apoptotic cell death of neurons. AD involves the inflammation of the brain, as well. β-Amyloid seems to stimulate CD40-CD40L interaction causing the activation of microglia. Microglial cells are important players in AD pathogenesis by promoting the degeneration of neurons. Although AD is generally attributed to the accumulation of pathological levels of Aβ¹⁻⁴², it is possible that the other cause of the disease is the lack of clearance of the plaques by the neprilysin-like neutral endopeptidase (NEP) and related enzymes. Insulin-degrading enzyme (IDE, 10q23-q25) in neurons and microglia degrades Aβ. Protein kinase PKCε upregulates endothelin-converting enzyme ECE and reduces the number of amyloid plaques, in transgenic mice (Choi

D-S et al 2006 Proc Natl Acad Sci USA 103:8215). In a mouse model, Aβ immunization appears to reduce plaques and fibrils in the brain and improves cognitive functions and memory. In transgenic mice models of AD, oral administration of cyclohexanehexol stereoisomers (before or after the onset of the symptoms), inhibits the aggregation of Aβ amyloid peptides into high molecular weight oligomers, ameliorates cognition, synaptic physiology, and cerebral pathology and reduces early mortality (McLaurin J et al 2006 Nature Med 12:801).

In LOAD the Aβ₄₂ level is elevated by genetic factors in human chromosome 10q (Myers A et al 2002 Am J Med Genet 114:235). Although at the moment there is no cure for AD, some environmental factors may exert beneficial effects. Increased cognitive/mental activity, consumption of a low-calorie diet rich in vitamins C and E, and physical exercise may delay or reduce somewhat the onset of AD. In a mouse model of AD, a diet rich in omega-3-fatty acids was found to protect against synaptic protein loss and memory deficits (Calon F et al 2004 Neuron 43:633). The APP cleavage product by α-secretase is neuroprotective due to the increased expression of transthyretin and an insulin-like growth factor (Stein TD et al 2004 J Neurosci 24:7707). Procedures of blocking the activities of β and γ secretases, chelation of copper and iron in the brain and immunization with Aβ₄₂, are currently being studied. A transgenic mouse model suggests that an “enriched environment,” i.e., exercise, elevates the level of the Aβ-degrading endopeptidase, neprilysin, and thus reduces the amyloid burden, selectively upgrading transcripts associated with learning, memory, vasculogenesis, neurogenesis and cell survival (Lazarov O et al 2005 Cell 120:701). A mouse model is available for early-onset behavior and synaptic deficits of AD (Jacobsen JS et al 2006 Proc Natl Acad Sci USA 103:5161). Intracerebral injection of dilute human Aβ or cerebral extract from Alzheimer patients, into an APP transgenic mouse induced β amyloidogenesis depending on the agent used or the recipient host (Meyer-Luehmann M et al 2006 Science 313:1781). This phenomenon bears some similarity to prion action, although this is not very clear.

The nematode *Caenorhabditis elegans* has a single APP-related gene, *apl-1*, that is expressed in multiple tissues. Loss of *apl-1* disrupts several developmental processes, including molting and morphogenesis, and results in larval lethality. *Apl-1* lethality can be rescued by neuronal expression of the extracellular domain of APL-1. These data highlight the importance of the extracellular domain of an APP family member and suggest that APL-1 acts in a non-cell-autonomous manner during development. Overexpression of APL-1 also causes several defects, including a high level of larval lethality. Decreased

A

activity of *sel-12*, a *C. elegans* homologue of the human γ -secretase component presenilin 1, partially rescues the lethality associated with APL-1 overexpression, suggesting that SEL-12 activity regulates APL-1 activity either directly or indirectly (Hornsten A et al 2007 Proc Natl Acad Sci USA 104:1971).

Serum response factor (SRF) and myocardin (MYOCD), two interacting transcription factors, orchestrate the vascular smooth muscle cells (VSMC)-differentiated phenotype. SRF-MYOCD overexpression in small cerebral arteries appears to initiate independently of A β , a pathogenic pathway mediating arterial hypercontractility, and cerebral blood flow dysregulation, which are both associated with Alzheimer's dementia (Chow N et al 2007 Proc Natl Acad Sci USA 104:823). ▶b-amyloid, ▶AMPA, ▶behavior human, ▶prion, ▶Creutzfeldt-Jakob disease, ▶scrapie, ▶encephalopathy, ▶sirtuin, ▶mental retardation, ▶Down's syndrome, ▶corticotropin releasing factor, ▶presenilins, ▶memory, ▶AGE, ▶microglia, ▶NF- κ B, ▶LDL, ▶VLDL, ▶ERAB, ▶frameshift, ▶ubiquitin, ▶tau, ▶excitotoxicity, ▶CDK, ▶p35, ▶secretase, ▶statins, ▶transthyretin, ▶BACE, ▶GSK, ▶ β sheet breaker peptides, ▶humanin, ▶fluorophore, ▶mitochondrial disease in humans, ▶microglia, ▶CD40, ▶CD40 ligand, ▶neprilysin, ▶endothelin, ▶protein kinase, ▶tomography, ▶sterols, ▶macular degeneration; Chapman PF et al 2001 Trends Genet 17:254; Wiltfang J et al 2001 Gerontology 47:65; Selkoe DJ 2001 Physiol Rev 81:741; Baekelandt V et al 2000 Curr Opin Mol Ther 2:540; Selkoe DJ, Podlisny MB 2002 Annu Rev Genomics Hum Genet 3:67, mouse model: Wong PC et al 2002 Nature Neurosci 5:633; Aguzzi A, Haass C 2003 Science 302:814; Cummings JL 2004 New England J Med 351:56, history of Alzheimer disease: Goedert M, Spillantini MG 2006 Science 314:777, potential approaches to treatment: Roberson ED, Mucker L 2006 Science 314:781, <http://www.alzforum.org/>.

Amacrine Cell: Amacrine cells are retinal neurons with short axons. ▶axon, ▶neurogenesis, ▶retina

Amanitin (C₃₉H₅₄N₁₀O₁₃S): ▶ α -amanitin

Amaranth: Amaranths are subtropical or tropical American seed plants with $2n = 2x = 32$.

Amastigote: ▶*Trypanosoma*

Amatoxins: Amatoxins are bicyclic octapeptides (e.g., α -amanitin) produced by the fungus *Amanita phalloides*. They inhibit the function of RNA polymerase II (occasionally pol III) of eukaryotes but do not affect the transcriptases of the prokaryotic type, e.g., transcriptases in the cytoplasmic organelles of eukaryotes. ▶RNA polymerase, ▶RNA replication, ▶transcription, ▶pol III

Amauris: *Amauris* is an African species of butterfly that is mimicked by the species *Papilio dardanus*. *Amauris* is distasteful to predators; hence the mimicking species improves its survival. ▶Batesian mimicry

Amaurosis Congenita (Leber congenital amaurosis, LCA): LCA refers to a group of autosomal recessive conditions of whole or partial blindness caused by a defect of the cornea (keratoconus). About 10% of the visually impaired suffer from LCA. LCA may also be caused by mutations in the photoreceptor guanylate cyclase (RETGC) or the retinal pigment epithelium (RPE), and in genes responsible for phototransduction and photoreceptor maintenance. Autosomal dominant photoreceptor-specific homeodomain gene (CRX), is responsible for cone-rod dystrophy of the retina. Activation of sensory transduction by opsin apoprotein in a light-independent manner may be one of the causes of LCA (Woodruff ML et al 2003 Nature Genet 35:158). LCA has been mapped to human chromosome 17p13.1. Another mutation was mapped to a retinitis pigmentosa locus (RET3C11) at 1q321-q32.1. This locus is called Crumbs Homolog 1 (CRB1) of a *Drosophila* gene. The cause of Type 1 amaurosis is located in chromosome 14 (Heilig R et al 2003 Nature [Lond] 421:601. Chromosome 6q14 encodes the ciliary protein, lebercillin, which interacts with 24 proteins and is associated with LCA (I den Hollander A et al 2007 Nature Genet 39:889). ▶eye diseases, ▶nephrolithiasis, ▶cilia; Seeliger MW et al 2001 Nature Genet 29:70; Cremers FPM et al 2002 Hum Mol Genet 11:1169

Amaurotic Familial Idiocy (AFI): Is the old name for Tay-Sachs disease. ▶Tay-Sachs disease, ▶Batten disease

Amber: Amber is a fossil tree resin up to millions of years old. It is hardened and resistant to most environmental factors. Frequently it contains microbes, plants or animals, or organic residue in a well preserved state, and thus may provide very valuable information on old organismal specimens, including genetic material. ▶ancient DNA

Amber: Amber also refers to a chain-terminator codon (UAG).

Amber Mutation: Amber mutation generates a chain-termination polar effect (the name has nothing to do with function; rather it was named after Felix Bernstein whose German family name translates into amber). ▶code genetic, ▶polar mutation; Epstein RH et al 1963 Cold Spring Harbor Symp Quant Biol 28:375.

Amber Suppressor: Amber Suppressor is a mutation in the anticodon triplet (3'-AUC-5') of a tRNA so that

the amber mutation (5'-UAG-3') may be read as a tyrosine codon and thus the translation not be terminated. *supC*, *supD*, *supE*, *supF*, *supG*, *supU*; Kiga D et al 2001 Eur J Biochem 268:6207.

Ambidextrous: ►handedness

Ambient Signals: The position of a particular cell determines its response to particular environmental stimuli.

Ambiguity In Translation (mistranslation, miscoding): Ambiguity may be brought about by antibiotics, or modification of the tRNA or the ribosomes (16S subunit). Consequently, an amino acid different from the original is incorporated into the nascent polypeptide. It seems the cognate tRNAs have ca. four orders of magnitude higher recognition rate than the non-cognate ones, measured on the basis of GTPase action rate in the EF-Tu-GDP ternary complex. Under normal circumstances, the estimated error per amino acid is 10^{-4} . ►error in aminoacylation, ►RAN, ►protein synthesis, ►EF-TU:GTP; Dong H, Kurland CG 1995 J Mol Biol 248:551; Ardell DH, Sella G 2001 J Mol Evol 53:269; Ogle JM, Ramakrishnan V 2005 Annu Rev Biochem 74:129.

Ambiguity of Restriction Enzymes: Such enzymes can cut more than a single sequence, although with varying efficiency, e.g., Hind I: GTT↓GAC, GTT↓AAC, GTC↓GAC.

Ambisense Virus (e.g., some bunyaviruses, arenaviruses) Ambisense viruses are transcribed into the mRNA, and also into the 5'-end of the RNA genome functioning as mRNA.

AMD: AMD is ARE- (AU-rich sequence) mediated mRNA decay. ►mRNA degradation, ►RNA surveillance, ►non-stop decay, ►RNAi, ►HuR

Ameiotic Recombination: ►parasexual mechanism, ►asexual

Amelia: ►limb defects in humans. ►thalidomide, ►phocomelia

Amelioration of Genes: DNA sequences incorporated into a genome by horizontal transfer, tend to adapt during evolution to the codon usage of recipient organisms. ►transmission, ►codon usage

Amelogenesis Imperfecta (AI): The autosomal dominant forms of this disease (ameloblastin and enamelin encoded within 4q11-q21) lead to softness of the tooth enamel caused by lack of calcium. Calcium deposits in the kidneys and variant symptoms indicate autosomal recessive inheritance as well. Two Xp22.3-p22.1- and Xq22-q28-linked forms are distinguished, one of which, is very similar in phenotype to the autosomal dominant form. The

enamel is softer than usual and of normal thickness in one these cases; while in the other, the enamel is hard but very thin. The combined prevalence of the two forms in Sweden is $\sim 1.4 \times 10^{-3}$. Various mouse mutants are available (Masuya H et al 2005 Hum Mol Genet 14:575). (►See entries under tooth; Rajpar MH et al 2001 Hum Mol Genet 10:1673)

Amelogenin Test: Amelogenin test is a forensic and archeological sex typing tissue test. The X chromosome- and the Y chromosome-derived amelogenin sizes are different and thus the test indicates sex of the specimen. In rare instances the AMELY gene (Yp11, Xp22.3-p22.1) is missing from the Y and in such a case, a male sample is indistinguishable from a female sample, unless other markers (e.g., the SRY gene) are involved in the test. Amelogenin is a dental enamel protein. (►SRY, ►sex determination; Buel E et al 1995 J Forensic Sci 40:641).

Amenorrhea: The absence of menstruation that may be caused by physiological factors (obesity or malnourishment, pregnancy), hormonal imbalance, age-related factors, disease-related factors, or genetic causes such as pseudo-hermaphroditism, Turner syndrome, absence of ovaries, uterus or vagina, etc. In the absence of structural deficiencies, selective estrogen-receptor modulating (SERM) drugs may be beneficial. Secondary amenorrhea occurs when menstruation is suspended or ceased after a period of time. In such cases hormone replacement therapy may be indicated. ►hermaphroditism, ►Turner syndrome

Amensalism: A condition in which one organism is inhibited by another, which is unaffected by this relationship.

American Type Culture Collection (ATCC): The ATCC maintains and catalogues microbial stocks, viruses, and cultured cells. <http://www.atcc.org/>.

Amerind (American Indians): Amerind refers to the ethnically diverse groups of people, which migrated 30–10 thousand years ago in several waves, apparently through the Behring Strait from Asia to North America, and eventually spread South. Anthropological and linguistic studies and DNA (mtDNA, Y chromosome) analysis permits the study of their origin, migration, and diversity. (►mtDNA, ►Y chromosome; Bortolini MC et al 2003 Am J Hum Genet 73:524).

Ames Test: Ames test is a bacterial assay based on backmutation of different histidine-requiring strains of *Salmonella typhimurium* (see Fig. A61). Reversions are capable of detecting various types of base substitutions and frameshift. A single plate generally detects mutations in 100,000 or more cells.

A

Figure A61. The Ames test with and without the use of the microsomal (S-9) fraction. It is clear that the microsomal enzymes do not affect the frequency of reversions without 2-AAF (2-acetylaminofluorene). Also 2-AAF without activation is not mutagenic. The S-9 fraction is prepared, usually, from rodent liver homogenate and in its presence, the promutagens can also be assayed. The bacteria lack the activating enzyme component. (Courtesy of Dr. D.M. Zimmer)

In some strains the *his*⁻ genes are present in multicopy plasmids to enhance the targets of the strains. Bacteria also carry mutations that interfere with genetic repair. The testing medium includes microsomal fractions of mammalian liver that can activate promutagens into ultimate mutagen. Thus the mutagenic effectiveness of a majority of chemicals may be increased by three orders of magnitude. The results of this assay are highly correlated with the carcinogenicity of the compounds being evaluated, yet its administration requires only two days compared with the several months that evaluations of rodent tests need. AMES is also inexpensive and permits the evaluation of a large number of compounds at low cost. ▶[bioassays in genetic toxicology](#), reversion studies in *Salmonella* and *E. coli* in ▶[genetic toxicology](#), ▶[microsomes](#), ▶[base substitution mutation](#), ▶[frameshift mutation](#), ▶[activation of mutagens](#); for statistical evaluations: Kim BS, Margolin BH 1999

Amethopterin: Amethopterin is an inhibitor of dihydrofolate reductase, an important enzyme in the de novo biosynthetic pathway of purine and pyrimidine nucleotides. Synonymous with methotrexate, amethopterin is used as an antitumor drug and as a selective agent in genetic transformation. It has also been used to treat rheumatoid arthritis and psoriasis. It is extremely toxic in concentrations of 10^{-8} to 10^{-9} , at which it may shut down the biosynthesis of nucleotides (see Fig. A62). It may also cause headaches, rashes, diarrhea, and cirrhosis of the liver. ▶[aminopterin](#), ▶[methotrexate](#), psoriasis.

Amino Acid: An amino acid is the building blocks of a protein. There are approximately 20 naturally occurring amino acids. amino acids.

Amino Acid Activation: ▶[aminoacylation](#)

Amino Acid Analyzer: The amino acid analyzer is an automated equipment, similar to a high-pressure liquid chromatography apparatus, that separates and

quantifies the amino acid composition of protein digests. ►chromatography

Amino Acid Index: The amino acid index reveals the physico-chemical properties of amino acids and sheds light on proteins. <http://www.genome.ad.jp/dbget/aaindex.html>.

Amino Acid Metabolism: Amino acids are derived from compounds in the glycolytic-, the citric acid-, and the pentose phosphate pathways. Biosynthetic systems in different evolutionary categories may vary. Bacteria and plants are normally able to synthesize all the 20 primary amino acids, whereas animals depend primarily on diet for the *essential amino acids* (Boudko DY et al 2005 Proc Natl Acad Sci USA 102: 1360). Genetics of microorganisms plays an important role in elucidating their pathways. Single gene mutations generate special requirement for all amino acids, which can be met by feeding the amino acid or the appropriate precursor. In higher plants, auxotrophy exists only for very few amino acids, probably because amino acids may be synthesized by parallel pathways or functionally duplicated genes. In humans and other mammals, certain genetic defects may affect in different ways all the natural amino acids and many of their derivatives, and thus cause inborn errors of metabolism. ►argininemia, ►citrullinemia, ►ornithine decarboxylase, ►ornithine aminotransferase, ►ornithine transcarbamylase, ►alanine aminotransferase [glutamate-pyruvate transaminase], ►alaninuria, ►aspartate aminotransferase [glutamate oxaloacetate transaminase], ►asparagine synthetase, ►aspartoacylase deficiency, ►cystinuria, ►cystinosis, ►cystathionuria, ►homocystinuria, ►cystin-lysinuria, ►glutamate synthesis, ►glutamate decarboxylase, ►glutamate dehydrogenase, ►glutamate formiminotransferase deficiency, ►glutamate pyruvate transaminase, ►glutamate oxaloacetate transaminase, ►glutaminase, ►glycine biosynthesis, ►glycinemia, ►methylmalonicaciduria, ►vitamin B₁₂ defects, ►histidine operon, ►histidase, ►histidinemia, ►isoleucine–valine biosynthetic pathway, ►isovalericacidemia, ►3-hydroxy-3-methylglutaryl CoA lyase deficiency, ►leucine metabolism,

Amino Acid Regulation: Amino acids and hormones, e.g., insulin, may regulate the translation of a specific amino acid mRNA or global protein synthesis, through an integrated pathway of signals.

Amino Acid Replacements: Amino acid replacements take place by base substitution in the codons, e.g., a glutamic acid (GAA) residue may be replaced by glutamine (CAA), lysine (AAA), glycine (GGA), valine (GTA), alanine, (GCA), aspartic acid (GAT), and so on. The rate of amino acid substitution per site in a protein has been estimated to average 10^{-9} /year during evolution. This average may vary by 3–4 orders of magnitude among different proteins, while the rate of substitution among genes may vary by three orders of magnitude (Wilson AC et al 1977 Annu Rev Biochem 46:573). In the enzyme 3-methyladenine DNA glycosylase (AAG), ~34% of the replacements lead to inactivation (Guo HH et al 2004 Proc Natl Acad Sci USA 101:9205).

In human disease, drastic changes in amino acid substitutions, e.g., deletions versus replacement by a similar amino acid (according to the Grantham classification), generally occur in more severe forms of the disease (Gillard EF et al 1989 Am J Hum Genet, 45:507; Miller MP, Kumar S 2001 Human Mol Genet 10:2319). ►PAM, ►mutation rate; Akanuma S et al 2002 Proc Natl Acad Sci USA 99:13549; Grantham's classification, amino acid replacement in human disease: Vitkup D et al 2003 Genome Biol 4:R72; prediction of substitutions: Ng PC, Henikoff S 2006 Annu Rev Genomics Hum Genet 7:61; <http://www.genome.ad.jp/aaindex/>; sorting intolerant from tolerant amino acid

Figure A64. Regulation of Protein and amino acid synthesis under the control of amino acids and insulin

A

substitutions in proteins: <http://blocks.fhcrc.org/sift/SIFT.html>.

Amino Acid Sequencing: Amino acid sequencing can be carried out in different ways. At present, the most commonly used method deduces the putative amino acid sequence indirectly from the codon sequences in DNA. Direct estimates can be obtained from polypeptides cleaved by proteolytic enzymes (trypsin, chymotrypsin, pepsin, other proteases, and cyanogen bromide) to obtain manageable smaller fragments of proteins. These agents prefer certain points of cleavage, represented by specific amino acids. Direct cleavage also utilizes the chemical breakage of disulphide bonds. This is followed by the Edman degradation, which uses end labeling and removes one amino acid at a time. Eventually, the sequenced fragments must be ordered on the basis of overlapping ends. ▶[Edman degradation](#), ▶[amino acid analyzer](#), ▶[sequenator](#), ▶[DNA sequencing](#), ▶[databases](#); Rajagopal I, Ahern K 2001 Science 294:2571; key amino acid positions in structurally similar proteins: <http://ckaaps.sdsc.edu>; sequencing aligning; structure tools: <http://toolkit.tuebingen.mpg.de/>.

Amino Acid Starvation: ▶[stringent response](#), ▶[stringent control](#)

Amino Acid Substitution: ▶[amino acid replacement](#)

Amino Acid Symbols in Protein Sequences: These are as follows: alanine A, aspartic acid or asparagine B, cysteine C, aspartic acid D, glutamic acid E, phenylalanine F, glycine G, histidine H, isoleucine I, lysine K, leucine L, methionine M, asparagine N, proline P, glutamine Q, arginine R, serine S, threonine T, valine V, tryptophan W, unknown X, tyrosine Y, glutamic acid or glutamine Z. ▶[amino acids](#)

Amino Acids: Amino acids are relatively simple yet diverse chemical compounds that all have at least one NH_2 group (see Fig. A65). **R** (see box) can be a *non-polar aliphatic* group: glycine (Gly), alanine (Ala), valine (Val), leucine (Leu), isoleucine (Ile), proline (Pro), *aromatic*: phenyl alanine (Phe), tyrosine (Tyr), tryptophan (Trp), *polar uncharged*: serine (Ser), threonine (Thr), cysteine (Cys), methionine (Met), asparagine (Asn), glutamine (Gln), *negatively charged*: aspartic acid (Asp), glutamic (Glu), *positively charged*: lysine (Lys), arginine (Arg), histidine (His). The 20 naturally occurring amino acids are known as the building blocks of proteins. Archaea and eubacteria encode, in addition, pyrrolysine (UAG) and selenocysteine (UGA, the latter also in animals). Some amino acids are modified in certain types of proteins. Cysteine and methionine always contain sulphur. In α -amino acids both the amino and carboxyl group(s) are attached to the same C atom.

The common natural amino acids in living organisms occur as the L enantiomorphs. The astrocytes in the brain, however, upon glutamate stimulation enzymatically synthesize D-serine, which facilitates synapsis between neurons by stimulation of the NMDA receptors. The amber suppressor, tRNA, aminoacylated with certain unnatural amino acids (fluoro-tyrosine, branched, and hydrophobic amino acids) can be incorporated into proteins and may be used to study the impact on hydrogen bonding, hydrophobic packing, and protein stability (Mendel D et al 1995 Annu Rev Biophys Biomol Struct 24:435). ▶[amino acid symbols in protein sequences](#), ▶[essential amino acids](#), ▶[nonessential amino acids](#), ▶[aminoacylation](#), ▶[amber suppressor](#), ▶[enantiomorph](#), ▶[unnatural amino acids](#), ▶[NMDA receptor](#), ▶[astrocyte](#), ▶[selenocysteine](#), ▶[pyrrolysine](#), ▶[genetic code](#), ▶[evolutionary clock](#)

Figure A65. Amino acids general formula

Amino Group: The amino group is derived from ammonia (NH_3) by replacing one of the hydrogens by another atom ($\text{H}_2\text{N}-$).

Aminoacidurias: Aminoacidurias are diverse groups of hereditary diseases characterized by the urinal excretion of cystine (in cystinosis), tyrosine (in tyrosinemia), all kinds of amino acids (in fructose intolerance), very large quantities of primarily threonine, tyrosine, and histidine (in Hartnup disease), hypervalinemia. Many diseases of the kidneys show excessive amino acid excretion. Dicarboxylic aminoaciduria is a defect of glutamate/aspartate transport at 9p24. Dibasic aminoaciduria is a defect of cystinuria and the failure of normal transportation of dibasic amino acids at 9q13.1. ▶[homocystinuria](#), ▶[Fanconi renal tubular syndrome](#), ▶[Hartnup disease](#), ▶[neuromuscular diseases](#), ▶[Rowley-Rosenberg syndrome](#), ▶[blue diaper syndrome](#), ▶[iminoglycinuria](#), ▶[tyrosinemia](#)

Aminoacylation: An ATP-dependent enzymatic process attaches an amino acid by its NH_2 end to the acceptor arm (CCA-OH) of tRNA. The rate of mischarging is 3×10^{-3} in prokaryotes and may be higher in yeast or higher eukaryotes. Although this reaction requires a protein enzyme, a ribozyme may also be adapted to carry out aminoacylating function in a manner analogous to the ribozyme, peptidyl transferase. Certain aminoacyl-tRNA synthetases have a particular site where the misactivated amino acid tRNA

complex is destroyed to maintain the correct protein structure. Aminoacylation takes place within the eukaryotic nucleus before the correct tRNA is released to the cytosol. A single defective editing domain generates global errors in translation (Bacher JM et al 2005 Proc Natl Acad Sci USA 102:1697). For the crystal structure of an editing domain see Dock-Bergeon AC et al 2004 Mol Cell 16:375. ▶tRNA, ▶amino acid-tRNA synthetase, ▶ribozyme, ▶aminoacyl-tRNA synthetase, ▶EF-TU·GTP, ▶error in aminoacylation, ▶operational RNA code, ▶suppressor tRNA, ▶unnatural amino acids; Rodnina MV, Wintermeyer W 2001 Annu Rev Biochem 70:415; Hendrickson TL et al 2002 Mol Cell 9:353; Fahlman RP et al 2004 Mol Cell 16:799.

Aminoacyl-tRNA: Aminoacyl-tRNA is an amino acid-charged tRNA at the 3' end. ▶tRNA, ▶protein synthesis, ▶aminoacyl-tRNA synthetase, ▶amino acylation

Aminoacyl-tRNA Synthetases: These enzymes carry out the aminoacylation of tRNA (see Fig. A66). First, the amino acid is attached to the α -phosphate group of an ATP molecule. This step is accompanied by the removal of an inorganic pyrophosphate group. The aminoacyl adenylate is then bound to the active site of one of the two types of aminoacyl-tRNA synthetase enzymes. Class I, mainly monomeric (except*), enzymes handle Arg, Cys, Gln, Glu, Ile, Leu, Met, Trp*, Tyr*, and Val. Class II dimeric enzymes are involved with Ala, Asn, Asp, Gly, His, Lys, Phe, Pro, Ser, and Thr (for these abbreviations see amino acids). Class I synthetase first attaches the aminoacyl-A to the 2'-OH of the terminal A of the amino arm of tRNA. Subsequently this is shifted to the 3'-OH by transesterification. The class II enzymes bypass the 2'-OH transfer step. Enzymes recognize, among the 40–80 or more tRNAs, the appropriate acid; and this rather complex recognition process is directed by the so-called *second genetic code*. Several sites on the tRNA determine the recognition of the appropriate tRNAs, most importantly by the anticodon. In *Drosophila*, there is a Glutamic acid-Proline tRNA synthetase (GluProRS). The amino-terminal domain is active for Glu, while the C-terminal fragment is functional for Pro. In some bacteria there are three types of glutamyl-tRNA synthetases. Their substrate could be either tRNA^{Glu} and tRNA^{Gln} singly, or both. The three tRNA species have two common elements, the augmented D-helix and the deletion of nucleotide 47 (Salazar JC et al 2003 Proc Natl Acad Sci USA 100:13863).

In some Archaea, e.g., *Methanococcus janaschii*, a single aminoacyl tRNA synthetase, ProCysRS, exists for both proline and cysteine. However, this synthetase never makes ProtRNA^{Cys} or CystRNA^{Pro}

(Stathopolous C et al 2000 Science 287:479). In *E. coli* the anticodon is crucial for the recognition of 17 of the 20 amino acids. For many of the isoaccepting tRNAs, the 73 position of the amino acid-accepting arm is very important along with the anticodon. The enzyme also capable of correcting errors in recognition, e.g., isoleucyl-tRNA, cannot entirely prevent valine from attaching to its binding site and may form a valyl-adenylate. This activated valine cannot, however, attach to either tRNA^{Val} or tRNA^{Ile}; rather it is hydrolyzed by tRNA^{Ile}, so no erroneous valyl-tRNA^{Ile} is formed. Another way to eliminate translational errors is to modify the amino acids attached to the wrong tRNA; thus, rarely can these misacylated tRNA be used for peptide elongation. Actually, misacylation may occur as an intermediate step but the mentioned quality control prevents most of the stated ambiguities and errors. Misacylation of amino acids is subjected to correction by an editing complex of the tRNA (Bishop AC et al 2002 Proc Natl Acad Sci USA 99:585). tRNA-dependent amino acid modifications are the only means for the formation of formylmethionyl-tRNA and others (Asp-tRNA^{Asn}, Glu-tRNA^{Gln}) in some bacteria, archaea, and organelles. The majority of the aminoacyl-tRNA synthetases either discriminate against the D-enantiomers at activation, or use, e.g., D-Tyr-tRNA^{Tyr} deacylase, to prevent the D form from being incorporated into protein. The elongation factors (EF-Tu, EF-1 α) also prefer the L enantiomorphs. The C-terminal domain of the tyrosyl-tRNA synthetase has ~49% homology with a cytokine (endothelial monocyte-activating polypeptide II [EMAPII]). This cytokine causes phagocytotic cells to express *tissue factor* and TNF α , and migrates to the sites of inflammations. The average error in amino acid incorporation is about 1/3,000 to 1/10,000. Nuclear genes encode the aminoacyl-tRNA synthetases of organelles; however, the enzymes are organelle-specific. Some nuclear genes may encode both types of enzymes by differential transcription and processing. A reactive RNA can also catalyze this reaction, normally catalyzed by aminoacyl-tRNA synthetase. The aminoacyl-tRNA synthetases of higher eukaryotes form multiprotein complexes. Incorporation of unnatural amino acids into protein can be achieved by screening for mutant aminoacyl-tRNA synthetase genes (Link AJ et al 2006 Proc Natl Acad Sci USA 103:10180). arginyl t-RNA synthetase, ▶glutamyl-tRNA synthetase, ▶histidyl tRNA synthetase, ▶leucine t-RNA synthetase, ▶threonyl tRNA synthetase, ▶methionyl tRNA synthetase, ▶tryptophanyl tRNA synthetase, ▶valyl tRNA synthetase, ▶ribozyme, ▶EF-TU·GTP, ▶ribosomes, ▶protein synthesis, ▶tRNA, ▶missing genes, ▶cytokines, ▶EMAPII, ▶wobble, ▶tmRNA,

Aminobenzyloxymethyl Paper: This is a diazotized (using 1-[(m-nitrobenzyloxy)-methyl] pyridinium chloride [NBPC]) Whatman 540 or other comparable paper, used for Northern blotting. ►Northern blotting

Amino-End: The amino end of a protein marks where the synthesis began on the ribosome. It is commonly a methionine residue, although during processing of the protein the first amino acid(s) may be removed. The amino end of the polypeptide corresponds to the 5' end of the mRNA. ►amino terminus, ►protein synthesis

Aminoglycoside Phosphotransferases (NPTII, aph(3')II): NPT II phosphorylates aminoglycoside antibiotics and causes resistance against these antibiotics. The

genes for the two related enzymes were isolated from Tn5 and Tn60 bacterial transposons, respectively, and are used as dominant selectable markers (with appropriate promoters) in transformation of animal and plant cells. ▶kanamycine resistance, ▶geneticin resistance, ▶neo^R, ▶neomycin phosphotransferase; Wright GD et al 1998 Adv Exp Med Biol 456:27; Boehr DD et al 2001 J Biol Chem 276:23929.

Aminoglycosides: Aminoglycosides form a group of antibiotics in which, a cyclic alcohol occurs in a glycosidic linkage with amino-substituted sugars. They (streptomycin, kanamycin, neomycin, gentamycin, paromomycin, etc.) affect the A site (16S rRNA in the 30S ribosomal subunit) of the prokaryotic/organelle ribosomes, where the codon-anticodon interact, and thus interfere with initiation of translation, fidelity of decoding of the codon, peptidyl transfer, and peptide translocation. Inhibition of eukaryotic ribosome function requires a higher-than-approximately-20-fold concentration of the antibiotic. Resistance,—which is widespread, may be accounted for by the ability of the cells to expel antibiotics, or by enzymatic modification either of the antibiotic or the cellular target. ▶ribosome, ▶kanamycin, ▶neomycin, ▶gentamycin, ▶A site, ▶protein synthesis, ▶phenotypic reversion; Ryu H, Rando RR 2001 Bioorg Med Chem 9:2601.

Aminolevulinic Acid: (ALA): ALA is a precursor of porphyrin, required for the production of hemoglobin and chlorophylls (see Fig. A67). The ALA dehydratase (ALAD) is coded in human chromosome 9q34. ▶chlorophyll, ▶hemoglobin, ▶porphyrin

Figure A67. Aminolevulinic acid

Aminopeptidases: Aminopeptidases are generally membrane ectoenzymes involved in the processing of proteins and hormones, in controlling cell adhesion, and in signal transduction.

Aminopterin: Aminopterin inhibits the activity of dihydrofolate reductase at concentrations of 10^{-8} to 10^{-9} . This enzyme is required for the biosynthetic pathway of both pyrimidines and purines, and is also used as a drug in the HAT medium to shut down the de novo synthetic pathway of nucleotides, when thymine-, kinase-, and hypoxanthine-guanine phosphoribosyl transferase mutations are screened for in mammalian cell cultures. ▶amethopterin, ▶HAT medium, ▶DHFR

2-Aminopurine (AP): AP is an adenine analog that may incorporate into DNA in place of adenine, and can form normal hydrogen bonds with thymine. It is prone to mispairing with cytosine, either with a single hydrogen bond in its normal state, or after tautomeric shift with two hydrogen bonds (see Fig. A68). The mispairing may result in a replacement of an AT pair by a GC pair and thus, in mutation. AP may be highly mutagenic in some prokaryotes but not in eukaryotes. base analogs, ▶base substitution, ▶hydrogen pairing

Figure A68. 2-Aminopurine

Aminoterminal: An aminoterminal is the only amino acid in a polypeptide chain with a free α -amino group; it occurs at the end of the chain. ▶amino end

Aminotransferase: Aminotransferases are transaminase enzymes that transfer α -amino groups from amino acids to α -keto acids.

3-Amino-1,2,4-Triazole: is a carcinogenic standard (non-mutagenic in the Ames test); it is now a banned herbicide. ▶Ames test

Amish: Amish refers to a Mennonite religious group that follow strict and conservative principles and lifestyle. Their communities are relatively isolated from surrounding populations. Actually, the Amish population in the USA in the 1960s, was organized in three approximately equal groups of ~14,000 people. Gene frequencies distinguish the three related groups. Incidence of endogamy and consanguineous marriage is higher, and certain genetically determined conditions more frequent, in these populations. The recessive Ellis-Van Creveld syndrome, pyruvate kinase deficiency, cartilage-hair hypoplasia, limb-girdle muscular dystrophy, and Christmas disease, are relatively common. The Amish brittle hair syndrome (also recessive) involving short stature, somewhat lower intelligence, brittle hair and reduced fertility, and low sulfur content of the nails was first recognized in such a population. ▶Ellis-Van Creveld syndrome, ▶Christmas disease, ▶cartilage-hair hypoplasia, ▶endogamy, ▶consanguinity, ▶ethnicity; McKusick VA 1980 Endeavour 42–52.

Amitochondriate: Amitochondriate organisms lack mitochondria, e.g., some microsporidian eukaryotic parasites of mammals with genomes of less than 3 Mb. More current evidence, however, indicates that these organisms may not be amitochondriate, but merely

A

containing mitochondria. ▶mitosome, ▶hydrogenosome, ▶mitochondria

Amitosis: Amitosis refers to nuclear division without the characteristic features of the mitotic apparatus, and involving the small (21 to 1,500 kb) and acentric chromosomes, in the macronucleus of some *Protists*. No mitotic spindle is evident and the nuclear membrane seems intact during the entire division. The distribution of the chromatin is nevertheless, not entirely random. ▶mitosis, ▶*Paramecia*, ▶fission, ▶acentric, ▶chromatin; Prescott DM 1994 Microbiol Rev 58:233.

Amixis: Amixis is the term fungal genetics uses for apomixis. ▶apomixis

Aml1: AML1 is an acute myeloid leukemia oncogene, a DNA-binding protein, encoded in human chromosome 21q22. ▶leukemias

Ammonification: Ammonification refers to the release of ammonia upon decomposition of compounds such as amino acids.

Ammunition: Ammunition refers to gene tagging with non-autonomous P elements of *Drosophila*, which remains in place even after the removal of the helper (complete) element. ▶hybrid dysgenesis, ▶smart ammunition

Amniocentesis: Amniocentesis is a prenatal diagnosis of the genetic constitution of a fetus by withdrawing fluid or cells from the abdomen (amniotic sac) of a pregnant woman. This procedure is applicable after about 16 weeks of the pregnancy by which time the amount of the amniotic fluid is sufficient. The tests can be cytological, enzymological, immunological, or molecular, and may involve cell cultures to amplify the material. Amniocentesis can also be used for genetic counseling. Normally it entails minimal risk to either the fetus or the mother, yet should be used only in cases when it is warranted by other parts of the diagnoses. Newer procedures are aimed at the very frequency ($\sim 10^{-6}$) of fetal cells, or at fetal DNA in maternal blood. ▶risk, ▶counseling genetic, ▶prenatal diagnosis, ▶PCR, ▶polymerase chain reaction, ▶maternal contamination; Trent RJ (ed) 1995 Handbook of prenatal diagnosis, Cambridge University Press, New York; Special Advances in Fetal Evaluation; <http://www.healthscout.com/ency/1/541/main.html>.

Amnion: Amnion is the strong membrane enveloping the mammalian fetus. It contains the amniotic fluid that protects the fetus during the entire pregnancy. A similar membrane is found in other animals too. The amnion is the layer closest to the embryo, followed by the allantoic mesoderm, while the chorion is the outer layer. ▶chorion, ▶allantois

Amoeba: Amoebas are free-living or parasitic single-cell eukaryotes (see Fig. A69). Some amoebas crawl by forming pseudopodia (leg-like extensions of the single). *Amoeba dubia* has a genome size (bp) of 6.7×10^{11} in n = several hundred chromosomes. ▶nuclear transplantation

Figure A69. Ameoba

Amorph Allele: Amorph alleles are inactive; they may also be deletions. ▶allele

Amova: AMOVA refers to the analysis of molecular variance. ▶ANOVA; Excoffier L et al 1992 Genetics 131:479.

Amoxicillin: Amoxicillin is an inhibitor of cell wall-crosslinking transpeptidase; thus it enhances the effect of β -lactam antibiotics (see Fig. A70). ▶clavulanate

Figure A70. Amoxicillin

Amp (ampicillin, 6-[D(-)a aminophenylacetamid]-penicillanic acid): AMP is a member of the penicillin family antibiotics. The *Amp^R* genes are common in genetic vectors (see Fig. A71). ▶antibiotics, ▶vectors genetic

Figure A71. Ampicillin

AMP: AMP refers to adenosine 5'-monophosphate (adenylic acid); when additional 2 phosphates are added to AMP, ATP is formed. ▶cAMP

AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolpropionate): AMPA is a member of the glutamate receptor family of proteins and it mediates the excitatory synaptic transmissions in the brain and the spinal cord. It also controls post-synaptic influx of Ca^{2+} , further

regulating synapse. The AMPA receptors are built from four variable subunits having large extracellular amino ends, three transmembrane domains, and an intracellular COOH end. PDZ domains mediate the cell targeting. AMPA channels are linked to elevated Ca^{2+} influx and to progressive decline and degeneration of spinal motor neurons. The channels may also be involved in the sporadic development of amyotrophic lateral sclerosis, when aided by $\text{Cu}^{2+}/\text{Zn}^{2+}$ superoxide dismutase (Kuner R et al 2005 Proc Natl Acad Sci USA 102:5826). The GRIP (glutamate receptor interacting protein) contains seven PDZ domains, interacts with C end, and links AMPA to other proteins. ▶[synaps](#), ▶[excitatory neurotransmitters](#), ▶[PDZ domains](#), ▶[NMDA](#), ▶[MAGUK](#), ▶[kainate](#), ▶[superoxide dismutase](#), ▶[amyotrophic lateral sclerosis](#), ▶[fragile X](#); Posser RA 2001 J Neurosci 21:7815; structure, conformation of AMPA receptors: Nakagawa T et al 2005 Nature [Lond] 433:545; Tomita S et al 2005 Nature [Lond] 435:1052; Nicoll RA et al 2006 Science 311:1253.

5'-AMP-Activated Protein Kinase: This kinase regulates energy balance (Kahn BB et al 2005 Cell Metabolism 1:15).

Ampere (A): Ampere is a electric unit. 1 A = 1 C/sec. 1C (Coulomb) = 1 As (Amperesecond). ▶[Volt](#), ▶[Watt](#)

Amphibolic Path: The amphibolic path of metabolism involves both anabolic and catabolic reactions.

Amphid: Amphid is a chemoreceptor in nematodes, e.g., in *Caenorhabditis*. ▶[Caenorhabditis](#)

Amphidiploid: A cell that contains 2 genomes from at least two different species; it is obtained by doubling the number of chromosomes of amphiploids. ▶[amphiploid](#), ▶[chromosome doubling](#); Kashkush K et al 2002 Genetics 160:1651.

Amphigamy: In the usual type of fertilization the gametic nuclei fuse. ▶[dikaryon](#)

Amphihaploid: Amphihaploid refers to the haploid cell of an amphidiploid, an allohaploid. ▶[haploid](#), ▶[amphidiploid](#), ▶[allohaploid](#)

Amphimeric Genomes: In amphimeric genomes, the inverted repeats are separated by wide sequences. They may be generated in the mitochondrial DNA of yeast. Their origin appears to be due to illegitimate recombination between a pair of short inverted repeats. In amplified genomes they are relatively common, and are presumably advantageous for DNA replication. (See Royko E, Goursot R 1999 Curr Genet 35:14)

Amphimixis: Amphimixis is another term for sexual reproduction. ▶[apomixis](#)

Amphipathic: An amphipathic compound has both a charged and neutral face (e.g., some proteins forming amphipathic helix), structures that have hydrophilic (polar) and hydrophobic (non-polar) surfaces, e.g., lipids. Generally, molecular surfaces tend to be hydrophilic whereas the inner residues are hydrophobic.

Amphiphile: Amphiphile refers to a nanomolecule with a peptide and a hydrocarbon tail. Amino acid sequences inserted into the peptide, may stimulate neural growth, tend to form connections with neighboring neurons, and can possibly repair neural cord injury when inserted into a defective spinal cord. ▶[nanotechnology](#), amphiphile for bone regeneration: Hosseinkhani H et al 2007 Tissue Eng 13:11.

Amphiphysin: Amphiphysin is a nerve protein of the synaptic vesicle bound to synaptotagmin, clathrin, and dynamin. It also participates in general endocytosis and in membrane remodeling. ▶[synaptotagmin](#), ▶[BIN1](#), ▶[endocytosis](#); Peter BJ et al 2004 Science 303:495.

Amphiploid: An amphiploid cell contains at least two genomes from more than one species. ▶[amphidiploid](#), ▶[allopolyploid](#)

Amphiprotic: An amphiprotic compound can donate or accept protons and thus can behave as a weak acid or alkali, e.g., water or amino acids. ▶[proton](#), ▶[amino acids](#)

Amphiregulin: Amphiregulin is a regulator with both positive and negative effects. It regulates the proliferation of keratocytes and some fibroblasts, and inhibits the proliferation of various tumor cells. It competes for the epidermal growth factor (EGF) receptor, is required for normal implantation of blastocytes and is regulated by progesterone. Amphiregulin is the unique EGF family member, which is transcriptionally induced by estrogen in the mammary glands of sexually maturing (pubertal) mice at the time of exponential expansion of the ductal system (Ciarloni L et al 2007 Proc Natl Acad Sci USA 104:5455). ▶[EGFR](#), ▶[keratosis](#), ▶[progesterone](#), ▶[embryogenesis](#); Akatsu N et al 2001 Biochem Biophys Res Commun 281:1051.

Amphistomatous: Amphistomatous leaves bear stomata on both surfaces. ▶[stoma](#)

Amphithallism: Amphithallism refers to homoheteromixis, i.e., both self-fertilization and outcrossing; it occurs in fungi.

Amphitropic Molecule: An amphitropic molecule carries out different functions at different sites.

A

Ampholine: Ampholine is an ampholyte used in polyacrylamide, agarose, and dextran gels, for density gradient stabilization in analytical and preparative electrofocusing. ► [isoelectric focusing](#)

Ampholyte: Ampholyte is an amphoteric electrolyte. ► [amphoteric](#), ► [electrolyte](#)

Amphoteric: An amphoteric substance has dual, opposing characteristics, such as behaving both as an acid and a base.

AMPHOTERINE: ► [Alzheimer's Disease](#)

Amphotropic Retrovirus (polytropic retrovirus) The polytropic retrovirus replicates both in the cells from where it was isolated, as well as in other types of cells. ► [ecotropic and xenotropic retroviruses](#)

Ampicillin: Ampicillin is an antibiotic that binds to the bacterial cell membranes and inhibits the synthesis of the cell wall. The ampicillin resistance gene (*amp^r*) codes for a β -lactamase enzyme that detoxifies this antibiotic; the *Amp^r* gene is used also as marker for insertional inactivation and concomitant ampicillin susceptibility. ► [antibiotics](#), ► [insertional mutation](#), ► [pBR322](#), ► [amp](#), ► [\$\beta\$ -lactamase](#), ► [see formula at AMP](#)

AMPK: AMPK refers to 5'-AMP-activated protein kinase.

Amplicon: Amplicon is a DNA fragment produced by polymerase chain reaction (PCR) amplification. It also refers to the amount of DNA present in an amplified gene, a chromosomal segment, or a reduced size viral construct used for genetic transformation. ► [PCR](#)

Ampliconic Region: The ampliconic region covers about half the extent of the euchromatin region of the Y chromosome and includes large palindromes. Gene conversion is frequent in these tracts. (See Rozen S et al 2003 Nature [Lond] 423:873; ► [euchromatin](#), ► [palindrome](#), ► [gene conversion](#), ► [Y chromosome](#))

Amplification: Amplification is the temporary synthesis of extra, functional copies of some genes, in vivo or in vitro, by some forms of the polymerase chain reaction. Bacteriophage λ can be amplified by a series of nitrocellulose filter transfers after in situ hybridization. The addition of chloramphenicol (10–20 $\mu\text{g/mL}$) to pBR322 and pBR327 may amplify plasmid yield, if the synthesis of protein is not completely prevented. Cosmid libraries may be amplified by starting on solid plates followed by liquid cultures. Replica-plating can amplify animal cell cultures. Approximately 5×10^4 colonies can be accommodated on a 138-mm filter, and this way about 30 filters are required to obtain a representative

library of overlapping fragments. DNA amplification can occur in a *genetically programmed and pre-determined* manner in eukaryotes. For example, in the ovarian follicle of *Drosophila*, large quantities of an egg-shell protein is needed during oogenesis. The need is met by a disproportionately favorable replication of the chorion gene clusters in the X-chromosome and chromosome 3. DNA replication is initiated bidirectionally at a replicational origin, and generates multiple copies of the genes needed. The replication tapers off after a distance and the flanking regions are amplified less and less in proportion to the distance from the origin. Similar programmed amplification takes place in the ribosomal genes of amphibia during intense periods of protein synthesis in embryogenesis. The approximately 500–600 genomic copies of rRNA genes may thus be increased by a factor of 1000. The replication of detached DNA sequences follows a rolling circle type process, and the new DNAs (in about 100 rDNA repeats) are separately localized in micronuclei. The replicates of these nuclei are structurally similar, indicating that they are the clonal products of a single replicating unit; but the new micronuclei generated in different cells may not be the same as judged by the differences in length in the intergenic spacers. Ribosomal DNA amplification takes place during the amitotic divisions of the protozoon, *Tetrahymena*. Here again, the macronuclear rDNA copies may be selectively amplified in the 10^4 range, whereas the micronuclear DNA contains only a single rDNA gene. A *genetically non-programmed amplification* takes place in several mutant cell lines to correct mutational defects. Producing multiple copies of gene-controlling low-efficiency enzymes may compensate for enzyme deficiencies. Transfection of ADA genes to mammalian cells may be amplified in the presence of dCF (see adenosine deaminase). Mammalian cells can be amplified if they are co-transfected with the *dhfr* (conveying methotrexate resistance) gene and other desired sequences. In the presence of methotrexate, the *dhfr* genes, as well as the flanking DNA, may be amplified (1000) fold. The amplified DNA, in stable lines, is integrated into the chromosome in *homogeneously stained regions* (HSRs). In unstable cell lines, *dhfr* occurs in autonomously replicating elements, called double-minute chromosomes (DMs), which have no centromeres and can be maintained only in cultures that contain methotrexate. Amplification may generate fragile sites in the chromosomes by integration of DMs sequences. Hypoxia may be a factor inducing such integration. Some general features of amplification are: (i) expansion of a particular locus and flanking regions, or the generation of small supernumerary chromosomes called double minutes that

contain the critical gene, (ii) possible rearrangements of the amplified unit (iii) the amplified sequences are not all identical and may change, but these changes are somewhat unusual because a larger number of copies may be altered simultaneously in an identical manner. In vivo amplification of genes during evolution may account for the presence of gene families. Some amplified genes, in which production of a larger number of copies was no longer advantageous, may have acquired new functions without entirely losing their structural similarity to the ancestral sequences. Other members of the amplified group lost their function(s) through deletions and mutations and became pseudogenes. Carcinogenesis commonly involves amplification of some oncogenes and genes involved with the cell cycle (cyclins). Fragile sites in some chromosomes aid amplification. ►PCR, ►MDA, ►nitrocellulose filter, ►in situ hybridization, ►chloramphenicol, ►pBR322, ►cosmid library, ►oogenesis, ►chorion, ►bidirectional replication, ►rolling circle, ►micro-nucleus, ►ADA, ►HSR, ►methotrexate, ►fragile sites, ►pseudogene, ►unequal crossing over, ►DM chromosome, ►adaptive amplification, ►breakage-bridge-fusion cycles, ►translocation heterozygote; Romero D, Palacios R 1997 Annu Rev Genet 31:91; Monni O et al 2001 Proc Natl Acad Sci USA 98:5711; Dean FB et al 2002 Proc Natl Acad Sci USA 99:5261; Tower J 2004 Annu Rev Genet 38:273.

Amplification Control Elements: Amplification of genes in chromosome 3 and the X-chromosome of *Drosophila*, are determined by DNA sequences measuring less than 5 kbp, which normally occur in the vicinity of the genes that are amplified under natural conditions of the genome (e.g., the chorion protein gene). If these control elements are isolated, inserted into genetic vectors (P-elements), and reintroduced at random sites into the *Drosophila* genome, they may amplify other sequences in their new neighborhood. ►amplification, ►hybrid dysgenesis

Amplified Fragment Length Polymorphism: ►AFLP

Amplitaq: Amplitaq is a taq DNA polymerase, a single polypeptide chain enzyme with minimal secondary structure. It is isolated from the bacterium *Thermus aquaticus*. Its temperature optimum is about 75 °C but it can withstand ≤95 °C without great loss of activity. It lacks intrinsic nuclease function but has a polymerization-dependent 5' → 3' exonuclease activity. It is a preferred enzyme for PCR. ►PCR, ►DNA polymerase, ►exonuclease, ►Taq DNA polymerase

Amplitype: ►DNA fingerprinting

Amputations: ►ADAM complex, ►limb defects

Amsterdam Criteria: Amsterdam criteria were established in (1990) at a meeting in Amsterdam for ascertaining the hereditary nature of non-polyposis colorectal cancer. The criteria are: 1. at least three family members, of which two are first degree relatives, are affected, 2. at least two generations are represented, and 3. at least one family member is below age 50 at the time of onset. ►hereditary non-polyposis colorectal cancer, relatedness, degree of, http://www.medscape.com/viewarticle/468147_4.

Amusia: Amusia is a deficit of music perception caused by a genetic or acquired brain anomaly. It may not affect any other brain function or intelligence. In some case it is associated with limitation of prosody, rhythm and pitch of speech. ►musical talent

AMV Oncogen (*v-amv*): ►MYB

α-Amylase: α-amylase hydrolyzes α-1-4 glucosidic linkages of amylose, amylopectin, and other carbohydrates and yields maltose, α-dextrin, and maltotriose. β-Amylase hydrolyzes starch into maltose. The human AMY genes are located in chromosome 1p21.

Amyloid Angiopathy: ►amyloidosis type VI

Amyloidosis: Amyloidosis involves extracellular deposition of variable amounts of amyloids. Amyloids are special fibrous glycoproteins of connective tissues, and are caused by protein misfolding. Some of the familial nephropathies (kidney diseases), heart diseases, and neoplasias involve amyloidosis. Heparanase overproduction digests heparans that are also essential for amyloid deposition (Li JP et al 2005 Proc Natl Acad Sci USA 102:6473). Genetically these are inhomogeneous groups of diseases mainly with dominant, but some with recessive, patterns of inheritance. Amyloidosis in some aging individuals manifests symptoms similar to the symptoms of Alzheimer's disease. The dominant genes were mapped to the same region of chromosome 21 as the genes behind AD, and also to 20p12, the site of the prion gene. The Swedish and Portuguese Amyloidosis I is a dominant polyneuropathy encoded near the centromere in the long arm of human chromosome 18. The Finnish Amyloidosis type V is apparently due to an autosomal dominant defect in gelsolin. The Icelandic Amyloidosis type VI involves high incidence of hemorrhages due to accumulation of amyloids. The afflicted individuals (dominant) are low in cysteine proteinase inhibitor, cystatin C, encoded in the region of human chromosome 20q13. The Ohio type Amyloidosis VII involves ocular and mental affliction. The German Amyloidosis type VIII is a visceral and renal disease. Amyloidosis IX is a skin disorder. The familial British dementia is a dominant, late onset brain degenerative

A

condition caused by the BRI gene in human chromosome 13q14. There are recessive amyloidoses affecting the gingiva (gum), eyelids, cornea (eyeball), and mental health. Amyloid formation may occur in a number of pathogenic conditions, but can also occur as a rather general feature of polypeptide chains. Under some conditions, there may be a cycle of dissociation re-association. (Carulla N et al 2005 Nature [Lond] 436:554) The gelatinous drop-like corneal dystrophy (GDLD, human chromosome 1p) is an amyloidosis caused by mutation in a gastrointestinal tumor-associated antigen. The small molecules of transthyretin (thyroxin-binding prealbumin) interfere with the misfolding of the protein, and may be considered for therapeutic use. Some mutations in the human lysozyme promote fibril and plaque formation, but a heavy chain domain of the camelid antibody raised against the wild type lysozyme may inhibit this deleterious aggregation (Dumoulin M et al 2003 Nature [Lond] 424:783). ▶cold hypersensitivity, ▶Mediterranean fever, ▶ β -amyloid, ▶Alzheimer disease, ▶scrapie, ▶prion, ▶encephalopathies, ▶gel-solin, ▶amyotrophic lateral sclerosis, ▶sterols; Pepys MB et al 2002 Nature [Lond] 417:254; Hammarström P et al 2003 Science 299:713.

Amyloids: Amyloids are fibrillar poorly soluble/insoluble proteins forming β sheets, e.g., apolipoproteins. Positional scanning mutagenesis reveals tolerant and restrictive sites in the peptide for fibril formation. Mutations that accelerate β -sheet polymerization do not necessarily increase amyloid formation. Some abundant mutant fibrils polymerize slowly, and some amino acid combinations disrupt aggregating capabilities (López de la Plaz M, Serrano L 2004 Proc Natl Acad Sci USA 101:87). Potent inhibitors of amyloid aggregation may involve synthetic molecules that can bind to chaperones (of the FK506 family), and can interact with amyloids by their increased size, required for interaction with proteins (Gestwicki JE et al 2004 Science 306:865). Proteoglycan-amyloid complexes are protected from proteolysis. Several neurodegenerative diseases (Alzheimer's disease, Parkinson's disease, prions) are caused by amyloid formation. Recent information indicates that it is not fibrillar amyloids, but rather their globular aggregation, which form ion channel-like structures, that act as the major pathological agents (Quist A 2005 Proc Natl Acad Sci USA 102:10427). According to the *amyloid stretch hypothesis* the tendency to form amyloids is localized in short stretches of the proteins in question (Esstera-Chopo A et al 2005 Proc Natl Acad Sci USA 102:16672). In addition, atomic structures, common to various amyloid proteins, have been determined (Sawaya MR et al 2007 Nature [Lond] 447:453).

Certain starch-like substances are also called amyloids. The amyloid Pml17 of melanosomes, promotes the polymerization of smaller molecules into melanin. Melanins, unlike many amyloid proteins, are beneficial molecules important in protecting against ultraviolet light and other oxidative damage. Pml17 protects cells against adverse effects of excessive melanin (Fowler DM et al 2006 PLoS Biol 4(1):e6). ▶amyloidosis, ▶Alzheimer's disease, ▶proteoglycan, ▶ β sheet, ▶protein structure, ▶FK506, ▶chaperone, ▶homolog-scanning mutagenesis, ▶melanin, ▶glaucoma

Amylopectin: Amylopectin is normally a minor variant of common starch. While starch (amylose) is an unbranched chain of D-glucose units of α 1–4 glycosidic linkages, amylopectin contains, in addition, at every 24 to 30 residues branch points in α 1–6 linkages (see Fig. A72).

Amylose is synthesized by an active granule-bound starch synthase; starch-branching enzymes SBEI and SBEII synthesize amylopectin. In monocots there are two isoforms of SBEII (a and b). In maize, deficiency of SBEIIb is the consequence of the *ae* (amylose extender) gene. Increased amounts of amylose vis-a-vis those of amylopectin lead to dietary and health-related advantages. Transgenic technology (RNAi) Can help reduce SBE enzyme levels, resulting in more than 70% amylose in wheat. (Regina A et al 2006 Proc Natl Acad Sci USA 103:3546). Cereal grains commonly contain amylose as the principal storage polysaccharide, but recessive mutations may cause the predominance of amylopectin (dextrin). Several genes of maize (*ae*, *du*) may substantially increase the amylose content relative to that of amylopectin.

These two types of starches are easily distinguished in situ by a drop of iodine solution (I_2 0.12 g + KI 0.4 g in 100 mL H_2O); amylose stains blue-black, while amylopectin appears red-brown. The amylose content of corn is desirable also to the film and fiber-manufacturing industry.

Figure A72. Stained sorghum pollen displays segregation for starch and amylopectin. (Courtesy of Dr. JR Quinby. See Karper RE (1933) J Hered 24:257)

Amyloplasts: Amyloplasts are plastids whose primary function is starch storage.

Amylose: ► amylopectin

Amyotrophic Lateral Sclerosis (ALS, Lou Gehrig disease): ALS is characterized by the hardening of the lateral columns of the spinal cord with concomitant muscular atrophy. This may spread and may cause death in a few years after onset. According to a mouse model, it is probably caused by a defect in the enzyme Cu/Zinc Superoxide Dismutase (SOD) in about 20% of the familial cases. The expression of mSOD1G93A results in activated and neurotoxic microglia, and suggests that the lack of mSOD1G93A expression in microglia may contribute to motor neuron protection (Beers DR et al 2006 Proc Natl Acad Sci USA 103:16021). SOD breaks down superoxide radicals (highly reactive compounds) to less reactive products; it may also form other types of free radicals. Under normal conditions, SOD exists in a dimerized state. Mutations may either destabilize the precursor monomers, or weaken the dimer interface, or both. In any case, the difference between various abnormal foldings of the protein leads to differing severity of the disease (Lindberg MJ et al 2005 Proc Natl Acad Sci USA 102:9754). In ALS, frontotemporal lobe degeneration occurs in the brain, displaying tau and synuclein inclusions. Ubiquitin is also present and cleaves the C-terminal fragment of the TDP-43/TARDBP protein that is detectable in the hippocampus, neocortex, and the spinal cord (Neumann M et al 2006 Science 314:130).

Not all cases of SOD dismutase apoprotein mutations are involved in reduced stability (Rodriguez JA et al 2005 Proc Natl Acad Sci USA 103:10516). Aggregation of the molecules results in ALS. SOD1 apparently causes neural death by acting on caspases that mediate apoptosis. The *Bcl-1* gene inhibiting apoptosis prolongs the life of mice affected by SOD. A subsequent study found, however, that neither the elimination, nor elevation of SOD activity in mice influenced the expression of ALS. Current research indicates that Zinc-deficient SOD, plays a role in nitric oxide-dependent apoptosis of some motor neurons. The SOD transgene effect can be restrained by N-benzoyloxycarbonyl-Val-Asp-fluoromethyl-ketone (zVAD-fmk), an inhibitor of caspases. This, in turn delays the onset of ALS in mice, and increases life expectancy. Mutations in SOD1 may cause aberrant decrease of *S*-nitrosothiol level and may be remedied by *S*-nitrosocysteine (Schonhoff CM et al 2006 Proc Natl Acad Sci USA 103:2404).

In G37R *SOD1* mice, administration of repeated injections of adjuvant/SOD1 mouse mutant with a final booster injection before symptoms manifested at 6 months of age, were effective in delaying disease

onset and extending the life span by >4 weeks. Western blot analysis with a monoclonal antibody specific to mutant *SOD1* forms provided evidence of clearance of *SOD1* species in the spinal cord of vaccinated animals. This vaccination failed to confer significant protection in G93A *SOD1* mice that showed extreme and excessive expression of mutant *SOD1*. Nonetheless, a passive immunization, in which an intraventricular infusion of purified anti-human *SOD1* antibody was administered through an osmotic minipump, succeeded in alleviating disease symptoms and in prolonging the life span of G93A *SOD1* mice (Urushitani M et al 2007 Proc Natl Acad Sci USA 104:2495). Adult motor neurons collected by laser microdissection from mice expressing dismutase active ALS-linked mutants were found to undergo an age-dependent mRNA change that developed presymptotically. In This change occurs due to the dysregulation of the D/L-serine biosynthetic pathway, previously linked to both excitotoxic and neurotrophic effects. An unexpected dysregulation, common to motor neurons expressing mutants that were either dismutase active, or inactive, comprised of the induction of neuronally derived components of the classic complement system, and the regenerative/injury response (Lobsiger CS et al 2007 Proc Natl Acad Sci USA 104:7319).

The gene leading to ALS symptoms is a dominant “gain-of-function” mutation within the area 21q22.1-q22.2 (*SOD1*, Cu/Zn superoxide dismutase). The syndrome, in different forms, occurs at a frequency of about 1×10^{-5} . About 10% of the cases are hereditary and 90% are sporadic. It is also called LGD after baseball infielder Henry Louis (Lou) Gehrig. Gehrig, who was elected to the US National Hall of Fame in 1939, suffered from this condition. ALS is sometimes associated with phenotypes like those in Parkinson’s disease and Alzheimer’s disease. This form may be caused or aggravated by nutritional factors (neurotoxins in the food, low calcium and magnesium uptake). Other dominant loci were assigned to 18q21 and 16q12.1-q12.2. The dominant juvenile form (ALS4) has been mapped to 9q34; a similar gene is located at 15q15-q22. A recessive autosomal type of ALS, with an early onset between the ages of 3 and 20, is assigned to human chromosome 2q33. The protein encoded, alsin, may directly affect motor neuron degeneration and may signal to GEFs. Copaxone (Cop-1), a synthetic copolymer of tyrosine, glutamate, alanine and lysine, may protect motor neurons against acute and chronic degeneration (Kipnis J, Schwartz M 2002 Trends Mol Med, 8:319). Retrograde transport of insulin growth factor 1 with the aid of adeno-associated vector, from axon terminal receptors to motor neurons of the spinal cord, appears very beneficial in animal models

A

(Kaspar BK et al 2003 Science 3001:839). VEGF mutations may increase the risk of developing ALS; in a mouse model a single injection of VEGF-expressing vector improved the host's condition and prolonged its survival (Azzouz M et al 2004 Nature [Lond] 429:413). It appears that mRNA editing in the GluR2 subunit of the AMPA receptor in the motor neurons may be critical for the disease (Kawahara Y et al 2004 Nature [Lond] 427:801). The pancreatic ribonuclease A family protein ANG (angiogenesis, 124 amino acid residues encoded at 14q11.2) can mutate at several sites. In addition to the catalytic center, it has a site for translocation to the nucleolus. ANG and VEGF variations in hypoxia-inducible genes increase ALS susceptibility, particularly in Irish and Scottish populations (Greenway MJ et al 2006 Nature Genet 38:411). Molecular evidence suggests common pathogenesis for sporadic and familial ALS, but no evidence suggests this commonality between ALS and normal or disease-affected tissues from other neurodegenerative diseases, including Alzheimer's, Parkinson's, and Huntington's diseases, and spinal muscular atrophy, a non-ALS motor neuron disease. This fact permits the use of ALS as a biomarker (Gruzman A et al 2007 Proc Natl Acad Sci USA 104:12524). ▶neuromuscular diseases, ▶Alzheimer disease, ▶Parkinson disease, ▶tau, ▶apoptosis, ▶filament, ▶SOD, ▶gain-of-function, ▶hypoxia, ▶GEF, ▶VEGF, ▶dynein, ▶VEGF, ▶AMPA, ▶TARDP; Julien J-P 2001 Cell 104:581; Yang Y et al 2001 Nature Genet 29:160; Giess R et al 2002 Am J Hum Genet 70:1277; SOD mutations: Selverstone J et al 2005 Annu Rev Biochem 74:563.

Amyotrophy, Hereditary, Neuralgic (HNA, 17q25): Amyotrophy is a recurrent muscle weakness affecting the neck and arms; it occurs due to defects in cervical and thoracic spinal nerves. It is generally triggered by stress, such as infection, immunization, or labor at childbirth. The mutation apparently occurs in the septin gene (SEPT9) involved in the formation of the cytoskeleton, in cell division, and in tumorigenesis. (See Kühlenbäumer G et al 2005 Nature Genet 37:1044; Parsonage-Turner syndrome, Guillain-Barré syndrome)

Anabasine (neonicotine): Anabasine is an alkaloid occurring in chenopods and solanaceous plants; it is highly toxic (LD₅₀ orally 5 mg/kg for humans). ▶LD₅₀

Anabolic Steroids: Anabolic steroids are androgens that promote protein synthesis, general growth, and the development of muscles and bones. Some synthetic forms (methyltestosterone, oxymetholone, norethandrolone) show higher anabolic than testosterone-related activity and are used illegally by athletes to

boost performance; literally, these steroids are “body builders.” Some androgenic and anabolic steroids are used as drugs in the treatment of impotence, anemias, and bone marrow aplasia. These compounds may cause liver adenomas that in rare cases may become cancerous. ▶steroid hormones, ▶adenoma, ▶impotence, ▶anemia, ▶aplasia, ▶steroid doping

Anabolism: Anabolism comprises the energy-requiring synthetic processes of cellular metabolism.

Anaerob: Anaerobs are organisms that live without atmospheric (free) oxygen.

Anaerobic: Anaerobic a processes take place in the absence of (air) oxygen.

Anagenesis: Anagenesis is an evolutionary change within a line of descent. ▶cladogenesis

Analbunimemia: Analbunimemia is a human chromosome 4 recessive absence or reduction of albumin from the blood serum. It does not lead to very serious ailments, although fatigue, mild anemia, and mild diarrhea may be associated with it. ▶albumins

Analgesic: An analgesic is a medication that alleviates pain without inducing loss of consciousness. Endocannabinoids mediate analgesic action; stress can mediate the response (Hohmann AG et al 2005 Nature [Lond] 435:1108). TRPM8 cold receptor and its central downstream mediators are elements of endogenous-cooling-induced analgesia, and they represent a novel analgesic pathway that can be exploited in chronic sensitized pain of nerves in rats (Proudfoot CJ et al 2006 Current Biol 16:1591). ▶nociceptor, ▶cannabinoid

Analogous Genes: Analogous genes have similar function without common evolutionary descent. ▶homologous genes

Analogue (analog): Analogue is a chemical counterpart to a natural compound, but it may or may not function in metabolism. It may even block the function of a normal metabolite or enzyme.

Analogy: Analogy is a similarity not based on common origin. ▶homology, ▶convergent evolution

Analysis of Variance: Analysis of variance is a statistical method that detects the components of variance. It is used for the evaluation of differences between experimental data from different treatments. The square root of the quotient of the sum of squares of the variants and the mean square of the error variance is equal to t , and the corresponding probability, at each degree of freedom, can be read from a t -distribution table. The results are usually presented in a table form such as shown (see Table A4).

Table A4. Analysis of variance

| Variance Source | Degree of Freedom | Sum of Squares (SS) | Mean Square (MS) | Mean Square Ratio (MSR) |
|-----------------|-------------------|---------------------|------------------|-------------------------------|
| Between Groups | k-1 | SSB | SSB/(k-1) | $\frac{SSB/(k-1)}{SSW/(N-k)}$ |
| Within Groups | N-k | SSW | SSW/(N-k) | |
| Total | N-1 | | | |

The MSR (mean square root) permits testing the significance of the data, also with the aid of an F table. Analysis of variance is also used in calculating heritability by intraclass correlation. ▶ [variance intraclass correlation](#), ▶ [F distribution](#), ▶ [t-distribution](#); Sokal RR, Rohlf FJ 1969 Biometry, Freeman, San Francisco, California.

Analyte: An analyte is a substance subjected to analysis. It frequently reveals the basis (by deficiency or overproduction) of a genetically determined disease.

Anandamide (*N*-arachidonylethanolamine): Anandamide is an endocannabinoid and vanilloid receptor that plays different roles in healthy and cancerous cells. It is a ligand for G proteins. It is produced at higher levels in the uterus before implantation of embryo, and is regulated to lower levels afterwards. G protein, ▶ [cannabinoid](#), ▶ [vanillin](#); Wang H et al 2003 Proc Natl Acad Sci USA 100:14914; biosynthetic pathway: Liu J et al 2006 Proc Natl Acad Sci USA 103:13345.

Anaphase: During *mitosis*, the centromere of the chromosomes splits at anaphase; this is what enables spindle fibers to pull the two identical chromatids towards opposite poles. This process ensures the daughter cells are identical. In *meiotic* anaphase I, the centromere does not split and the chromatids are held together as they move toward the poles. Thus, it is the means for the reduction of chromosome number. Anaphase II of meiosis essentially resembles anaphase in mitosis. Microtubules and special motor proteins mediate the movement of chromosomes. The molecular mechanism of the process is only partly known. In yeast, the *MAD* (mitotic arrest deficient) and *BUB* (budding inhibited by benzimidazole) gene products seem to be the sensors of those kinetochores, which have not yet tackled the spindle fibers. Before the sister-chromatids can separate, the anaphase-promoting complex (APC) degrades the inhibitors of the process (Pds1/Cut2). Proteins Cdc20/Slp1 and Hct1/Cdh1 digest other inhibitory proteins (Cib2 and Ase1). ▶ [meiosis](#), ▶ [mitosis](#), ▶ [microtubules](#), ▶ [motor protein](#), ▶ [APC](#), ▶ [cell cycle](#), ▶ [spindle](#), ▶ [sister chromatid cohesion](#), ▶ [cohesin](#), ▶ [separins](#); Nasmyth K 2005 Cell 120:739.

Anaphase-Promoting Complex: ▶ [APC](#)

Anaphora: Originally anaphora is a rhetorical device of repeating a word or phrase in successive clause(s) or sentences. In science writing, the name of a compound, gene, or protein is generally referred to, after first instance, with the word “it” or with a previously given abbreviation.

Anaphylactic Shock: Anaphylactic shock refers to immediate hypersensitivity to specific antigens or haptens, resulting in dangerous loss of respiratory function. ▶ [anaphylatoxins](#), ▶ [anaphylaxis](#)

Anaphylatoxins: Anaphylatoxins are fragments released during activation of the serum complement C proteins of antibodies. C3a, C4a, and C5a (each ~10 kDa) anaphylatoxins are proteolytically cleaved from the corresponding complement components. These activation peptides are called anaphylatoxins because they may elicit reactions similar to anaphylactic shock (violent reaction to antibodies and/or haptens that may be fatal). These fragments enhance vascular permeability, cause contraction of the smooth muscles, and trigger the release of histamine, other vasoactive amines, and lysosomal enzymes. ▶ [antibody](#), ▶ [complement](#), ▶ [histamine](#), ▶ [lysozymes](#); Gerard C, Gerard NP 1994 Annu Rev Immunol 12:775; Sunyer JO et al 2005 Vet Immunol Immunopathol 108:77.

Anaphylaxis: Anaphylaxis is a rapid serological (antigen-antibody) reaction of an organism to a foreign protein. Either the crystalline fragment of the antibody (Fc), or its complement is involved. Prior sensitization may turn the reaction quite violent and even lead to death. Anaphylaxis may be treated with adrenaline. ▶ [immune system](#), ▶ [antibody](#), ▶ [complement](#), ▶ [allergy](#)

Anaplasia: Anaplasia is another term for dedifferentiation.

Anaplasma marginale: *Anaplasma marginale* causes tick-borne rickettsia of livestock. The genome of the sequenced strain has 1,197,687 bp. ▶ [rickettsia](#); Brayton KA et al 2005 Proc Natl Acad Sci USA 102:844.

A

Anaplastic Lymphoma (large-cell non-Hodgkin lymphoma): Anaplastic lymphoma is a lymphoma in children, and is caused by a 2p23:5q35 chromosomal translocation fusing a protein tyrosine kinase gene, ALK, to the nucleolar phosphoprotein genes (NPM, nucleophosmin). The resulting anomaly affects the small intestine, testis, and brain, but not the lymphocytes. ALK is related to the insulin receptor tyrosine kinases and may eventually cause malignancies. Translocations involving 1q21-q23, the site of the IgG Fc receptor (FcγRIIB), are also responsible for this malignant lymphoma. ►leukemias, ►lymphoma, ►Duncan syndrome, ►Hodgkin disease, ►antibody, ►immunoglobulins; Pulford K et al 2001 Curr Opin Hematol 8(4):231.

Anaplerosis: Anaplerosis is biological repair or replacement.

Anastomosis: Anastomosis refers to formation of a reticulate arrangement, fusion between vessels.

Anastral Spindle: Anastral spindle is a mitotic spindle without asters, such as in higher plants. ►aster

Anatomy: Anatomy is the biological discipline dealing with body structure. For functional anatomy see: <http://bodymap.jp/>.

Anautogenous Control: The organism requires an external factor for the completion of a developmental process, e.g., the mosquito *Aedes aegypti* requires a meal of blood to activate its reproductive cycle. ►autogenous, ►mosquito

Ancestral: Ancestral is a trait inherited from a remote forebear or derived from a precursor molecule. Modern ancestry inferences are based on multilocus genotypes and allelic frequencies. Various statistical tools make inferences meaningful (Rosenberg NA et al 2003 Am J Hum Genet 73:1402).

Ancestral inheritance as a theory based on the false assumptions of a non-particulate genetic material, was developed by Francis Galton (1897), but lost meaning after Mendelism.

Ancestral Repeats (AR): The origin of ancestral repeats predates the separation of two species, e.g., mice and humans. ARs can be exploited for the estimation of neutral substitutions in the genomes.

Ancestry Markers: Ancestry markers can provide information on the descent of a population or an individual, because certain alleles occur in characteristic frequencies in some populations.

Anchor Cell: An anchor cell is a gonadal cell of *Caenorhabditis* that in the vulval opening induces the development of its neighboring cell. ►Caenorhabditis, organizer, ►morphogenesis

Anchor Locus: Anchor locus is a gene with well-known map position and can be used as a reference point for mapping new genes. ►anchoring

Anchor Residues: Anchor residues are amino acids of those peptides that attach to MHC molecules. ►MHC

Anchorage Dependence: Normal mammalian cells grow in culture in a monolayer attached to a solid surface; cancer cells are not contact-inhibited and pile upon each other. It appears that the suppression of cyclin E-CDK2 activity is required for cell anchorage. In transformed fibroblasts, the cyclin E-CDK2 complex is active regardless of anchorage. The surface of the cell substrate has an impact on differentiation, development, regeneration, and disease of cells (Discher DE et al 2005 Science 310:1139). ►CATR1, ►AIG, ►cyclins, ►cancer cells, ►anoikis, ►CAM, ►RGD, ►tissue engineering

Anchored Periplasmic Expression (APEX): APEX permits the isolation of ligand-binding proteins from combinatorial libraries anchored to the inner periplasmic face of *E. coli*. The procedure serves the same purpose as phage display, but the larger bacterial (or yeast) cells allow screening by flow cytometry of labeled proteins and antibodies. ►periplasma, ►phage display; Harvey BR et al 2004 Proc Natl Acad Sci USA 101:9193.

Anchoring: DNA fragments obtained during the initial stages of physical mapping must be tied together by contigs. Large capacity YACs are used for the establishment of contigs. These YACs must be correlated with molecular markers (anchors) along the length of the chromosome. RFLPs, RAPDs, STSs, and even the recombination maps obtained by strictly genetic methods may be used as anchors. The relative position of two YACs is revealed when a YAC is found to bridge two anchors to each of which, one of the two YACs each is attached (see Fig. A73).

Anchoring may provide the means for correlating genetic linkage maps with physical maps that are based on nucleotide sequencing. The principle of the procedure is diagrammed. (See also Matallana E et al 1992 In: Koncz C et al (eds) Methods in Arabidopsis Research, World Scientific, Singapore, p. 144)

Ancient DNA: DNA from ancient bones, older than 50,000–100,000 years or even more, may still be analyzed. Clear family lines between parents and children could be ascertained among bone samples collected from cemeteries in Mongolia that are older than (2000) years. This was done on the basis of the autosomal short tandem repeat of mtDNA and Y chromosomal DNA (Keyser-Tracqui C et al 2003 Am J Hum Genet 73:247). Obtained from hair and wool,

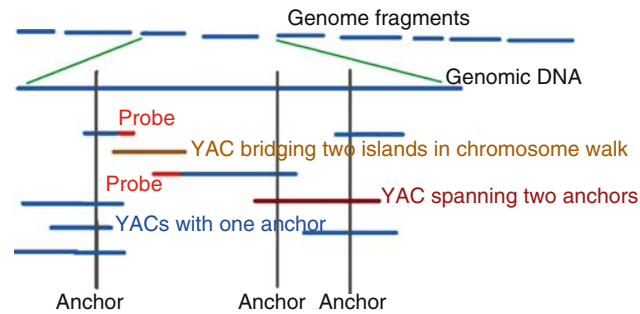

Figure A73. Anchoring

mtDNA has been successfully analyzed in samples ranging from 100– to 9,400 years old (Gilbert MTP et al 2004 *Current Biol* 14:R463). From the more-than-40,000-years-old Australian remains of the now extinct cave bear (*Ursus spelaeus*), 26,861 bp sequences of its genome have been sequenced. This revealed the extinct species' evolutionary relationship to the extant bear species (Noonan JP et al 2005 *Science* 309:597).

Samples preserved in amber may last longer. Mitochondrial DNA extracted 80 million years and amplified by PCR has shown sequences different from all known sequences. The validity of reports on very old DNA samples have thus seriously been questioned and contamination may not be ruled out. The condition of preservation is critical in DNA analysis. Often, the washed fossil bones stored in museums do not permit any DNA amplification; all recently excavated bones, however, are shown to yield authentic aurochs sequences. During the 57 years when the aurochs bones were stored in a collection, at least as much amplifiable DNA was lost as during the previous 3,200 years of burial (Pruvost M et al 2007 *Proc Natl Acad Sci USA* 104:739). It is very important that the greatest caution is exercised to avoid contamination during PCR analysis. It is advisable to test not just the sample but its immediate environment and the reagents themselves, and verify that the sample conforms to that of a species. Fragments that are too long are suspicious. Statistical tests have been developed for compensation for the miscoding (C→U, G→A) changes due to degradation and contamination with DNA of more recent origin (Helgason A et al 2007 *J Mol Evol* 65:92). In case a protein is present, the high ratio between D and L aspartic acid indicates that most likely the DNA has been degraded. The purposes of the analysis of ancient DNA are to obtain information on individuals and groups and to assess evolutionary relations. The mtDNA (~17,000 bp) of two kinds of moa birds extinct for 400 years has been fully recovered. Analysis of ancient DNA has some limitations yet it may be the only means of inquiry

into some problems of speciation, history of pathogens, human evolution, and migration. Some of the problems encountered with degradation of ancient fossil samples (~2,000–10,000 years old) of animal and human bones have been overcome by using crystal aggregates, which preserve DNA much better than they preserve entire bone samples. Sodium hypochlorite washing also removes all contaminations of recent DNA samples. Using these techniques, fossils yielded upon PCR procedures longer sequences of intact DNA (Salamon M et al 2005 *Proc Natl Acad Sci USA* 102:13783). Cross-linking is a more important cause of deterioration of ancient DNA than single- or double-strand breaks (Hansen AJ et al 2006 *Genetics* 173:1175). Ancient DNA can shed some light on the diet of ancient animals and humans, domestication of plants and animals, etc. (Pääbo S et al 2004 *Annu Rev Genet* 38:645). Ancient mitochondrial DNA may show C/G→T/A transitions upon amplification (Stiller M et al 2006 *Proc Natl Acad Sci USA* 103:13578), yet new methods facilitate to some extent, the reconstruction of at least the mtDNA. ▶ancient organisms, ▶Neanderthal people, ▶mammoth, ▶PCR, ▶ice man, ▶mummies, ▶coproscopy, ▶Romanovs, ▶hominidae, ▶out of Africa; Hofreiter M et al 2001 *Nature Rev Genet* 2:353; Lambert DM et al 2002 *Science* 295:2270; Gilbert MTP et al 2003 *Am J Hum Genet* 72:32; Jones M 2002 *The Molecule Hunt*. Arcade Publishing, New York)

Ancient Organisms: Extinct species recognized as paleontological relics are difficult to study even by the most modern research techniques because the organic material has decayed. A 25–40 million-years-old bacterial spore, discovered in the digestive tract of an extinct bee species, preserved in amber, was reported to be revived. It was found that its 16S ribosomal RNA was quite similar to that of the living *Bacillus sphericus*. Actually, the calculated rate of nucleotide substitution in the 16S RNA encoding DNA segment appeared to be 1.8 to 2.4×10^{-9} per site per year. Although the isolation of the spore from

A

the amber was carried out with extreme caution, some questions regarding possible contamination may be raised and newer studies failed to confirm DNA in amber. More recently (in 2000), 250 million-years-old spore-forming bacilli have been revived, and the authenticity of their age confirmed (Science 308:603). ▶[ancient DNA](#), ▶[mummies](#), ▶[ice man](#), ▶[amber](#), ▶[mammoth](#); Hofreiter M et al 2001 Nature Rev Genet, 2:353.

Ancient RNA: Ancient RNA is retrieved from extinct or very old specimens. ▶[ancient organisms](#)

ANCOVA: ANCOVA is the abbreviation for analysis of covariance. ▶[correlation](#)

Ancylostoma: ▶[AcAP](#), ▶[hookworm](#)

Andalusian Fowl: The Andalusian fowl is frequently used as an example for co-dominant segregation. When a black fowl is crossed with a white fowl, in the F₂ 1 black: 2 blue: 1 white individuals are found; the “blue” has black and white (white-splashed) feathers (see Fig. A74). ▶[codominance](#)

Figure A74. Andalusian fowl

Andersen's Disease 3p12: Andersen's disease is an autosomal recessive deficiency of amylotrans glucosidase(s) that causes liver, heart, and muscular disease because of the defect in glycogen storage. ▶[glycogen storage disease](#) [▶[Type IV](#)].

Andersen's Syndrome (KCJN2, 17q23): Andersen's syndrome is a periodic paralysis accompanied by heart arrhythmia and deformations. The basic defect is in an inwardly rectifying potassium channel (KCJN2). ▶[ion channels](#); Plaster NM et al 2001 Cell 105:511.

Anderson's Disease: Anderson's disease involves lipid transport defects of the intestines and the retention of chylomicrons. ▶[lipids](#), ▶[chylomicron](#)

Anderson-Fabry Disease: Anderson-Fabry disease is a human X-chromosome linked deficiency of α -galactosidase resulting in angiokeratoma (red or pink skin or mucous membrane lesions caused by dilation of veins). The relevant gene is 12 kb with 7

exons encoding a 427 amino acid protein. ▶[galactosidase- \$\beta\$](#) , ▶[angiokeratoma](#).

ANDi (inserted DNA [in reverse]): ANDi was the name given to the first transgenic (rhesus) monkey.

Androdioecy: Androdioecy is the phenomenon in which male and hermaphrodite flowers are found in separate plants like in some maples, ash trees, and others. This breeding system also occurs in *Caenorhabditis elegans*, fresh water shrimps (*Eulimnada texana*), and other invertebrates. The only vertebrate capable of self-fertilization (see Fig. A75), killifish (*Kryptolebias marmoratus*), can display androdioecy and extensive outcrossing (Mackiewicz M et al 2006 Proc Natl Acad Sci USA 103:9924). ▶[hermaphrodite](#), ▶[dioecy](#); Wolf DE et al 2001 Genetics 159:1243.

Figure A75. Killifish

Androecium: Androecium is the male part of a flower (the stamens). ▶[stamen](#)

Androgen: Androgen refers to a hormone that promotes virility, but is also present in lower concentrations in females. Androgens are formed by hydroxylation of progesterone. The most important androsterone is testosterone. Androgen has important roles in the development of the male and in prostate cancer. ▶[animal hormones](#), ▶[testosterone](#), ▶[estrogen](#), ▶[FGF](#), ▶[aromatase](#), ▶[steroid hormones](#), ▶[probasin](#), ▶[sex differences](#), ▶[prostate cancer](#); Cifuentes E et al 2004 Proc Natl Acad Sci USA 101:464.

Androgen Receptor: Androgen receptors in muscle cells are activated by a 205-kDa actin-binding protein, supervillin. ▶[hormone response elements \(HRE\)](#), ▶[Kennedy disease](#), ▶[gynecomastia](#), ▶[testicular feminization](#), ▶[histone demethylation](#); Reid KJ et al 2001 J Biol Chem 276:2943; Ting H-J et al 2002 Proc Natl Acad Sci USA 99:661.

Androgen-Insensitivity (Xq11-q12): Androgen insensitivity is caused by a defect in the dihydrotestosterone receptor. ▶[testicular feminization](#), ▶[Kennedy disease](#), ▶[Reifenstein syndrome](#)

Androgenesis: Androgenesis is the development of the male gamete into a paternal haploid or diploid embryo under natural conditions; it can be obtained by in vitro culturing and regeneration of plants from microspores. In vitro androgenesis can be *direct* when the microspores develop directly into plantlets, or *indirect* when the microspores form first a callus,

which then regenerate plantlets. Androgenesis may also arise when all the chromosomes of the female are lost in a fertilized egg, and only male chromosomes remain. Androgenesis occurs in both plants and animals. ▶apomixis, ▶embryo culture, ▶anther culture, ▶microspore culture, ▶hydatidiform mole, ▶gynogenesis, ▶hemiclinal, ▶hybridogenetic; Kermicle JL 1969 Science 166:1422; Corley-Smith GE et al 1996 Genetics 142:1265.

Androgenital Syndrome: ▶pseudohermaphroditism

Androgenote: An androgenote is a diploid embryo with only the paternal sets of chromosomes. ▶androgenesis

Androgenous: Androgenous describes a pseudo- or true hermaphroditic stage in mammals or plants. ▶hermaphrodite

Andromerogony: Andromerogony is the development of an egg (or its part) containing only the male pronucleus; the egg's own nucleus was removed prior to fusion with the male nucleus. ▶androgenesis, ▶pronucleus

Andropause: Andropause is the period of decline of the free testosterone level in human males after its peak at age 30, yet at 60 the testosterone level is still comparable to that at 20. Muscle strength may be increased by replacement therapy but impotence is usually not cured. ▶menopause

Androsome: An androsome is a chromosome, which normally occurs only in males. ▶sex chromosomes

Androstanes: Androstanes are androstanol and androstenol steroids.

Androstanol (5 α -androstan-3 α -ol): Androstanol is a mammalian pheromone, inhibitory to constitutive CAR- β . ▶CAR- β , ▶androstane, ▶androstenol

Androstenol (5 α -androsten-16-en-3 α -ol) Androstenol is a mammalian pheromone, inhibitory to constitutive CAR- β . ▶CAR- β , ▶androstane, ▶androstanol

ANE Genes: ANE genes stand for annotated non-expressed genes. ▶annotation, ▶AE genes, ▶NAE genes

Anemia: Anemia is a reduction of the red blood cells and hemoglobin below the normal level. It occurs when the production of erythrocytes does not keep up with losses. Several human diseases involve anemia, including some that are hereditary, such as thalassemias, sickle cell anemia, glucose-6-phosphate dehydrogenase deficiency, etc. Some anemias appear under autosomal dominant, autosomal recessive, or X-linked control. ▶Cooley's anemia, ▶Fanconi's anemia, ▶elliptocytosis, ▶hemolytic anemia, ▶sickle cell anemia, ▶pyruvate kinase deficiency,

▶pyrimidine 5-nucleotidase deficiency, ▶glutathione synthetase deficiency, ▶thalassemia, ▶siderocyte anemia, ▶transcobalamin deficiency, ▶magaloblastic anemia, ▶atransferrinemia, ▶acculoplasminemia, ▶hemochromatosis, ▶diphosphoglycerate mutase deficiency, ▶adenylate kinase deficiency, ▶IRE

Anemophily: Anemophily is pollination by wind.

Anencephaly (spina bifida): Anencephaly is a perinatal disorder of fetuses and newborns where the brain is absent (cerebrum and cerebellum); many of the afflicted die before birth, 1/16 of all cases survive birth but rarely live beyond a week. Anencephaly may be due to a recessive mutation but some cases can be attributed to non-genetic causes. Its prevalence is less than 1/1000. Prenatal test may be carried out if family history indicates genetic causes. Microhydranencephaly maps to 16p13.3-p12.1. Porencephaly is encoded in human chromosome 13q34. ▶neural tube defects, ▶prenatal diagnosis, ▶genetic screening, ▶MSAPF, ▶Arnold-Chiari malformation, ▶hydrocephalus MDM2

Anergy: Anergy is a lymphocyte's non-responsiveness to an antigen because, e.g., a slightly modified peptide-MHC is attached to the T cell receptor, or some inductive factors are not functioning adequately. Anergized CD4⁺ T cells are not completely idle but have some regulatory function. ▶T cell, ▶HLA, ▶MHC; Jooss K et al 2001 Proc Natl Acad Sci USA 98:8738; Schwartz RH 2003 Annu Rev Immunol 21:305.

Anesthetics: Anesthetics numb the nerve receptors; they generally affect the ligand-gated ion channels, and lipids and proteins in cell membranes. In mammals, stomatin and degenerin, and in *Caenorhabditis* the product of the *UNC-1* gene, may affect the critical ion channels. ▶ion channels, ▶stomatin, ▶degenerin; Humphrey JA et al 2002 Hum Mol Genet 11:1241.

Aneugamy: In case of aneugamy the chromosome number of the two gametes involved in fertilization is different. ▶anisogamy, ▶isogamy, ▶heterogamet-ic, ▶homogamet-ic

Aneuhaploid: is a haploid, which has incomplete set(s) of chromosomes. ▶aneuploidy, ▶haploid

Aneuploidy: Chromosome numbers in case of aneuploidy are either more or less than $2n \pm 1$ or ± 2 or ± 3 , etc. Aneuploids are trisomics or monosomics, single or multiple (see Fig. A76).

Aneuploidy is frequent in cultured cells and in cancer cells. Hamerton (1971), after surveying 1291 spontaneous human abortions, found 5%

A

Figure A76. Normal female, normal male and various aneuploids of *Drosophila*. (From Morgan TH et al 1925 Bibl Genet 2:3)

monosomics, 11.9% trisomics, 4.1% triploids, and 1.2% tetraploids (note that the triploids and tetraploids are polyploids but not aneuploids, whose frequency is included only for comparison.). Among live human births chromosomal anomalies are close to 1%. Aneuploids are usually very deleterious yet sex-chromosomal aneuploidy e.g., Turner syndrome XO, Klinefelter syndrome XXY, etc. are not generally lethal in humans or other animals. In the 47 XXY individuals the anomaly in the majority of cases is due to nondisjunction of the XY bivalent. This high frequency may be attributed to the fact that usually even under normal conditions only a single chiasma occurs between the X and the Y (in the pseudo-autosomal region), and if this chiasma fails to materialize, nondisjunction takes place. A clinical test based on cytology and quantitative fluorescent polymerase chain reaction on X, Y, 21, 13, and 18 chromosomes is commercially available to test human aneuploidy. Monosomics ($2n-1$) have been

very skillfully exploited for mapping genes to chromosomes in polyploid plants (wheat, oats, etc.).

Microarray hybridization profiles reveal aneuploidy without cytological analysis because the expressions of large tracts of genes are detectable. Aneuploidy may lead to cancerous growth. Increased rate of aneuploidy drives an elevated level of spontaneous lymphomas and lung tumors in aged animals. Remarkably, however, in examples of chemically- or genetically-induced tumor formation, an increased rate of aneuploidy is a more effective inhibitor than initiator of tumorigenesis, probably because the aneuploid cells have diminished selective value. These findings reveal the additional role of aneuploidy and chromosomal instability in preventing tumorigenesis (Weaver BAA et al 2007 Cancer Cell 11:25). A cause of aneuploidy is probably the abnormal organization of the centrosome of animals. Animal histones are deacetylated during meiosis in the female, and it has been suggested that decreased

deacetylation can be a cause of aneuploidy and embryonic death in mice (Akyama T et al 2006 Proc Natl Acad Sci USA 103:7339). (See ►[illustration](#), ►[hypoploid](#), ►[hyperploid](#), ►[triploid](#), ►[pentaploid](#), ►[monosomic analysis](#), ►[MSAFP](#), ►[pseudoautosomal](#), ►[chiasma](#), ►[microarray hybridization](#), ►[centrosome](#), ►[polymerase chain reaction](#), ►[mosaic variegated aneuploidy](#); Jacobs PA, Hassold TJ 1995 Adv Genet 33:101; Hassold T, Hunt P 2001 Nature Rev Genet 2:280; Yuan L et al 2002 Science 296:1115; cancer: Rajagopalan H, Lengauer C 2004 Nature [Lond] 432:338)

Aneurysm: Aneurysm refers to the formation of small sacs of blood caused by the dilation of veins. Both abdominal aneurysms (more common in females) and brain aneurysms are under autosomal dominant control. Aortic aneurysm (15q21) is a heart disease involving fibrillin. Apparent linkage to 5q22-q31, 7q11 and 14q22 have also been reported. Thoracic aneurysm/aortic dissection (splitting of the arterial wall resulting in hemorrhage, TAAD) and patent ductus arteriosus is located to human chromosome 16p12.2-p13.3. It is caused by mutation in myosin 11-heavy chain (Zhu L et al 2006 Nature Genet 38:343). ►[collagen](#), ►[fibrillin](#), ►[patent ductus](#), ►[myosin](#), ►[Marfan syndrome](#), ►[Loeys-Dietz syndrome](#); Onda H et al 2001 Am J Hum Genet 69:804.

Aneusomatic: Aneusomatic describes the condition in which the somatic chromosome number varies among cells because of the presence of supernumerary chromosomes and because of their frequent somatic nondisjunction. Aneusomy is one of the most common causes of cancer. ►[supernumerary chromosomes](#), ►[nondisjunction](#), ►[aneuploidy](#); Fabarius A et al 2002 Proc Natl Acad Sci USA 99:6778.

Aneusomy, Segmental: ►[contiguous gene syndrome](#)

Angelman Syndrome (Happy Puppet Syndrome): Angelman syndrome is apparently an autosomal recessive human defect with somewhat irregular inheritance. Cytologically and molecularly detectable deletion in the 15q11-q13 region (similar to the Prader-Willi syndrome) has been observed. The unusual feature of this condition is that it is transmitted only through the mother whereas, in the Prader-Willi syndrome the transmission is via the father, the gene on the maternal chromosome being inactive. Imprinting has been suggested for the phenomenon. It has been suggested that in the female germline the so-named BD RNA transcripts induce methylation in the promoter of snRNP genes. Affected individuals have motor function defects (see Fig. A77), mental retardation, epilepsy, speech defect or absence, and a frequently

protruding tongue accompanied by excessive laughter (hence the name HPS). It appears that the syndrome is effected by abnormal ubiquitin-mediated degradation of a brain ligase (UBE3A, Xq28) of the E6-AP class. ►[disomic](#), ►[Prader-Willi syndrome](#), ►[mental retardation](#), ►[imprinting](#), ►[epigenesis](#), ►[head/face/brain defects](#), ►[snRNP](#), ►[ubiquitin](#), ►[Ube3](#), ►[E3](#), ►[imprinting box](#), ►[Rett syndrome](#); Jiang Y-H et al 1999 Am J Hum Genet 65:1.

Figure A77. Angelman syndrome

Angina Pectoris: Angina pectoris is characterized by spasmodic chest pain that may radiate to the arms (primarily the left) and breathing difficulties. It is caused by arterial ischemia and heart disease. It is a symptom also of several hereditary syndromes. ►[ischemia](#)

Angioectasis: Angioectasis is the excessive dilation of blood vessels.

Angioedema: Angioedema is the dilation of the subcutaneous capillary veins leading to skin, respiratory tract, and gastrointestinal fluid accumulations. The hereditary dominant form has been attributed to mutations in a serpin gene or to complement inhibitory factor deficiency (C1-INH). The condition may be haplo-insufficient. ►[serpin](#), ►[complement](#), ►[haplo-insufficient](#)

Angiogenesis: Angiogenesis refers to the formation of blood vessels and chronic inflammation. The vascular endothelial growth factor and its two receptors Flt-1 and Flk-1/KDR are required in rodents for angiogenesis. Vasculogenesis factor (VEGF) peptide hormones, secreted by tumors, increase blood supply and ensure neoplasias and their further growth. There are two angiogenesis pathways. Actually some pro-angiogenesis factors (FGF family) can eventually restore blood supply even after blocking VEGF receptors (Casanovas O et al 2005 Cancer Cell 8:299). The fibroblast growth factor- or tumor necrosis factor- α initiated path depends on integrin $\alpha_v\beta_3$, whereas angiogenesis initiated by vascular endothelial growth factor, transforming growth factor- α , or phorbol ester uses the $\alpha_v\beta_5$ path.

A

Disruption of the matrix metalloproteinase 2 binding to integrin inhibits angiogenesis, and it may be relevant to tumor control. The tumor necrosis factor- α induced angiogenesis uses the B61 cytokine-inducible ligand for the Eck protein tyrosine kinase receptor (RPTK).

VEGF dynamically regulates tumor endothelial expression of Delta-like ligand 4 (Dll4), which was shown to be essential to normal embryonic vascular development. Blocking of Dll4 resulted in markedly increased tumor vascularization, associated with enhanced angiogenic sprouting and branching. Paradoxically, this increased vascularization was non-productive—as shown by poor perfusion and increased hypoxia, and most importantly, by decreased tumor growth—even for tumors resistant to anti-VEGF therapy. Thus, VEGF-induced Dll4 acts as a negative regulator of tumor angiogenesis; its blockade results in a striking uncoupling of tumor growth from vessel density, and may offer a novel therapeutic approach even for tumors resistant to anti-VEGF therapies (Noguera-Troise I et al 2006 Nature [Lond] 444:1032).

Angiogenesis also promotes the proliferation of tumors, but the process can be restricted by the antibiotic minocycline, AGM, interferon $\alpha/\beta/\gamma$, angiostatin, endostatin, interferons, etc. Antiangiogenic therapy may destroy the vasculature of the solid tumors and neutralize VEGF signaling. Normalization can occur by recruiting pericytes (flexible cells, which wrap around the pre-capillary vessels and stabilize them transiently). The normalization is mediated by angiopoietin-1 and metalloproteinases, and provides an opportunity for radiation and chemotherapy (Lin M Ii, Sessa WC 2004 Cancer Cell 6:529).

The combined action of the three classes of angiostatic compounds, each targeting different aspects of the angiogenic process, was tested using a VEGF aptamer chemically identical to Macugen, recently approved for the treatment of neovascular eye diseases. The small-molecules $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin antagonists targeted the extracellular matrix-mediated endothelial cell survival. To block endothelial intracellular adhesion and lumen formation, T2-TrpRS (T2) was used. This is a proteolytic fragment of tryptophan tRNA synthetase that exhibits angiostatic activity, which is linked to its ability to block vascular endothelial-cadherin-mediated adhesion. The combination angiostatic therapy significantly reduced the compensatory upregulation possible in case a component of the blocking system had been used. The synergistic antiangiogenic activity appeared effective for the treatment of neovascular disease (Dorrell MI et al 2007 Proc Natl Acad Sci USA 104:967).

Tilted (or oblique-oriented) peptides are short peptides known to destabilize membranes and lipid cores. They are characterized by an asymmetric distribution of hydrophobic residues along the axis when helical, and are antiangiogenic. 16-kDa fragments of the members of the human prolactin/growth hormone (PRL/GH) family are potent angiogenesis inhibitors. All these fragments possess a 14-amino acid sequence having the characteristics of a tilted peptide. Tilted human peptides induce endothelial cell apoptosis, inhibit endothelial cell proliferation, and inhibit capillary formation both in vitro and in vivo. These antiangiogenic effects are abolished when the peptides' hydrophobicity gradient is altered by mutation. Well-known tilted peptides of simian immunodeficiency virus gp32 and Alzheimer's disease amyloid peptide are also angiogenesis inhibitors (Nguyen N-Q-N et al 2006 Proc Natl Acad Sci USA 103:14319).

Promoters of angiogenesis include cytokines (EGF, TGF, TNF), various carbohydrates, angiogenin, and several other molecules. The ligands of the Tie receptors, Angi1 and Angi 4, regulate angiogenesis positively, whereas Angi3 is a negative regulator. MicroRNA (miR-17-92) is an important factor for adenocarcinomas because it regulates vascular endothelial growth factor (VEGF). miR-17-92 represses anti-angiogenic factors thrombospondin-1 and connective tissue growth factor (CTGF), which are upregulated by KRAS and cMyc protooncogenes and are involved in tumorigenesis (Dews M et al 2006 Nature Genet 38:1060).

Gene *ING4* is known to control angiogenesis. In the presence of the *ING4* gene transcript, angiogenic vasculature is repressed (see Fig. A78) relative to the control, whereas when the transcript is reduced by antisense RNA (*as-ANG4*) angiogenesis and glioma growth are enhanced. *ING4* physically interacts with RelA subunit of NF- κ B. These images were obtained from human glioblastoma (U87MG) grafted into the brain of a mouse. Several new drugs are now available to fight angiogenesis, such as Avastin, an antibody that blocks VEGF, and Sutent and Sorafenib that block angiogenesis indirectly by inhibiting tyrosine kinases and appear effective against cancer.

Although inhibition of angiogenesis deprives tumors of the blood supply essential for proliferation, it also hinders the targeted delivery of therapeutic chemicals; furthermore hypoxia-inducible factor (HIF1- α) accumulates and leads to an increase in metastasis. A nanoparticle has been designed to target tumors, to overcome these problems. The outer envelope of the nanocell releases temporally an anti-angiogenesis agent combretastatin at first, and then a doxorubicin-PGLA (poly-(1-lactic-co-glycolic) acid, a biodegradable, non-bioactive polymer)

Figure A78. Angiogenesis. (Courtesy of Dr. Igor Gardatsev; see also Garkatse, I. *et al.* 2004 Nature [Lond] 428, 328)

conjugate is slowly released inside the tumor. The nanocell prefers tumor cells. This targeted approach hurts the tumor, and also comparatively reduces toxicity for normal cells (Sengupta S *et al* 2005 Nature [Lond] 436:568).

Angiogenins: Angiogenins are RNases stimulating blood vessel formation. ►ribonucleases

Angiokeratoma: Angiokeratoma is a recessive X-chromosome linked skin disease involving dilation of the small veins, warty growth, and thickening of the epidermis primarily on fingers, toes, and the scrotum. ►Anderson-Fabry disease, ►Kanzaki disease, ►fucosidosis

Angioma: Angioma is a tumor of the blood or lymph vessels or a neoplasia, which forms blood and lymph vessels. Many forms exist in humans; they are controlled by dominant genes at chromosomes

7q11.2-q21 (CCM1), 7p15-p13 (CCM2), and 3q25.2-q27 (CCM3). The CCM1 locus encodes RAP1A interacting KRIT1 protein. ►hemangioma, ►RAP1

Angioneurotic Edema: Angioneurotic edema is a dominant chromosome 11q11-q13.1 deficiency of complement C1 inhibitor, causing edema of the air passageway. The reduced level of the inhibitor leads to excesses of the C4 and C2 kinin fragments. Angioneurotic edema is a hereditary disease. ►complement, ►angioedema, ►kinin

Angioplasty: Angioplasty corrects narrowed blood vessels. One procedure involves inflation of a balloon inside an artery to break up plaque(s) in order to restore free blood flow.

Angiopoietin: Angiopoietin-1 is a blood-vessel differentiation factor that promotes tissue vascularization. Angiopoietin-2 is an antagonist of angiogenesis. ►VEGF, ►angiogenesis

Angiosperm: Angiosperms are plants that bear seeds within an ovary; the majority of higher plants belong to this taxonomic category. Fossil evidence points to their presence in the Jurassic period (137–190 Mya). ►Mya, ►geological time periods

Angiostatin: Angiostatin is a 38-kDa protein with some homology to plasminogen. It is an anticancer agent with the twin advantages that it can deprive cancer cells from developing new blood vessels and that resistance mutations against it (common to most anticancer drugs) have not yet been observed. The therapeutic effectiveness in the cure of human cancer has not been completely accepted, although some positive results have been obtained, especially in combination with radiation treatment. Angiostatin

A

may act by inhibiting endothelial ATP synthase, possibly required for supplying the energy for tumorigenesis. ►endostatin, ►cancer, ►angiogenesis, ►plasminogen, ►cancer therapy; Moser TL et al 2001 Proc Natl Acad Sci USA 98:6656.

Angiotensin: Asp - Arg - Val - Tyr - Ile - His - Pro - Phe peptides stimulate the smooth muscles of the blood vessels, reduce the blood flow through the kidneys and decrease the excretion of fluid and salts, increase the secretion of aldosterone, and stimulate the reabsorption of sodium. These peptides are known as angiotensins. They are involved in the hereditary disorders of adrenocortical steroid biogenesis (see Fig. A79). Angiotensin I receptor AT₁ mediates the enhancer (higher blood pressure) and angiotensin II receptor AT has the opposite (depressor) effect. The drugs Lisinopril and Losartan, frequently prescribed against high blood pressure, are inhibitors of the ACE enzyme and reduce hypertension. Angiotensin II cell surface receptor is directly stimulated by the Jak/STAT signal transduction pathway. The angiotensin converting enzyme (ACE, 17q23) is a dipeptidyl carboxypeptidase (kininase) that catalyzes the conversion of angiotensin I to angiotensin II. ACE2 was located to human Xp22; angiotensinogen (AGT) is at 1q42-q43. aldosterone, ►hypertension, ►eclampsia, ►signal transduction, ►tachykinin, ►pseudoaldosteronism, ►angiostatin, ►SARS, ►BBB, ►DCP1, ►rennin, ►Marfan syndrome, Zhu X et al 2001 Am J Hum Genet 68:1139; Morimoto S et al 2002 Physiol Genomics 9:113, review: Keidar S et al 2007 Cardiovasc Res 73:463.

Figure A79. Renin protease cleaves angiotensinogen into the inactive decaemic angiotensin I (AngI) and the angiotensin converting enzyme (ACE) cleaves it into the active octamer angiotensin II (AngII). This can promote hypertension and renal Na reabsorption. ACE2 inactivates AngII and protects against acute lung injury by receptor AT1 with the aid of AT2. Imai, Y. et al. 2005 Nature 436:112; Danilczyk, U. et al. 2006 Nature 444: 1088

Ångström (Å): Angstrom is a unit in measurement. 1 Å = 1/10 nanometer (nm).

Angular Transformation (arcsine transformation): Angular transformation is used with percentages and proportions. In a binomial distribution the variance is a function of the mean. The arcsine transformation prevents that $\theta = \arcsin \sqrt{p}$, where p is a proportion which stands for an angle whose sine is the given quantity. The transformation stretches out both ends of a distribution of percentages and compresses the middle. It may be usefully applied to genetic data when the figures fall outside the 30% and 70% ranges. ►arcsine, sine.

Anhidrosis: Anhidrosis is reduction or lack of sweating. An X-linked hypo- or anhidrotic ectodermal dysplasia is caused by mutation in a transmembrane protein. Ectodermal dysplasia is a part of about 150 syndromes. ►ectodermal dysplasia, ►pain-insensitivity

Anhidrotic Ectodermal Dysplasia: ectodermal dysplasia.

Anhydride: An anhydride is a compound that results from a condensation reaction where water was eliminated (between carboxyl and phosphate groups).

Animal Genetics: ►individual animal species, ►OMIA, ►breeding value, ►heritability, ►QTL, ►GOBASE; Fadiel A et al 2005 Nucleic Acids Res 33:6308.

Animal Genome Size: <http://www.genomesize.com>.

Animal Hormones: Hormones are the first chemical messengers secreted by certain tissues to be carried by the bloodstream to the specific sites of action where regulatory functions are enacted. Hormones regulate either the synthesis or activity of enzymes, or affect membrane transport in cooperation with the second messengers, cyclic adenosine monophosphate and cGMP. There are of three major types of hormones, which are detailed as follows. **PEPTIDE HORMONES:** secreted by the hypophysis of the pituitary gland, are somatotropin (general growth hormone, GH), corticotropin (adrenocorticotropin, ACTH in the kidneys), thyrotropin (thyroid-stimulating hormone, TSH), follitropin (FSH, in gonads), lutotropin (luteinizing hormone, LH, in gonads), and prolactin (in mammary glands). Secreted by the neurohypophysis are: oxytocin (controls uterine contractions and milk production), vasopressin (antidiuretic hormone that controls water reabsorption of the kidneys and blood pressure). Secreted by the middle section of the hypophysis are Melanotropins (control melanin pigments). The pancreas secretes insulin (controls carbohydrate, fatty acid, and cholesterol metabolism), and glucagon (stimulates glucose production by the liver). The ovary produces relaxin (controls pelvic ligaments, the uterine cervix, thereby labor), the thyroid gland is the source of parathyrin (involved in calcium and phosphorus metabolism), the kidneys release

erythropoietin (a glucoprotein involved in erythrocyte production by the bone marrow), and renin (causes constriction of the blood vessels). The digestive tract secretes gastrin (promotes digestive enzymes), enterogastrone (controls the gastric secretion), cholecystokinin (regulates gall bladder), secretin (controls pancreatic fluids and bile production), and pancreaticozym (of duodenal origin, stimulates pancreatic functions). **AMINO ACID HORMONES:** thyroxine and triiodothyronine are secreted by the thyroid gland and affect many functions in the body. The kidney tissues secrete epinephrine (adrenaline) and norepinephrine (triiodothyronine) that regulate blood pressure and heart rate, while the pineal gland (a cone-shaped epithelial body at the base of the brain) produces melatonin, which affects the pigment producing melanophore cells. The nerve cells produce serotonin (5-hydroxytryptamine) affecting contraction of the blood vessels and nerve function. Serotonin controls the central nervous system and therefore, alertness, sleep, mood, aggressiveness, etc. **STEROID HORMONES:** are produced in the testes (testosterone, regulates male reproductive capacities), in the ovaries (estrogen [estradiol-17 β], involved in female reproductive functions), in the corpus luteum of the ovary. Progesterone is produced in the Schwann cells of the peripheral nervous system. It functions during menstrual cycles, pregnancy, and in myelin formation. In the kidney cortex cortisol (corticosterone) is synthesized affecting glucose utilization and glucose levels in the blood. Although estrogen is typically a female hormone, yet extremely high concentrations occur in the fluids of the testis, and it is important for male fertility. Progesterone is necessary for the maintenance of pregnancy. It binds to the oxytocin receptor (OTR) and prevents uterine contractions. **EICOSANOID (HORMONELIKE) SUBSTANCES:** include prostaglandins (trigger smooth muscle contraction, control fever and inflammations), leukotrienes (secreted by the white blood cells and affect hypersensitivity reactions and pulmonary functions), and thromboxanes (produced by the blood platelets and other cells, involved in blood clotting, blood vessel constriction, etc.) A large number of other hormones also exist, and perform important functions. ►hormones, ►hormone receptors, ►hormone response elements, ►opiocortin, ►oxytocin

Animal Host Cells: Host cells are used for genetic transformation. *Xenopus* oocytes are well suited for such studies because they can propagate foreign genes in appropriate vectors quite efficiently. Similarly, COS cells of mice and other somatic cells have been used effectively. Recently available techniques for the transformation of animal zygotes and embryos

have enabled that genetic information be added or replaced in the germline, and transmitted to the sexual progeny. ►transformation of animal cells, ►COS, ►vectors genetic, ►germline

Animal Models: Certain biological phenomena cannot be studied in humans because mutants are not available and cannot be produced or manipulated effectively. In such cases animals such as *Caenorhabditis*, *Drosophila*, and mice are used for the experimentation (in behavioral genetics, neurobiology, various diseases, etc.). Animal models may have an important role in improving the techniques of gene therapy. The “shiverer” deletion in mice, resulting in convulsions because of the loss of a gene coding for a myelin protein, has been genetically cured by transfection of the wild type allele into the gamete. Similarly, the size of mice could be genetically increased by transformation using the rat somatotropin (RGH, growth hormone) gene fused to and regulated by a metallothionein promoter. The following monogenic human genetic disorders have models in mouse [abbreviations h. chr. = human chromosome, m. chr. mouse chromosome]: *adenomatous polyposis* (protrusive growth in the mucous membranes, h. chr. 5q21-q22, mouse homolog *Apc*^{Min}, chr. 18), *androgen insensitivity* (sterility, h. chr. Xq11.2-q12, mouse gene *AR*^{Tfm}, m. chr. X), *X-linked agammaglobulinemia* (deficiency of γ globulin in blood, h. chr. Xq21.33-q22, mouse gene *Btk*^{Xid}, m. chr. X), *Duchenne muscular dystrophy* (an early muscular disability), h. chr. Xp21.3-p21.2, mouse *Dmd*^{mdx}, m. chr. X), *Greig cephalopolysyndactyly* (multiple fusion of digits, h. chr. 7p13, mouse gene *Gli3*^{Xt}, m. chr. 13), *mucopolysaccharidosis type VII* (a type of lysosomal storage disease, h. chr. 7q22, mouse gene *Gus*^{m^{ps}}, m. chr. 5), *α -thalassemia* (defect in the hemoglobin α chain, h. chr. 16p13.3, mouse gene *Hba*th, m. chr. 11), *β -thalassemia* (defect in the β -chain of hemoglobin, h. chr. 11p15.5, mouse gene *Hbb*th, m. chr. 7), *piebaldism* (color patches on the body, h. chr. 4p11-q22, mouse gene *Kit*^W, m. chr. 5), *ornithine transcarbamylase* (defect in the transfer of a carbamoyl group, H₂N - C = O, from ornithine to citrulline, h. chr. Xp21.1, mouse gene *Otc*^{Spf}, m. chr. X), *tyrosinase-positive type II* (oculocutaneous albinism, h. chr. 15q11-q12, mouse gene *p*^p, m. chr. 7), *phenylketonuria* (phenylalanine hydroxylase deficiency, h. chr. 12q22-q24.2, mouse gene *Pah*^{enu2}, m. chr. 10), *Waardenburg syndrome type I* (h. chr. 2q35-q37, mouse gene *Pax3*^{Sp}, m. chr. 1), *aniridia* (absence of the iris, h. chr. 11p13, mouse gene *Pax6*^{Sey}, m. chr. 2), *pituitary hormone deficiency* (h. chr. 3q, mouse gene *Pit1*^{dw}, m. chr. 16), *Pelizaeus-Merzbacher disease* (central brain sclerosis, h. chr. Xq21.33-q22, mouse gene *Plp*^{ilp}, m. chr. X),

A

Charcot-Marie-Tooth disease type 1A (a progressive neuropathic muscular atrophy, h. chr. 17p12-p11.2, mouse gene *Pmp22^{Tf}*, m. chr. 11), *retinitis pigmentosa* (sclerosis and pigmentation of the retina, h. chr. 6p21.2-cen, mouse gene *RD2^{Rd2}*, m. chr. 17), *gonadal dysgenesis* (underdeveloped germ cells in the testes) h. chr. Y11.2-pter, mouse gene *Sry^{Sxr}*, m. chr. Y), *tyrosinase negative oculocutaneous albinism* albinism, h. chr. 11q14-q21, mouse gene *Tyr^c*, m. chr. 7. By disruption of hexosaminidase α subunit, a model for the Tay-Sachs disease has been generated in mice. Interestingly, these animals suffered no obvious behavioral or neurological deficit. Disrupting the hexosaminidase β subunit (Sandhoff disease model) resulted in massive depletion of spinal cord axons and neuronal storage of ganglioside G_{M2}. The two latter examples indicate possible complications with animal models (see Fig. A80).

Mouse polygenic disorders with similarities to human conditions [human problem - mouse strain]: alcoholism and opiate drug addictions - C57BL/6J, asthma - A/J, atherosclerosis - C57BL, audiogenic (sound-induced) seizures - DBA, cleft palate (fissure in the mouth) - A, deafness - LP, dental disease - C57BL, BALB/c, diabetes - NOD, epilepsy - EL, SWXL-4, granulosa cell tumors in the ovary - SWR, germ cell tumors in the ovary - LT, germ cell tumors in the testes - 129, hemolytic.

Anemia - NZB, hepatitis - BALB/c, Hodgkin disease (pre-B cell lymphoma - SJL, hypertension - MA/My, kidney adenocarcinoma - BALB/c Cd, leprosy (*Mycobacterium leprae*) - BALB/c, leukemia - AKR/J, C58/J, P/J, lung tumors - A, Ma/My, measles - BALB/c, osteoporosis - DBA, polygenic obesity - NZB, NZW, pulmonary tumors - A/J, rheumatoid arthritis - MRL/Mp, spina bifida (defect of the bones of the spinal cord) - CT, systemic lupus erythematosus

(a skin degeneration) - NZB, NZW, whooping cough - BALB/c. Some of the diseases (e.g., various types of cancer) occur sporadically because of mutations occurring during the course of the development of animals/humans. The introduction of a functional oncogene into the germline or into the soma line of a person cannot appropriately represent the conditions emerging in sporadic cases. Usually in cancer the sporadic occurrence of mutation is predominant. Normal cells generally surround the mutation in the soma and through bystander effect these may modify the expression of the mutant cell and its clonal derivatives, unlike the cases when the mutation has occurred in the male/female germline before fertilization. The former condition can be simulated in a genetic model, if, e.g., through recombination between one of the wild type RAS oncogene and its mutant a potentially proliferative allele is activated. The construction of such a model may be represented graphically.

Despite their usefulness for the study of human diseases, animal models may not always represent completely the human condition. For instance, mice deficient for both copies of the insulin receptor are born with normal weight but die from ketoacidosis soon after birth. The analogous null mutant humans are small at birth but rarely develop ketoacidosis. Human mutants of PPAR γ Pro467Leu develop extreme insulin resistance, diabetes mellitus, and hypertension. Mice with the same mutation are also hypertensive but display normal insulin-sensitivity and glucose homeostasis (O'Rahilly S et al 2005 Science 307:370). (See terms and diseases under separate entries).

Animal Pole: The animal pole is the dorsal end of the (animal) egg opposite the lower end, the vegetal pole, and the site of the entry of the sperm. After the entry,

WILD TYPE PROTOONCOGENE

MUTATIONALLY ACTIVATED AND GENETICALLY ENGINEERED ONCOGENE CONTAINS THE SELECTABLE MARKER INTO THE WILD TYPE LOCUS

SUCH A CONSTRUCT MAY RECOMBINE WITH THE WILD TYPE LOCUS AND PRODUCE A FUNCTIONAL TUMOR SUPPRESSOR:

OR AN ACTIVE ONCOGENE:

Figure A80. A genetic construct simulating the sporadic occurrence of oncogenic mutations. (See Johnson L et al (2001) Nature (Lond) 410:1111)

the egg cortex rotates slightly and in some species at the side opposite the entry a *gray crescent* is formed.

►vegetal pole

Animal Species Hybrids: The most familiar examples are the hybrids of the mare (*Equus caballus*, $2n = 64$) and the jackass (*Equus asinus*, $2n = 62$), and the stallion and the she-ass (see Fig. A81).

Figure A81. Hybrid of the male Grant's zebra and the female black Arabian ass, Gloucester zoo. (From Gray, A.P. Mammalian Hybrids. Commonwealth Agric. Bureau. Farnham Roal, Slough, UK)

Hybrid males do not produce viable sperm although they may show normal libido. The females may have a uterus and ovulate but there is no proven case of fertility. Zebras ($2n = 44$) also may form hybrids with both donkeys and horses. Buffalo (*Bison bison*, $2n = 60$) may be crossed reciprocally with cattle (*Bos taurus*, $2n = 60$) but their offspring (cattalo) has reduced fertility. The domesticated pig (*Sus crofa*, $2n = 38$) forms fertile hybrids with several wild pigs with the same number of chromosomes. The sheep (*Ovis aries*, $2n = 54$) interbreeds with the wild mouflons but the sheep x goat (*Capra hircus*, $2n = 60$) hybrid embryo rarely survives. Some monkeys can be interbred but primates are generally sexually isolated.

There is no sexual barrier among various human races, indicating close relationship, but no hybrids are known between humans and other species. These general rules do not hold for somatic cell hybrids because human cells can be fused with rodent or plant cells but they cannot be regenerated or even maintained successfully for indefinite periods of time. somatic cell hybrids, ►goat ►x sheep hybrids, ►transformation genetics

Animal Transformation Vectors: Most commonly used transformation vectors in animals are Simian virus 40

(SV40) and Bovine papilloma virus (BPV) based vectors. The BPV vectors can be used for the synthesis of large amounts of proteins specified by the gene(s) carried by the expression vectors. In addition, the BPV vectors can be maintained for long periods of time in cell cultures and may yield 10 mg of specific protein(s) per liter of culture/24 hr. The SV40 vectors can also be used for gene amplification in COS cells. Both these vectors can serve as shuttles between animal and prokaryotic cells. ►BPV and SV40 ►constructs, ►adenovirus, ►adenoassociated virus, ►retroviral vectors, ►lentivirus, ►vaccinia virus, ►COS cells, ►gene therapy

Animal Viruses: Animal viruses include viruses found in both invertebrates and vertebrates. The Rhabdoviridae and the Bunyoviridae may also infect plants. The double-stranded DNA viruses that may have been *enveloped* include Baculoviridae, Poxviridae, Herpesviridae, Hepadnaviridae, and Polydnaviridae. Double-stranded DNA viruses *without envelope* comprise Iridoviridae, Adenoviridae, and Papovaviridae. Parvoviridae have single-stranded DNA and do not have an envelope. The single-stranded RNA and *enveloped* group includes the Togaviridae, Bunyaviridae, Rhabdoviridae, Coronaviridae, Paramixoviridae, Toroviridae, Orthomyxoviridae, Arenaviridae, Flaviviridae, Retroviridae, and Filoviridae. The single-stranded RNA and *non-enveloped* viruses are: Picornaviridae, Tetraviridae, Nodaviridae, and Caliciviridae. The double-stranded RNA and *non-enveloped* viruses are Reoviridae and Birnaviridae. Their genetic material varies in size from 5 kb in the Parvoviridae to 375 kbp in the Poxviridae. The Polydnaviridae may have several copies of double-stranded circular DNAs. The Papovaviridae have only a single double-stranded DNA genetic material. The others may have two or more segments of linear nucleic acid genetic material. ►viruses, <http://www.ncbi.nlm.nih.gov/ICTVdb/ictvdb.htm>.

Animal Welfare: Animal welfare is a serious societal concern that seeks to balance the interest and need of medical research with the humane treatment of animals. Among the goals are Refinement, Reduction, and Replacement of animals as much as possible in experiments. The idea is to limit their use to the minimal and most indispensable experimentation that is in the best interest of humans as well as animals.

Animalcules: The pioneer microscopist Anthony Leuwenhoek (17th century) believed he could see small encapsulated animals in the sperm of various animals and this apparent observation supported his view that inheritance travels only through the sperm and the females serve only as incubators. His observations lead

A

to the notion of preformation, rather than epigenesis (see Fig. A82). ►preformation, ►epigenesis, ►sperm

Figure A82. Animalcule

Animation: The condition of being alive and maintaining at least limited metabolic activity (suspended animation). Nitric oxide may favor *Drosophila* survival under hypoxia. ►hypoxia, ►nitric oxide; Teodoro RO, O'Farrell PH 2003 EMBO J 22:580)

Anion Exchange Resin: A polymer with cationic groups, the anion exchange resin traps anionic groups and thus can be used in chromatographic separation.

Anions: Anions are negatively charged ions.

Aniridia: Aniridia refers to the absence or reduction of the iris of the eye (see Fig. A83). It is frequently accompanied by cataract (opacity of the eye[s]), glaucoma (increased intraocular pressure causing deformation of the optic disk), nystagmus (involuntary movement of the eyeball), etc.

Figure A83. Hypoplastic iris and enlarged excentric pupil in adult aniridia

The condition is caused by dominant defects in human chromosomes 2 and 11. In a sample population from Michigan, the rate of mutation was 4×10^{-6} . Aniridia may involve Wilms tumors and genital abnormalities due a deletion in human chromosome 11p13 (PAX6). Aniridia may be haplo-insufficient. The *Drosophila* locus *eyeless* and the mouse *Sey/Pax-6* are the corresponding homologs. ►Wilms tumor, ►WAGR, ►deletion, ►eyeless, ►haplo-insufficient

Anisogamy: the gametes are not identical, e.g., male and female (+ or -) are distinguishable. ►isogamy

Anisomycin: Anisomycin is an antibiotic isolated from *Streptomyces griseolus*. It inhibits peptidyl transferase during protein synthesis on the ribosomes. It also inhibits pathogenic fungi (e.g., mildew) in plants and it was found to be useful against infection by various species of the parasitic flagellate, *Trichomonas*, causing inflammation of the gums, diarrhea, vaginal discharge, and irritation in humans and animals (particularly poultry and pigeons). ►antibiotics, ►protein synthesis

Anisotropic: Anisotropic describes the condition in which the material varies in different directions, responds differently to external effects depending on direction.

Anj1: A heat and other stress-inducible membrane-associated chaperone of higher plants. The Cys-Ala-Gln-Gln C-terminus may be subject to farnesylation. ►heat-shock proteins, ►chaperones, ►DnaK, ►prenylation

Ankyloblepharon: Ankyloblepharon describes fused eyelids. ►Hay-Wells syndrome

Ankylosing Spondylitis (AS): AS is an autosomal dominant rheumatism-type disease with reduced penetration. The greatest susceptibility to AS is associated with MHC (HLA B27), but spurious or fair linkage was observed with chromosomes 1p, 2q, 6p, 9q, 10q, 16q and 19q. The onset of AS occurs after age 20. ►HLA, ►immunodeficiency, ►connective tissue disorders, ►autoimmune disease, ►penetrance; Laval SH et al 2001 Am J Hum Genet 68:918.

Ankyrin: Ankyrins are protein motifs capable of binding fibrous proteins (e.g., spectrin) of the cytoskeleton, and thus may be involved in some polar transports within the cell. Several ankyrin and ankyrin-like proteins are encoded in different human chromosomes (8p11.2, 4q25-q27, 10q21, etc.). Ankyrin B mutations may be involved in type 4 LQT cardiac arrhythmia. Ankyrin repeats may form superhelical spirals and have spring-like function in *Drosophila* hairs and bristles, among others (Lee G et al 2006 Nature [Lond] 440:246). ►LQT, ►cytoskeleton, ►spectrin, ►elliptocytosis, ►poikilocytosis, ►IkB, ►spherocytosis, ►tankyrase, ►Wolbachia; Hayashi T, Su T-S 2001 Proc Natl Acad Sci USA 98:491.

Anlage: Anlagen are a group of cells of the embryo that initiate specific biological structures. ►primordium

Annealing: Annealing is the formation of double-stranded nucleic acid when two complementary single stranded chains meet (nucleic acid hybridization, attachment of a primer). Used to estimate DNA complexity, the process identifies the presence of homologous sequences in the genome with the help

of radioactively labeled or fluorescent homologous and heterologous probes. ►*c₀t* curve, ►probe, ►chromosome painting, ►FISH, ►DNA hybridization, ►primer

Annexins: Annexins are proteins composed of four or eight conserved 70-amino acid domains with variations mainly at the amino end. In mammals, there are at least 10 annexins; others exist in lower eukaryotes. Annexins bind to negatively charged phospholipids in the membranes. Annexins V and VI form voltage-regulated ion channels for different cations, whereas VII is specific for Ca²⁺. Annexin V can reveal apoptosis in imaging technology. Annexins II may assist exo- and endocytosis. An annexin-like protein may be involved in mitigating H₂O₂ stress. Annexin 7 (ANX7, 10q21) is a tumor suppressor. ►ion channels, ►endocytosis, ►exocytosis, ►imaging; Bendorowicz-Pikula J et al 2001 *Bioessays* 23:170.

Annotation of the Genome: The identification of the function of open-reading frames and other elements. This is also called *one-dimensional annotation*. When the annotation extends also to the interaction of components identified in one dimension, *two-dimensional annotation* results. *Three-dimensional annotation* identifies the spatial positions within the chromosome and *four-dimensional annotation* considers the genome changes during adaptive evolution (Reed JL et al 2006 *Nat. Rev Genet* 7:130). During recent years many of the early sequenced genomes required re-annotation because the original procedures were loaded with substantial errors (Haas BJ et al 2005 *BMC Biology* 3:7).

In microbial genomes, when an annotated gene is linked to an unclassified one either by genetic linkage in a related species or microarray profile or protein-protein interaction, there is a high probability that they are members of the same functional category. Silencing the expression of a gene may also reveal its function. The expansion of annotations will be the task of the proteome projects. Comparative sequencing of many (16) eutherian mammals may greatly facilitate the identification of evolutionarily preserved sequences (Margulies EH et al 2005 *Proc Natl Acad Sci USA* 102:4795). A precisely annotated human genome is of great significance for medicine (Bentley DR 2004 *Nature [Lond]* 429:440; Cobb JP et al 2005 *Proc Natl Acad Sci USA* 102:4801). and for basic research (<http://www.ncbi.nlm.nih.gov/projects/CCDS>). ►proteome, ►gene prediction, ►DAS, ►silencer, ►insertional inactivation, ►RNAi, ►degron, ►RefSeq, ►VEGA, ►genome annotation, ►Recon; Marcotte EM et al 1999 *Science* 285:751; Mount SM 2000 *Am J Hum Genet* 67:788; Karlin S et al 2001 *Nature [Lond]* 411:259; Auburg S, Rouze P 2001 *Plant Physiol Biochem* 39:181; Stein L

Annulus (a ring): For example, specialized cells in a sporangium involved in opening.

Anodontia: ►tooth agenesis, ►hypodontia, ►Rieger syndrome

Anoikis: Anoikis is the loss of cell anchorage to a substrate that may lead to apoptosis and may be the requisite for metastasis. Some cell lines resistant to anoikis display increased metastasis because the probability of apoptosis is reduced. Rac GTP-ase may protect against anoikis. Neurotrophic tyrosine receptor kinase receptor (TrkB) suppresses anoikis and promotes metastasis (Douma S et al 2004 *Nature [Lond]* 430:1034). ►apoptosis, ►metastasis, ►anchorage dependence, ►receptor tyrosine kinase Coniglio S et al 2001 *J Biol Chem* 276:28113.

Anomalous Genetic Ratios: Genetic ratios that are caused by many different mechanisms. Defective chromosomes or chromosomes carrying deleterious genes are transmitted at lower than normal frequencies and reduce the expression (transmission) of the genes residing in that chromosome (conversely the other allele may appear in excess). Monosomy and trisomy also modify segregation ratios. The genetic ratios may be altered by preferential segregation of certain chromosomes in meiosis. Similarly, segregation distorter genes can cause dysfunction of the sperm carrying them. Meiotic drive in a population

A

can work against the more fit alleles. ► **Mendelian segregation**, ► **chromosomal breakage**, ► **aneuploidy**, ► **deletion**, ► **segregation distorter**, ► **gametophyte factor**, ► **certation**, ► **meiotic drive**, ► **preferential segregation**, ► **monosomic analysis**, ► **trisomic analysis**, ► **gene conversion**, ► **drift genetic**, ► **penetrance**, ► **Muller's ratchet**

Anomalous Killer Cell (AK): A T cell grown in the presence of IL-2 and which acquires natural killer cell (NK)-like properties. ► **killer cell**, ► *Paramecium*

Anomer: Stereoisomers of sugar, differing only in the configuration of the carbonyl residue, e.g., α -D-(+)-glucose and β -D-(+)-glucose.

Anonychia/Hyponychia Congenita: A human chromosome 20p13 recessive condition involving no or incomplete finger and toenail development controlled by R-spondin 4 (encoding a receptor of Frizzled in the Wnt pathway. (Blaydon DC et al 2006 Nature Genet 38:1245). ► **wingless**

Anonymous DNA Segment: Mapped DNA fragment without known gene content.

Anonymous Gene: A mapped gene without information about its molecular mechanisms but known to affect the expression of a quantitative response such as a behavioral trait. If it displays two allelic states it can be used for (DNA) mapping. ► **behavior**, ► **behavior genetics**

Anonymous Probe: A DNA probe with no known gene(s) and unknown function. Nevertheless, it provides information on the presence of sequences homologous to it and thus may be useful for taxonomic or evolutionary studies. ► **physical mapping**, ► **microsatellites**

Anopheles Mosquito: The host and vector of the protozoan *Plasmodium falciparum*, the cause of malaria. *Anopheles gambiae* (278,244,063 bp) carries one major and two minor genes that control the formation of melanin-rich capsules in the midgut, thus disarming the *Plasmodium*. *Plasmodium* resistance in *Anopheles* is regulated by a leucine-rich repeat protein, similar to the role of leucine-rich repeats in plant and animal resistance to pathogens (Riehle MM et al 2006 Science 312:577). *Anopheles* control may be a major objective of fighting malaria. ► **thalassemia**, ► **sickle cell anemia**, ► *Wolbachia*, ► **leucine-rich repeats**, Atkinson PW, Michel K 2002 Genesis 32:42, ► *Aedes aegypti*, *Anopheles gambiae* genome sequence: Holt RH et al 2002 Science 298:129, systematics: Krzywinski J, Besansky NJ 2003 Annu Rev Entomol 48:11, *Anopheles* database: <http://www.anobase.org/>.

Anophthalmia: Anophthalmia is the lack of rudimentary eyes. It is caused by deletions or chromosome breakage at 3q27, the location of the SOX2 transcription factor gene involved in the control in eye, eye lens and the nervous system. Terminal deletion of chromosome 6p also causes anophthalmia among many craniofacial abnormalities (Bogani D et al 2005 Proc Natl Acad Sci USA 102:12477). The Pax6 may also be involved. ► **eye diseases**, ► **eyeless**, Fantes J et al 2003 Nature Genet 33:461.

Anophthalmos: An autosomal recessive bilateral defect in the formation of the optic pit. It has been reported also as an Xq27-encoded fusion of the eyelids and other complications. ► **microphthalmos**, ► **eye diseases**

Anorexia: Lack of appetite or *anorexia nervosa* is a psychological disturbance of adolescents (primarily females) caused by an abnormal fear of gaining weight and therefore refusal to eat. It is characterized by habitual self-induced vomiting, unnecessary use of laxatives leading to emaciation, irregular or lack of ovulation, reduced interest in sex, and other anomalies. Medical treatment may be required. Ciliary neurotrophic factor (CNTF) shows anorectic effect by overcoming leptin resistance through activation of hypothalamic neurons. This effect of CNTF could be abolished by knocking out pro-opiomelanocortin-specific glycoprotein 130 (gp130) in mice (Janoschek R et al 2006 Proc Natl Acad Sci USA 103:10707). The melanocyte-stimulating hormone, α -MSH, and analogs may be responsible for anorexia and weight loss. Oleyethanolamide may be a regulator of feeding. Susceptibility loci appear to be in chromosomes 1, 2 and 13. ► **obesity**, ► **leptin**, ► **bulimia**, ► **ciliary neurotrophic factor**, ► **melanocyte stimulating hormone**; Rodríguez de Fonseca F et al 2001 Nature [Lond] 414:209; Adan RA, Vink T 2001 Eur Neuropsychopharmacol 11[6]:483; Devlin B et al 2002 Hum Mol Genet 11:689.

Anosmia: Anosmia is the inability to smell.

ANOVA: Abbreviation for analysis of variance. ► **analysis of variance**, ► **AMOVA**

Anoxia: Absence or deficiency of oxygen; it reduces chromosomal damage during irradiation. ► **radiation effects**, ► **ARE**

Anserine (β -alanine-1-methylhistidine): A dipeptide occurring in birds and some mammals but not in humans. ► **carnosinemia**

Ant (*Formica sanguinea*): $2n = 48$. The family of ants includes about 11,000 species ~2% of the total insect fauna. Ants generally follow the pattern of reproduction of other Hymenoptera. The females are the

products of sexual reproduction and are diploid whereas the males hatch from unfertilized eggs and are haploid. The workers are also diploid, like the queen, but due to developmental control they do not develop into functional female queens. In five species of ants, unmated workers may reproduce by thelytokous parthenogenesis and produce females from unfertilized eggs. *Cataglyphis cursor* females (queens) without mating may have parthenogenetic offspring by the fusion of four products of meiosis; such offspring develops into a queen. ▶[parthenogenesis](#), ▶[thelytoky](#), ▶[honeybee](#), ▶[social insects](#); Percy M et al 2004 Science 306:1780; phylogeny: Wilson EO, Hölldobler B 2005 Proc Natl Acad Sci USA 102:7411.

Antagomirs: Short RNAs, which antagonize micro-RNAs. Their silencing effect—after injecting them into mice—is very specific and long lasting. They appear promising for therapeutic silencing (Krützfeldt J et al 2005 Nature [Lond] 438:685). Antagomirs harbor optimized phosphorothioate modifications and require > 19-nt length for highest efficiency and can discriminate between single nucleotide mismatches of the targeted miRNA. Degradation is independent of the RNA interference (RNAi) pathway (Krützfeldt J et al 2007 Nucleic Acids Res 35:2885). ▶[microRNA](#)

Antagonist: An antagonist blocks biological receptor activation. ▶[agonist](#)

Antecedent: precursor, forerunner

Anteater (*Tamandua tetradactyla*): $2n = 54$.

Antelope: (*Antilocapra americana*): $2n = 58$.

Antenatal Diagnosis: The determination of a particular condition before birth by amniocentesis or blood samplings or by other means. amniocentesis, ▶[prenatal diagnosis](#), ▶[fetoscopy](#)

Antenna: Feeler organ on the head of insects. ▶[Drosophila](#) (see Fig. A84).

Figure A84. Antenna

Antenna Pigments: Present in chloroplasts, they collect light energy that is transmitted to the reaction centers for photochemical use. ▶[chloroplasts](#), ▶[chlorophyll](#), ▶[photosynthesis](#)

Antennapedia: *Drosophila* gene (*Antp*; map location 3–47.5, salivary bands 84B1-2) with numerous alleles. The null alleles result in embryonic lethality. Initially the locus was recognized by mutations that transform the antennae into mesothoracic legs. Numerous other homeotic changes may accompany the mutations. The different alleles may involve various types at the locus. The gene occupies about 100 kb, containing eight exons. These exons are transcribed from promoters P1 or P2 or from both. The transcripts may undergo alternate splicing. The homeobox motif is in exon 8. Actually *Ant* promotes leg differentiation by suppressing antenna-determining genes *extradenticle* (*exd*, 1–54) and *homothorax* (*hth*, 3–48). ▶[homeotic genes](#), ▶[morphogenesis](#), ▶[Polycomb](#)

Anterior: Indicates a direction in front of something or towards the head.

Anterior-Posterior Polarity: Head to tail anatomical direction.

Anterograde: Ahead or forward moving. ▶[retrograde](#)

Anther: The pollen-containing parts of the male flowers (see Fig. A85). ▶[gametogenesis](#)

Figure A85. Anther

Anther Culture: Used for the isolation of haploid plants. The culture may start with microspores that are directly regenerated into plantlets (without an intermediate callus stage) or from anthers. Haploid tissues are isolated and first a callus is formed, then the calli are regenerated into plants. Both procedures use tissue culture methods under aseptic conditions. The haploid cells may diploidize spontaneously or by induction and that results in perfect homozygosis of the plants. ▶[androgenesis](#), ▶[Asparagus](#), ▶[gametogenesis](#), ▶[embryo culture](#), ▶[YY plants](#); Jahne-Gartner A, Lörz H 1999 Methods Mol Biol 111:269.

Antheridium: The male sex organ (gametangium) of lower plants and fungi.

Anthesis: The time of pollen-shedding or receptivity of a flowering plant.

Anthocyanin: Plant flower pigments (delphinidin, cyanidin, pelargonidin, peonidin, petunidin, malvidin, etc.) are synthesized from phenylalanine via

A

Figure A86. Pelargonidin displays an OH group at position 4', cyanidin has two OH groups at 3' and 4', delphinidin has three OH groups (3', 4' and 5'). Peonidin (not shown) has 3' OCH₃ and 4' OH. Petunidin: 3' OCH₃, and 5' OH. Malvidin: 3' and 5' OCH₃ and 4' OH. Further color variations may be brought about by glycosylation and acetylations of the A ring(s) [at left]

trans-cinnamic acid and cinnamoyl-CoA, chalcones and flavonones (see Fig. A86). CH₃ and OH groups on the B ring determine the color produced; glycosylation (hexose or pentose) at the 3 and 5 positions (or at both) on the A ring increases stability of the pigments, and these glycosides are called anthocyanidins. In the petals of roses, a single glucosyltransferase adds a glucosyl group to both the 5 and 3 positions of the A ring of anthocyanidin (Ogata J et al 2005 Nature [Lond] 435:757). Each enzymatic step is controlled by different genes and these original discoveries, beginning in the early twentieth century, prepared the way for biochemical genetics. The color is affected also by the pH of the vacuoles and those too are under genetic control. By the use of antisense constructs of the gene chalcone synthase (CHS), the activity of this enzyme and chalcone flavonone isomerase (CHI) could be reduced indicating that CHS regulates also the expression of CHI. ▶[chalcone](#), ▶[grape](#); Markham KR et al 2000 Phytochemistry 55:327; Rasusher MD et al 1999 Mol Biol Evol 16:266; van Houwelingen A et al 1998 Plant J 13:39.

Anthranilic Acid: Synthesis begins with the condensation of erythrose-4-phosphate + phosphoenolpyruvate, and from this shikimate and then chorismate are formed. Chorismate through prephenate contributes to phenylalanine and tyrosine and through another path is a precursor of the amino acid tryptophan (actually indole-3-glycerol phosphate ® indole and serine are converted to this amino acid). ▶[tyrosine](#), ▶[phenylalanine](#)

Anthrax: A toxin produced by *Bacillus anthracis*, an endospore-forming bacterium of $\sim 5.23 \times 10^6$ bp sequenced genome with two plasmids, pXO1 (181 bp) and pXO2 (94,829 bp), that carry virulence genes; but the large chromosome also has virulence factors (Read TD et al 2003 Nature [Lond] 423:81). The toxin affects, primarily, herbivorous animals but it may spread to carnivorous predators and also to humans through the skin, by ingestion or inhalation of dust

contaminated by the bacterial spores (see Fig. A87). Inhaling the spore of the most virulent strains may be lethal in 80–90% of the cases. The toxin consists of three proteins: (i) protective antigen (PA) facilitates the formation of a membrane channel for the (ii) edema factor (EF, an adenylate cyclase) and (iii) lethal factor (LF, a zinc-dependent metalloprotease and selective inhibitor of MAPK and MAPKK). For the manifestation of the toxic effects of anthrax the presence of low-density lipoprotein receptor LRP6 must be present. LRP6 enables internalization of the toxin by interacting with PA receptors TEM8/ATR (tumor endothelial marker) and/or CMG2 (capillary morphogenesis gene 2), which is a transmembrane cellular receptor. LRP6 appears to be a good candidate target for anti-anthrax therapy (Wei W et al 2006 Cell 124:1141).

The LF and the EF have a similar effect on *Drosophila* as in mammals and can be used to test the toxic functions in vivo in a much simpler system (Guichards A et al 2006 Proc Natl Acad Sci USA 103:3244). Although LF targets mainly MAPKK, apparently it hydrolyzes also a number of peptide hormones: granuloliberin R, dynorphin A (a 17-amino acid neuropeptide), kinetensin and angiotension-1 (brain peptides). The toxin represses the glucocorticoid receptor. The chemical PD09859 is also a MAPKK inhibitor but it acts differently from LF. Mutation in PA may prevent the uptake of EF and LF and thus in a dominant negative manner may become a potential tool in preventing the toxic effects. Another preventive approach is to block the formation of the heptameric cell-binding subunit of the toxin by a synthetic polyvalent inhibitor (Mourez M et al 2001 Nature Biotechnol 19:958). The bacteriolysin PlyG produced by the γ phage of *B. anthracis*, a monomeric protein of M_r of $\sim 27K$, detects and kills the anthrax bacterial spores. The antimicrobial peptide defensin and human neutrophil protein HNP-1 protects against the lethal toxin of this bacterium (Kim C et al 2005 Proc Natl Acad Sci. USA 102:4830). Ciprofloxacin antibiotic provides effective protection. A complex molecule of

a hydroxamate (2R)-[4(fluoro-3-methylphenyl)sulfonylamino]-*N*-hydroxy-2-[-2H-pyran-4-yl) acetamide interacts with LF and may provide up to 100% protection against the bacterium, especially in combination with ciprofloxacin (Shoop WL et al 2005 Proc Natl Acad Sci USA 102:7958). In case of inhalational exposure, vaccination and ciprofloxacin have synergistic protection (Vietri NJ et al 2006 Proc Natl Acad Sci. USA 103:7813).

The virulence genes are borne by the pXO1 plasmid and are regulated by temperature and carbon dioxide as well as by bacterial chromosomal genes encoding surface proteins of the semi-crystalline S-layer. A wide range of cancer cells exhibit increased surface urokinase activity. An engineered anthrax toxin equipped with urokinase plasminogen activator within the furin protease selectively increases the toxicity for cancer cells but not for normal cells. Furin and other proteases destroy the protective antigen of the toxin. The modified toxin thus can destroy cancer cells (Liu S et al 2003 Proc Natl Acad Sci 100:657). ▶adenylate cyclase, ▶metalloproteases, ▶toxins, ▶furin, ▶urokinase, ▶MAPKK, ▶bioterrorism, ▶microfluidics, ▶ciprofloxacin, ▶*Bacillus cereus*; Sellman BR et al 2001 Science 292:695; Mock M, Fouet A 2001 Annu Rev Microbiol 55:647; Bhatnagar R, Batra S 2001 Crit Rev Microbiol 27(3):167; Schuch R et al 2002 Nature [Lond] 418:884; danger as a weapon: Webb GF 2003 Proc Natl Acad Sci USA 100:4355; synthetic inhibitors of LF; Forino M et al 2005 Proc Natl Acad Sci USA 102:9499; anthrax inhalation risks based on the Sverdlovsk/Yekaterinburg, Russia accident: Wilkening DA 2006 Proc Natl Acad Sci USA 103:7589; toxin receptor binding: Young JAT, Collier RJ 2007 Annu Rev Biochem 76:243; *B. anthracis* database: [http://cmr.tigr.org/tigr-scripts/CMR/GenomePage.cgi?database=gba](http://cmr.tigr.org/tigr-scripts/CMR/GenomePage.cgi?database=gba;); <http://www.fda.gov/cder/drug/infopage/cipro/>.

Anthropology: The science of human evolution, diversity, development and distribution, including the various human races. The database ALFRED (allele frequency database, <http://alfred.med.yale.edu/alfred/>) provides comprehensive information on human variation.

Anthropometric Traits: Those physical or physiological characters of humans (such as weight, head circumference, hair color, protein differences, behavior, etc.) that may be used for the characterization of human populations. ▶anthropology

Anthropomorphism: The study of behavior assuming that animals share many traits resembling the conscience, cognition and feelings of human beings.

Anti: A conformation of nucleotides, the CO and NH groups in the 2 and 3 positions of the pyrimidine ring (1, 2, 6 positions in the purine ring) are away from the glycosidic ring, while in the SYN conformation they lie over the ring. The anti conformation is most common in nucleic acids and free nucleotides. Kornberg A 1982 DNA replication, Freeman, San Francisco, California.

Antiauxin: Interferes with the action of auxins, e.g., 2,3,5-triiodobenzoic acid inhibits the growth promoting action of 2,4-D (dichlorophenoxyacetic acid) or the indoleacetic acid (IAA) analog 5'-azido-indole-3-acetic acid interferes with enzymes involved with IAA. ▶plant hormones

Anti-4-1BB Monoclonal Antibody: A co-stimulatory receptor expressed on activated T cells; it may be effective in amplifying T-cell-mediated immunity in cancer therapy. When used for intra-tumoral adenoviral gene transfer, it improved survival rate and reduced metastasis substantially. ▶cancer gene therapy; Martinet O et al 2002 Gene Ther 9:786.

Antibiotic Resistance: Resistance to antibiotics is brought about either by enzymatic inactivation of the antibiotic, or modification of the target, or active efflux of the substance or sequestration by binding to special proteins. Today, antibiotic resistance in the major infectious agents may be up to 98%, depending on the agent and the antibiotic used. Genes in bacterial plasmids and transposons generally determine it. The antibiotic producing organisms have some special means (proteins) to protect themselves against their products. The mechanisms of resistance vary: penicillins and cephalosporins (β-lactamase hydrolysis); chloramphenicol (detoxification by chloramphenicol transacetylase that acetylates the hydroxyl groups or interferes with uptake); tetracyclines (interference with uptake or maintenance of the molecules); aminoglycosides (streptomycin, kanamycin, etc. enzymatic modification of the drug [phosphorylation] interferes with uptake or action); erythromycin, lincomycin (methylation of the small ribosomal subunit). Tetracycline pactamycin and hygromycin B modify, in special ways, the 30S ribosomal subunit and affect the decoding of mRNAs. In the 16S rRNA subunit, 53 sites were

A

identified that are, potentially, sites for inhibition of protein synthesis. The majority of these sites affect either protein synthesis or the assembly of the small subunit of the ribosome (Yassin A et al 2005 Proc Natl Acad Sci USA 102:16620). The SOS response (error-prone repair) facilitates the horizontal spread of antibiotic resistance genes (Beaber JW et al 2004 Nature [Lond] 427:72).

Mutations in DNA topoisomerase and genes affecting cell permeability may result in resistance to ciprofloxacin. Ciprofloxacin-caused DNA damage can be corrected by nucleotide excision repair or by homologous recombination. Upon autoprotoleolysis, the SOS repair repressor *lexA* gene is sufficiently weakened so it no longer suppresses prokaryotic DNA polymerases Pol II, Pol IV, Pol V, which are accessory or conditional repair genes. Blocking autoprotoleolysis may be one way to interfere with the development of resistance to ciprofloxacin and rifampicin type antibiotics (Cirz RT et al 2005 PLoS Biol 3(6):e176). The use of antibiotics can contribute to bacterial competence and antibiotic stress can facilitate the acquisition of resistance to different antibiotics. In *Streptococcus pneumoniae*, kanamycin, streptomycin and mitomycin C triggered competence, but erythromycin, tetracycline, novobiocin, rifampicin, vancomycin, and cefotaxime did not. Mitomycin C and fluoroquinolones also induced SOS repair and competence in *E. coli*, but streptomycin and kanamycin did not. This indicates that stress responses are processed differently in these two bacteria (Prudhomme M et al 2006 Science 313:89).

Switching to another antibiotic if failure of effectiveness is encountered may minimize antibiotic resistance. Never switching to a new drug always minimizes the occurrence of a resistant strain but maximizes the failure in the treatment. Immediate switching usually maximizes resistance and minimizes failure. Thus, in most circumstances, the early use of a new drug enhances the effectiveness of the treatment while promoting the rise of high-level resistance in later generations of the bacteria (Wang YC, Lipsitch M 2006 Proc Natl Acad Sci USA 103:9655).

Antibiotic resistance acquired through conjugative transfer of the resistance factors or mutation pose serious problems to medicine, e.g., the recent resistance of *Mycobacterium tuberculosis* to all known antibiotics. Antibiotic resistance genes are used generally to assure the removal (by carbenicillin or claphoran [cefotaxime]) of the carrier *Agrobacteria* after infection with plant transformation vectors. Also, the transformed bacterial, fungal, animal and plant cells are selectively isolated on the basis of antibiotic resistance. Insertional mutagenesis in bacteria is monitored by the inactivation of the

resistance genes upon integration. Various antibiotics are used all over the world in animal feed to increase animal productivity by 4–5%. Unfortunately, some of the antibiotic resistance genes may become incorporated into (facultative) human pathogens through animal products and waste and may pose a threat to human health. The soil seems to be an inexhaustible source of antibiotic resistance (D'Costa VM et al 2006 Science 311:374). The advantages gained by antibiotics in the feed may be partially compensated for by improved animal hygiene. ▶antibiotics, ▶pBR322, ▶lactamase, ▶aminoglycoside phosphotransferases, ▶clavulanate, ▶amoxicillin, ▶vancomycin, ▶tetracycline, ▶decoding on ribosomes, ▶LexA, ▶DNA polymerases, ▶biofilm, ▶fratricide, ▶SOS repair; Witte W 1998 Science 279:996 Walsh C 2000 Nature [Lond]: 407:775; Walker ES, Levy F 2001 Evolution 55:1110; Schlünzen F et al 2001 Nature [Lond] 413:814; Hughes D 2003 Nature Rev Genet 4:432; Miesel L et al 2003 Nature Rev Genet 4:442; Heymann DL 2006 Cell 124:671.

Antibiotics: A wide variety of chemicals produced by microorganisms and plants (also now by organic laboratory synthesis) that are toxic to other organisms. The major types of antibiotics are penicillins, ampicillin and cephalosporins (interfere with bacterial cell wall biosynthesis). Chloramphenicol binds to the 50S ribosomal subunit and blocks the peptidyl transferase ribozyme function during protein synthesis of prokaryotes. Tetracyclines inhibit the entry of the charged tRNA to the A site of the ribosome in prokaryotes. Streptomycin blocks the process of prokaryotic peptide chain elongation, and this as well as paromomycin, can also cause reading errors during translation. Spectinomycin inhibits the function of the 30S ribosomal subunit and reduces ribosomal translocation along with hygromycin B, edeine and pactamycin. Edeine has wide effectiveness but because of its toxicity is not useful as an antibiotic. Kanamycin, geneticin (G418), neomycin, gentamycin, and hygromycin bind to 30S and 50S ribosomal subunits and prevent protein synthesis or cause misreading. Erythromycin inhibits the translocation of the nascent peptide chain on the prokaryotic ribosomes. Lincomycin inhibits chain elongation on the prokaryotic ribosome by its effect on peptidyl transferase but not in eukaryotes. Rifampicin interacts with the β subunits of the prokaryotic RNA polymerase. Fusidic acid interferes with the binding of aminoacylated tRNAs to the ribosomal A site by inhibiting the release of prokaryotic elongation factor EF-G and also eukaryotic elongation factor eEF-2. Kasugamycin blocks the attachment of tRNA^{fMet} to the P site of the prokaryotic ribosome. Kirromycin actually promotes the binding

of elongation factor EF-TU-GTP complex to the prokaryotic ribosome but then inhibits the release of the elongation factor. Thiostrepton, from *Streptomyces azureus*, blocks prokaryotic peptide elongation from both prokaryotic and eukaryotic ribosomes. Cycloheximide interferes with peptide translocation on the eukaryotic ribosome. Anisomycin blocks the peptidyl transferase on the eukaryotic ribosomes and is comparable in effect to that of chloramphenicol in prokaryotes. Streptolydigin does not block RNA initiation but interfere with the elongation of the RNA chain in prokaryotes. Ciprofloxacin interacts with DNA gyrase. Actinomycin D inhibits, primarily, RNA polymerase II and to a lesser extent the other RNA polymerases but not DNA polymerase in either prokaryotes or eukaryotes; α -amanitin also inhibits eukaryotic RNA polymerase II and in very high concentration Pol III but not Pol I. Pactamycin blocks the eukaryotic initiator tRNA^{Met} to attach to the P site of the ribosome. Showdownmycin interferes with the formation of the eukaryotic eEF-tRNA^{Met} complex. Sparsomycin is a eukaryotic peptide chain translocation blocker; it is not very effective against microbes but works as an anticarcinogen. Cefotaxime (synonym claforan), carbenicillin, and vancomycin are more effective as antibacterial agents than their toxicity to eukaryotic cells and are frequently used in plant tissue culture to prevent bacterial growth. Macrolide antibiotics block the exit tunnel of the peptides on the ribosome. Antibiotics, which interfere with protein synthesis on prokaryotic ribosomes, cause similar damage to the ribosomes of eukaryotic organelles (mitochondria, plastids). The availability of antibiotics in the 1940s opened a new era in medicine and they became, in the 1970s, the most important selectable markers for the construction of vectors for genetic engineering. Antibiotics are used for selective isolation of various genetic constructs in microbial, plant and animal cell genetics. The number of antibiotics is continuously increasing because of the need for effective new drugs since microorganisms develop resistance to the old antibiotics. *Staphylococcus aureus* bacteria are resistant to all antibiotics except vancomycin and it will only be a matter of time when resistance mutations will develop to this too. Actually, fosfomycin (see Fig. A88) is effective against methicillin and vancomycin resistant *S. aureus* (Higgins LJ et al 2005 Nature [Lond] 437:838). There are already

Figure A88. Fosfomycin

Enterococcus faecium strains that are resistant to vancomycin. The development of new antibiotics is becoming increasingly more difficult. A large fraction of the bacterial enzymes are not essential for infection because the metabolites they produce are available in the host cells. The existing antibiotics mostly target the enzymes that are essential for the pathogens and even a most comprehensive survey of the proteome of bacteria will probably reveal only few new targets (Becker D et al 2006 Nature [Lond] 440:303). Recently, a new class of antibiotics (platensimycin; see Fig. A89) was discovered that targets lipid biosynthesis and blocks the membrane system of a wide range of Gram-positive bacteria (Wang J et al 2006 Nature [Lond] 441:358).

Figure A89. Platensimycin

Antibodies: Specific immunoglobulins that react—as a cellular defense—with foreign antigens. Antibodies contain two light chains, either κ or λ and one of the five heavy-chains (μ , δ , γ , ϵ , α) and their variants. Both light and heavy-chains contain variable and constant regions. The specificity resides in the variable regions. Antibodies have specificities to about a million different antigens. This specificity is achieved with the aid of a much smaller number of antibody genes by differential processing of the transcripts, mutation, recombination, gene conversion, and transposition within the families of immunoglobulin genes (see Fig. A90). Antibodies are made by the lymphocytes and may be attached to their membrane or may become humoral antibodies (secreted into the blood stream by the B lymphocytes). One particular B cell synthesizes only one type of antibody molecules. Each B cell deposits the first 100,000 antibodies it makes in its plasma membrane and serves there for antigen receptors.

A

Figure A90. Antibodies have three main domains, the two Fab domains (Fragment antigen binding), including the light chains and parts of the heavy-chains and one Fc (Fragment crystalline) domain. The light chains have a size of about 23 kDa, the heavy-chains vary from 53 to 70 kDa. X-ray crystallography revealed the domains as 2×4 nm, oval or cylindrical in shape, and the polypeptide chain in each domain is folded in pleated β -sheets. Disulfide bonds hold the dimeric structure of the light and heavy-chains together in variable numbers, depending on the particular molecules. The inter- and intra-chain disulfide bonds are not shown, except at the proline-rich hinge area that provides the molecules with some flexibility. The IgM and the IgE antibody monomers lack hinges but have an additional C-terminal heavy-chain domain. At the amino end of the light and heavy-chains are the variable and hyper variable regions that determine the specificity of the antibody. This region includes approximately 100 to 115 amino acids. The specificity is determined by complementarity between antibody and antigen in the antigen-binding "pocket" arms of the antigen around the area. Induced mutagenesis of the complementarity region may substantially increase the effectiveness of the antibody (Thom G et al 2006 Proc Natl Acad Sci USA 103:7619). The various specificities are determined by combinations of the variable (V), diversity (D) and junction (J) genes that account for about 25% of the amino acid residues, and the remaining 75% are considered the framework. CDR1, CDR2 and CDR3 (shown by the dark bands) generally identify the complementarity determining regions. The variable regions in the light and heavy-chains are homologous. The constant regions (C) show very little variability within a species. There is a glycosylation site in the constant heavy-chain region within the Fc domain (*). Also, in the constant heavy-chains there are sites for binding the activator of the complement (- - -). The complement consists of about 30 different proteins of catabolic functions that are activated in a cascading manner after the binding of the antigen to the antibody and carry out the destruction of the foreign antigen

When a particular antigen binds to the B cell, it stimulates its clonal division and the production of more antibodies. These series of the antibody are then made at the amazing rate of about 2,000 molecules/second and then secreted into the blood plasma. An individual can make about 10,000 different heavy-chain variants and about 1,000 different light chain variants. Since these chains can combine freely,

the total number of different antibodies can be $10^4 \times 10^3 = 10^7$. IgM type antibodies (containing gamma immunoglobulin chains) occur at the largest concentration in the blood serum and their half-life is the longest. The general structure of the antibody molecules is diagramed here. Each antibody molecule has two identical antigen-binding sites (see diagram). The majority of the antigens have, however, several

to many antigenic determinants (epitopes). Some of these antigens may be built of repeating units and in these cases they are *multivalent* because they have multiple copies of the epitope. The binding between epitopes (e) and antibody (a) is a concentration-dependent, reversible process: $(a + e) \rightleftharpoons (ae)$. When the concentration of the epitope increases, the binding to the antibody is increasing and the intensity of the reaction is expressed by the *affinity constant*: $(k) = (ae)/(a)(e)$. When half of the (a) sites are filled $k = 1/e$, the values of (k) range from 5×10^4 to 10^{12} moles. Conformational diversity of the same antibody may result in affinity for multiple, distinct antigens (James LC et al 2003 Science 299:1362).

The *avidity* of an antibody for an antigenic determinant depends also on how many binding sites are available. The affinity is increasing with time after immunization (affinity maturation). Antibodies are involved in the destruction of invaders, either through stimulating the macrophage cells to phagocytosis, or by ions, using the complement enzymes or activating the killer cells. It was recently discovered that antibodies could generate H_2O_2 by oxidation of water with the aid of singlet oxygen ($^1O_2^*$). This ability adds a chemical to their repertoire of defense (Wentworth P et al 2001 Science 293:1806). Usually their turnover is rapid; the half-life of antibodies is days to a few weeks. By chemical modifications antibody/ligand complexes can be generated that do not dissociate and do not cross-react appreciably with other ligands (Chmura AJ et al 2001 Proc Natl Acad USA 98:8480). About 20% of the total plasma proteins represent a diverse set of antibodies. After the B lymphocytes respond to an antigen and differentiate into plasma cells, their rate of antibody production may reach 1,000 molecules/second after immunization (affinity maturation). Receptors (FcRn) of the Fc domain (see diagram) contribute toward the phagocytotic functions, cytotoxicity and to neonate immunity. In the maternal uterus, FcRn/IgG has been detected. The FcRn receptors transfer maternal humoral immunoglobulins to the newborn before the immune system of the progeny is activated. During nursing, the FcRn class receptors mediate the transfer of the IgG/FcRn complex through the milk. Antibody genes can be expressed not just in lymphoid cells but also ectopically, e.g., in bacterial cells when introduced by transformation. In such a system they may form inclusion bodies either in the cytoplasm or in the periplasmic space or may be present as soluble proteins secreted into the cytoplasm. In the periplasmic space disulphide isomerase-like and proline cis-trans isomerase (rotamase) proteins may exist that mediate folding of the antibodies or fragments. The prokaryotic chaperones may also participate in

the folding. In the *Camelidae* (camels and llamas), the antibodies contain only heavy-chain (Hamers-Casterman C et al 1993 Nature [Lond] 363:446) and the first domain of the constant region is absent although it is present in the genome (see Fig. A91); but it is not retained during mRNA processing (Nguyen VK et al 1999 Mol Immunol 36:515; Nguyen VK et al 2002 Immunogenet 54:39). The antibody-based immune system is restricted to vertebrates and is present in all gnathostomes (jawed vertebrates); but it is apparently absent from agnathans (jawless vertebrates), such as lamprey and hagfish (Klein J, Nikolaidis N 2005 Proc Natl Acad Sci USA 102:169). ▶immunoglobulins, ▶immune system, ▶complement, ▶monoclonal antibodies, ▶single-chain Fv fragment, ▶hybridoma, ▶antibody polyclonal, ▶recombinant antibody, ▶HLA, ▶lymphocytes, ▶T cell, ▶TCR, ▶B lymphocyte receptor, ▶killer cell, ▶antigen, ▶antigen presenting cell, ▶MHC, ▶neutralizing antibody, ▶immunization alloantibody, ▶natural antibody, ▶periplasm, ▶rotamase, ▶chaperone, ▶antibody engineering, ▶anti-idiotypic antibody, ▶anti-DNA antibody, ▶internal image antibody, ▶catalytic antibody, ▶plantibody, ▶antibody gene switching; Heyman B 2000 Annu Rev Immunol 18:709; Ravetch JV, Bolland S 2001 Annu Rev Immunol 19:275; antibody evolution by conformation selection and mutation: Zimmermann J et al 2006 Proc Natl Acad Sci USA 103:13722, <http://www.antibodyresource.com/onlineData.html>.

Figure A91. Camelid Antibody

Antibody Antigenization: The modification of the hypervariable region of an antibody by protein engineering in order to enhance the recognition of the new antibody to foreign epitopes by the B and T lymphocytes. ▶antibody, ▶antigen, ▶epitope, ▶B lymphocyte, ▶T cells

A

Antibody, Bispecific: A bispecific antibody has affinity to two different antigens. Such an antibody may not exist.

Antibody, Bivalent: A bivalent antibody has two antigen-binding sites.

Antibody, Chemically Programmed (cpAB): A small molecule is covalently added to an antibody and providing an extension for its effective range (Guo F et al 2006 Proc Natl Acad Sci USA 103:11009)

Antibody, Chimeric: Can be produced with the aid of genetic engineering by fusing the variable regions of one type to the constant region of another antibody. It can also be produced in vivo by homologous recombination in hybridoma cells or by using the *Cre-loxP* system. hybridoma, ►*Cre/loxP*, ►HAMA, ►primatized antibody; Presta LG 2006 Adv Drug Deliv Rev 58:640.

Antibody Detection: Antibody detection is possible through several procedures: antibodies bound to proteins expressed in *E. coli* are detected by I^{125} (isotope)-labeled antibodies that react to the species-specific determinants of the primary antibodies. Protein A labeled with I^{125} second antibody, conjugated to horseradish peroxidase (HRP) or HRP coupled to avidin, may be used to detect a second antibody coupled to biotin or by a second antibody conjugated to alkaline phosphatase, using radio-labeled ligands. Antibodies can also be detected by agglutination and complement fixation. In agglutination, a precipitate is formed upon the reaction. One of the procedures is the *Ouchterlony assay* where the antibody and the antigen are placed in the neighboring wells of agar plates; upon diffusion a visible precipitate is formed about midway between the two wells if the antigen (e) and antibody (a) recognize each other (see Fig. A92).

Figure A92. Ouchterlony test

The complement fixing procedure has a unique feature inasmuch as the complement binds only to the antibody that is complexed with the antigen. If the complement is fixed, adding red blood cells and a cognate antibody to the reaction mix, resulting in no hemolysis, it is proof of fixation of the complement and the procedure can be quantitated by employing a series of dilutions. ►antibodies, ►complement, ►immunostaining, ►antibody microarray

Antibody Effector Functions: These functions are carried out by activation of the complement system and by interactions of the antigen through the Fc domain receptors (e.g., FcγR) leading to ADCC. ►antibody, ►complement, ►FcγR, ►ADCC

Antibody Engineering: Antibody Engineering involves genetic modification of the immunoglobulin genes, particularly the complementarity determining regions of the antibody. ►antibody, ►humanized antibody, ►plantibody, ►phage display, ►immunotoxin, ►monoclonal ►antibody, ►transgenic, ►bispecific monoclonal antibody, ►Fv, ►gene fusion, ►antibody polymers, CDR; Maynard J, Georgiou G 2000 Annu Rev Biomed Eng 2:339.

Antibody Fusion: Antibody fusion constitutes gene fusions, which most commonly involve the antibody heavy-chain and enzyme-coding sequences (nuclease, glucuronidase, etc.) or toxins (e.g., angiogenin toxin, neurotoxin), cytokinins (interleukin 2, TNF, IGF), and labeling proteins (aequorin, avidin).

Antibody Gene Switching: is preceded by the pairing between members of the antibody constant heavy-chain gene families and the formation of loops that are then cut off at the stem. This cutting off/deletion produces different heavy-chain elements in the vicinity of the J (junction) genes. The site-specific switch then permits the expression of the genes that are moved to the vicinity of the J genes after the stem of the loop is cut off and the DNA strands are religated. The transcript is further processed by the removal of the introns. This is one of the mechanisms to generate greater diversity in the heavy-chain antibody proteins. The switching is stimulated by cytokines secreted by the T_H lymphocytes. In mouse cells, the IL-4 induces the switch from IgM to IgG1 or IgE. Interferon-γ causes switching from IgM to IgG2a and TGF-β mediates the switch from IgM to IgG2b or IgA or IgE. A defect in switching may result in Hyper-IgM syndrome and the patients thus become susceptible to infections because of low concentrations of IgG and IgA. The murine heavy-chain constant region has eight different genes. A switch region flanks each constant gene, except C_γ . The mammalian switch regions vary substantially yet they are highly repetitive, especially in Gs in the non-template strand. The switch repeats include AGCT and GGGGT subrepeats.

Upon transcription, the RNA:DNA hybrid forms in the switch region, in vitro, and the non-template strand remains single-stranded. At the switch regions, S γ 3 and S γ 2b loops form in the lipopolysaccharide (LPS)-stimulated B cells (see Fig. A93). Most of the recombination (>90–95%) occurs in these two switch

Figure A93. Antibody gene switching

regions respectively (Huang F-T et al. 2006 Proc Natl Acad Sci USA 103:5030).

The basic leucine zipper proteins of the Maf family and Bach transcription factors (Bach2, 6q15; Bach1 21q22.1) regulate the switching from IgM to other immunoglobulins in B cells and are critical for somatic hypermutation (Muto A et al 2004 Nature [Lond] 429:566). Activation-induced cytidine deaminase (AID) seems to be involved in the mediation of switching (Rush JS et al 2005 Proc Natl Acad Sci USA 102:13242). The deamination contributes to the formation of dU:dG lesions, and their resolution leads to class-switch recombination and somatic hypermutation (Rada C et al 2004 Mol Cell 16:163). Switching is different from the V(D)J recombination process. In the jawless (agnathan) fish, the lamprey variable lymphocyte receptors, composed of highly diverse leucine-rich repeats, are sandwiched between the amino- and carboxy-terminal of the receptors. This arrangement can generate large diversity when recombined for the anticipatory (adaptive/acquired) immune reaction (Pancer Z et al 2004 Nature [Lond] 430:174). Translocation between c-myc and IgH is also regulated by AID and uracil glycosylase (Ramiro AR et al 2006 Nature 440:105), a frequent cause of B lymphocyte malignancies. ▶immunoglobulins, ▶antibodies, ▶V(D)J, ▶RAG, ▶T_H, ▶immune system, ▶germline transcript, ▶somatic hypermutation, ▶hypermutation, ▶ectodermal dysplasia, ▶class switching, ▶MSH5, ▶acquired immunity, ▶AID (activation induced deaminase), ▶myc, ▶glycosylases; Kataoka T et al 1981 Cell 23:357; Revy P et al 2000 Cell 102:565; Stavnezer J 2000 Science 288:984; Honjo T et al 2002 Annu Rev Immunol 20:165; AID mechanisms: Honjo T et al 2004 Immunity 20:659.

Antibody, Intracellular: By introducing specific antibody genes into a cell and if the transgene is expressed, various processes, interactions between macromolecules, fixing enzymes in active or inactive states, modifying (binding) ligands, targeting intracellular signals, etc., can be explored. Tissue targeting vectors can be constructed for the introduction of genes to specific locations. In these systems, antibodies are coupled to viral vectors, liposomes, or directly to the passenger DNA. Antibodies can be targeted to T cell receptors (TCRs). Bispecific antibodies can be used to re-target effector cells to tumors. ▶KDEL, ▶monoclonal antibody therapies, ▶immune system, ▶viral vectors, ▶liposome, ▶T cell receptor, ▶monoclonal antibody therapies; Brekke OH & Sandlie I 2003 Nature Rev Drug Discov 2:52.

Antibody, Isomeric: Isomeric antibodies may exist in two conformational state and thus can bind two structurally distinct antigens. antibody, ▶antigen, ▶isomers

Antibody Lattice: An antibody lattice or alternating antigen-antibody complex is formed when the cognate antibody is in excess of the antigen, between the Fc domain of the IgG and the antigen. ▶antibody, ▶antigen

Antibody Microarray: An antibody microarray is the high-throughput profiling of a relatively smaller number of proteins (compared to mass spectrometry). Antibodies are spotted on solid surface and a complex mixture of cell lysates or serum labeled by a fluorescence tag are allowed to recognize the antibodies. Similarly, antigens can be spotted on glass and reacted with cognate antibodies. Allergens, glycans

A

and other molecules can be studied in an analogous manner. This procedure is well suited to various biological purposes. ▶protein profiling; Huang RP et al 2001 Anal Biochem 294:55; Sreekumar A et al 2001 Cancer Res 61:7585.

Antibody Mimic: An antibody mimic is a small synthetic polypeptide with specificity for a particular natural or synthetic epitope. ▶epitope, ▶antibody

Antibody, Monoclonal: ▶monoclonal antibody

Antibody, Monovalent: A monovalent antibody has only a single binding site for an antigen. Normally the antibody is divalent, i.e., it has antigen-binding sites at both of the light and heavy-chain variability regions. By linking together multiple binding sites the avidity of the antibody increases. ▶antibody, ▶antibody bispecific

Antibody, Neutralizing: It results in the loss of infectivity, which ensues when antibody molecule(s) bind to a virus particle, and usually occurs without the involvement of any other agency. As such this is unusual of an antibody and is paralleled only by the inhibition of toxins and enzymes (Dimmock NJ 1995 Rev Med Virol 5:165; Finke D et al 2003 Proc Natl Acad Sci USA 100:199). HIV-1 may escape from the neutralizing antibody by N-linked glycosylation of the viral *env* gene (Wei X et al 2003 Nature [Lond] 422:307). ▶acquired immunodeficiency

Antibody, Polyclonal: A polyclonal antibody is a collection of antibodies secreted by different B lymphocytes in response to the epitopes of the same antigen and are therefore not entirely identical. Human polyclonal antibodies can be obtained by transferring them into bovine embryonic cells and thus into calves both the heavy and the lambda-chains of immunoglobulin gamma genes on a human artificial chromosome vector. ▶epitope, ▶antigen, ▶monoclonal antibody, ▶recombinant antibody, ▶human artificial chromosome, ▶nuclear transplantation; Kuroiwa Y et al 2002 Nature Biotechnol 20:889.

Antibody Polymers: Antibody polymers are formed by fusion of immunoglobulin chains. In this process, the immunoglobulin μ chain tailpiece fuses to the C-end of the γ chain which may increase, by two orders of magnitude, the activity of the complement system. Also, simple IgM, IgG tetramers are more effective than dimers. ▶antibody, ▶immunoglobulins, ▶tailpiece, ▶complement, ▶pIgR

Antibody Preparation: Antibody preparation involves injecting an animal with a pure antigenic molecule. After 2 to 3 weeks the animal develops antibodies against the epitope. The animal is then bled and the antibody removed from the serum by precipitation

Figure A94. Antibody preparation

with the cognate antigen and further purified. Hundreds of different antibody preparations are commercially available from biochemical supply companies.

Antibody Purification: There are different methods of purifying antibodies. The protein antigen may be coupled to a cyanogen-bromide-activated Sepharose. The epitope then retains the cognate antibodies while all other antibodies flow through. Breaking the complex (with potassium thiocyanate, low-pH buffers, etc.) can then retrieve the antibody. The methods must be adapted to the different proteins. Another procedure is to adsorb antibodies to protein antigens immobilized on diazotized paper or nitrocellulose filters following electrophoresis by SDS-polyacrylamide gels. The antibodies are then eluted with a suitable buffer. Antibodies can be used for qualitative and quantitative assays of antigens, including immunoprecipitation, western blotting and solid-phase radioimmunoassays (RIA). ▶Sepharose, ▶epitope, ▶cyanogen bromide, ▶diazotized paper, ▶nitrocellulose filter, electrophoresis, ▶SDS-polyacrylamide gels, ▶immunoprecipitation, ▶radioimmunoassay

Antibody, Secondary: A molecule, cell, or tissue may be labeled with the cognate antibody (primary antibody). In order to boost the level of recognition, the primary antibody is reacted with another antibody (secondary antibody), labeled with an isotope (e.g., I^{125}) or a fluorochrome to obtain a stronger signal. ▶antibody, ▶fluorochromes

Antibody, Single Chain: ▶single-chain fragment Fv, ▶scFv

Antibody Valency: Specifies the number of antigen-binding sites. ▶antibody monovalent

Anticancer Agents: Include alkylating agents, cytotoxic and cytostatic agents, antibiotics (bleomycin, chlorambucil), topoisomerase inhibitors (etoposide, podophyllotoxin), ionizing radiation, etc. ▶chemotherapy, ▶cancer therapy, ▶cancer gene therapy, ▶ionizing radiation

Anticarcinogen: ▶antimutagens

Antichaperone: Antichaperone is a protein factor promoting aggregation of other proteins. ▶ [chaperone](#)

Antichromatin: Antichromatin is a state of the chromatin not conducive for active transcription. ▶ [chromatin](#), ▶ [pro-chromatin](#)

Anticipation: In successive generations it may appear as if the genetic trait (disease) would have occurred with an earlier onset in the more recent generations. Frequently this is, however, an artifact because when the investigator knows what is expected, the recognition becomes easier. There is also the possibility that individuals with early onset of the disease died early or failed to leave offspring. In the cases of diseases based on expansion of trinucleotide repeats there is a possibility of increased severity and earlier onset if the patients leave offspring. ▶ [ascertainment test](#), ▶ [trinucleotide repeats](#); Kovach MJ et al 2002 Amer J Med Genet 108:295.

Anticlinical Selection: An anticlinical selection is the selection that takes different directions in different environments compared to the *synclinal selection* when the direction is the same. ▶ [cline](#)

Anticoagulation: Blood coagulation is positively regulated by antihemophilic factors. Negative regulation (shutting down the coagulation pathway) is mediated by thrombomodulin, which binds thrombin and activates protein C, which in turn binds protein S and causes factors Va and VIIIa to be degraded. Thrombomodulin (an epidermal growth-factor like molecule) works by binding to thrombin at an exosite where otherwise thrombin would bind fibrinogen. Coumarin impairs the pro-coagulants thrombin, antihemophilic factors Xa, IXa and VIIa and the anticoagulant proteins C and S. Heparin enhances the inhibition of thrombin and factor Xa by antithrombin III. ▶ [blood clotting pathways](#), ▶ [antihemophilic factors](#), ▶ [thrombin](#), ▶ [exosite](#), ▶ [protein C](#), ▶ [protein S](#), ▶ [antithrombin](#), ▶ [vitamin K](#)

Anticoding Strand: An anticoding strand is the transcribed strand of DNA. ▶ [antisense RNA](#), ▶ [coding strand](#), ▶ [template strand](#), ▶ [sense strand](#), ▶ [plus strand](#)

Anticodon: An anticodon is part of the tRNA, which recognizes an mRNA code word by complementarity. It is one of the means of tRNA identity (see Fig. A95).

In the mitochondria the “universal” genetic code does not entirely prevail but different eukaryotic mitochondria (except higher plants) use a somewhat different codon dictionary. In these systems the anticodons are also different inasmuch as there are no separate tRNAs for each of the synonymous codons.

Figure A95. The Anticodon–Binding α -Helix Bundle of Bacterium tRNA^{Met} Synthetase. The Stick-and-Ball Structure shows the exposed side chains of the Amino acids (Courtesy of professor M. Konno. See also Sugiyama I et al 2000 Structure 8: 197)

Rather, the mtDNA codons are recognized in pairs or in four-member sets of codons, and the anticodon–codon interaction is by G•U pairing or the 5'-terminal U of the anticodon of the four-member set can pair with any of the four bases in the mRNA codon. Although there are 61 different sense codons in eukaryotes, there are only 54 anticodons in the universal code and 46 species of tRNAs and anticodons are sufficient for protein synthesis on the ribosomes. ▶ [tRNA](#), ▶ [genetic code](#), ▶ [wobble](#); Jukes TH 1984 Adv Space Res 4 (12):177.

Anticorrelation Genes: Have similar (analogous) function and can complement each other without substantial structural homology. Morett E et al 2003 Nature Biotechnol 21:790.

Antideterminant: Ribonuclease III, which processes about 20-bp double-stranded RNAs may not cut at any position because some Watson-Crick pairs interfere with scission and serve as an antideterminant. Such an antideterminant is, e.g., a 3-bp sequence from the selenocysteine-accepting tRNA (tRNA^{Sec}) and is an antideterminant for EF-Tu binding to this tRNA. ▶ [ribonuclease III](#), ▶ [selenocysteine](#), ▶ [EF-TU-GTP](#); Evguenieva-Hackenberg E, Klug G 2000 J Bacteriol 182:4719; Mohan A et al 1999 RNA 5:245.

Antidiuretic Hormone (vasopressin): Vasopressin is a small peptide hormone (ADH, M_r 1040) which increases water reabsorption in the kidneys and also blood pressure; it affects a variety of functions, including learning and behavior (aggression).

A

Nephrogenic diabetes insipidus an X-chromosomal human disease, with problems of maintaining water balance, fails to respond to ADH and is very similar to oxytocin; only two amino acid difference exists between the two. The structure of vasopressin is (see Fig. A96):

Figure A96. Antidiuretic hormone

It binds to receptor molecules in the plasma membrane in the kidneys and blood vessels and activates a specific membrane, phospholipase. The phospholipase then breaks the bond between glycerol and phosphate in phosphatidylinositol-4,5-bisphosphate and releases inositol-1,4,5-triphosphate and diacylglycerol. Vasopressin is encoded in the short arm of the human chromosome 20 along with oxytocin. [▶oxytocin](#), [▶diabetes insipidus](#), [▶phospholipase](#), [▶diacylglycerol](#), [▶inositol](#), [▶phosphoinositids](#), [▶nocturnal enuresis](#)

Anti-DNA Antibody: DNA is a poor antigen although in the autoimmune disease lupus erythematosus antibodies bind to DNA. Most DNA antibodies are not entirely specific because they bind to repetitive sequences. DNA tracts with stably bound proteins can, however, be used as antigens to specific sequences. [▶autoimmune disease](#), [▶antibody](#), [▶antigen](#); Stollar BD1986 CRC Crit Rev Biochem 20:1; Cerutti ML et al 2001 J Biol Chem 276:12769.

Antidote: Antidotes may be specific for reversing the toxic effect of a compound or nonspecific, e.g., an emetic, which induces vomiting.

Antiestrogen: Antiestrogens bind to the estrogen receptors and antagonize the effects of the hormones. Some, however, may have various levels of agonist activity. [▶tamoxifen](#), [▶raloxifene](#)

Antifreeze Protein: Antifreeze protein is present in several species of fishes living in the northern regions. The glycoprotein binds, through free OH groups of amino acids, to the first ice crystals and thus prevents the expansion of the ice and thus the fish is protected. In fishes there are more than eight forms of antifreeze protein, encoded as different proteins, yet they all contain tripeptide (Thr-Ala-Ala/Pro-Ala-) repeats. Mainly, Leu/Phe-Ile/Asn-Phe spacers link the monomers into a large polypeptide. The antifreeze glycoprotein (AFGP) genes usually contain two exons (the small for a signal peptide and the large for the antifreeze) separated by a single intron. Somewhat similar proteins may play a role in other organisms too. A very efficient antifreeze protein was

isolated from the insect *Tenebrio monitor*. A 36-kDa glycoprotein isolated from cold-acclimated carrot taproots is similar in sequence to polygalacturonase inhibitor proteins. The antifreeze protein in perennial ryegrass (*Lolium perenne*) appears to control more ice crystal growth than preventing freezing *per se*. [▶hysteresis](#), [▶cold hypersensitivity](#), [▶thermo-tolerance](#), [▶mealworm](#); Miao M et al 2000 Eur J Biochem 267:7237; Tomczak MM et al 2001 Biochim Biophys Acta 1511:255; Haymet AD et al 2001 FEBS Lett 491:285; Fairly K et al 2002 J Biol Chem 277:24073.

Antifungal Response: Insects defend themselves against fungi and microorganisms by the production of proteolytic enzymes, phagocytosis and by the production of antimicrobial peptides. In *Drosophila*, antifungal drosomycin and several antimicrobial/antibacterial peptides, cecropins, diptericin, drosocin, attacin and defensin are produced. The *spätzle*, *Toll*, *cactus*, and *dorsal* dorsoventral regulatory genes (corresponding to the mammalian NF-κB cascade) and the immunodeficiency gene, *imd*, mediate these responses. Several species of yeasts also exert antifungal action. [▶antimicrobial peptides](#), [▶morphogenesis in Drosophila](#), [▶host-pathogen relationship](#), [▶NF-κB](#)

Antigen: An antigen is a substance (usually a protein) which, either alone or in combination with a protein, elicits antibody formation. The protein antigen may be a large molecule with more than a single specificity due to its different subunits. A particular specificity of the antigen is determined by the epitope or a hapten conjugated with the protein molecule to form an antigen that reacts with the paratope of the antibody. The antigen is usually chopped into small fragments to be effectively presented to the lymphocytes. In some cases, internal sequences of the peptides are deleted by a proteasome system and, e.g., the originally 16 residues are spliced into a 9-residue antigen (Vigneron N et al 2004 Science 304:587). [▶antibody](#), [▶antigen presenting cell](#), [▶epitope](#), [▶paratope](#), [▶superantigen](#), [▶TI antigens](#), [▶lipid antigen](#); Kurosaki T 1999 Annu Rev Immunol 17:555; Zinkernagel RM, Hengartner H 2001 Science 293:251.

Antigen, Male Specific: [▶grafting in medicine](#), [▶H-Y antigen](#)

Antigen mimic: An antigen mimic is a short polypeptide used for screening specific paratope sites. [▶paratope](#), [▶antibody mimic](#)

Antigen Presenting Cell (APC): APC binds antigens, internalizes, processes and expresses them on their surface in conjunction with class II type molecules (one of the two type of molecules coded for by the

MHC genes). T cells recognize the presented antigen through their receptors. Helper T cells can be activated only in the presence of APC cells. Macrophages, dendritic (branched) cells and B lymphocyte cells express class II antigens and can thus serve as APC in vitro and in vivo macrophages and dendritic cells are apparently most important as APC (see Fig. A97).

The activation of helper T cells requires that the T cells and the APC be derived from animals (mice) syngeneic in region *I* of the MHC, and the production of the lymphokine, interleukin-1 (IL-1) and also family member, CD80. Macrophages are rich in lysosomes and can therefore rapidly break up antigens, whereas dendritic cells are poor in lysosome activity and have a more limited capacity for degradation. ▶antigen, ▶immune system, ▶T cell, ▶T cell receptor, ▶cytotoxic T cell, ▶clonal selection, ▶CD40, ▶HLA, ▶syngeneic, ▶lymphokines, ▶interleukins, ▶affinity maturation, ▶CD80, ▶CD1, ▶proteasomes, ▶MHC, ▶cross presentation; Jenkins MK et al 2001 Annu Rev Immunol 19:23; Guernonprez P et al 2002 Annu Rev Immunol 20:621.

Antigen Processing and Presentation: Antigen-presenting cells mediate the association of the native antigen with an MHC molecule and thereby the antigen is recognized by the T lymphocytes. The antigenic protein must be degraded to some extent by immunoproteasomes and processed for presentation to the MHC molecules. The processing takes place either within endosomal compartments of the cell or by the proteases secreted onto the surface of the immature dendritic cells. The final step in sizing the antigen is mediated by the enzyme ERAAP (endoplasmic reticulum aminopeptidase), which is upregulated by interferon γ (Serwold T et al 2002 Nature [Lond] 419:480). The MHC I associated peptides are generally shorter (9 ± 1 amino acids) than those associated with MHC II molecules that are derived from excreted proteins or other external proteins. Protein disulfide isomerase play a critical role in selecting MHC I molecules (Park B et al 2006 Cell 127:369). Usually the peptides enter the endoplasmic reticulum before their epitope is presented to the MHC molecules. If the

proteins lack the signal peptide to be transferred to the endoplasmic reticulum, their epitope may still be presented to the MHC molecules. The MHC Class II molecules are associated with the invariant I_i polypeptide that mediates the folding of the MHC II molecules in the endoplasmic reticulum and compartmentalizing the MHC II molecules for special peptide binding in the endosomes. The processing is mediated by cathepsins but an asparagine-specific cysteine endopeptidase may also be involved in degrading microbial antigens. ▶antigen presenting cell, ▶HLA, ▶lymphocytes, ▶immunoproteasomes, ▶endosome, ▶CLIP, ▶major histocompatibility complex, ▶TAP, ▶T cell, ▶cathepsins; York IA, Rock KL 1996 Annu Rev Immunol 14:369; Watts C 1997 Annu Rev Immunol 15:821.

Antigen Receptors: Antigen receptors are molecules on lymphocytes, responsible for the recognition and binding of antigens and antigen-MHC. ▶lymphocytes, ▶HLA, ▶receptor editing, ▶LFA, ▶CD2, ▶CD4, ▶CD8, ▶CD28, ▶CD45, ▶CTLA-4, ▶ICAM; Davis MM et al 2003 Annu Rev Biochem 72:717.

Antigene Technology: Antigene technology is used for triple helix formation. ▶triple helix formation

Antigenic Determinant: ▶epitope, ▶antibody

Antigenic Distance: The antigenic distance indicates the degree of similarity between/among antigens.

Antigenic Drift: Antigenic drift is the process by which the surface antigens of a pathogen may change by mutation. ▶antigenic variation, ▶phase variation, ▶*Borrelia*, ▶*Trypanosoma*

Antigenic Shift: Antigenic shift is a rearrangement in the genetic material of a virus resulting in an escape of the normal immune reaction. ▶antigenic drift, ▶antigenic variation

Antigenic Sin: Propensity of individuals who had been previously exposed to one virus and later encountered another virus variant of the same subtype, can make antibodies against the original viral hemagglutinin (HA) and also to the new one. This happens because

Figure A97. Antigen presenting cell

A

the memory B cells or the T cells were activated in a way specific for the progenitor virus. In some instances the variant virus may escape the immune defense of the host because the lymphocyte receptor is altered by mutation although the histocompatibility class I molecules may bind normally. ▶**hemagglutinin**, ▶**immune system**, ▶**antigen**, ▶**HLA**; Good MF et al 1993 *Parasite Immunol* 15:187.

Antigenic Variation: Antigenic variation is the property of prokaryotic and eukaryotic microorganisms to switch on the synthesis of different surface proteins to escape the immunological defense system of the host organisms. This goal is reached generally by transposition of genes relative to the promoter. In *Plasmodium falciparum*—the malaria parasite—the PfEMP1 (erythrocyte membrane protein family), encoded by ~60 *var* genes determine virulence by immune evasion and intravascular sequestration of the parasite in the host. The PfEMP1 molecules adhere to the surface of the red blood cells and evade detection by the immune system at this place of hiding. By multiplying in the capillaries, clogging and malaria develops. Evasion of the host immune system takes place by switching on one or another member of the PfEMP1 family members while the other alleles are excluded from function. The expression of the *var* genes is controlled by one or another of the upstream promoters (*upsA*, *upsB*, *upsC*). The telomeric *var* gene promoters have expression sites near the periphery of the nucleus where they move by an unknown epigenetic mechanism of chromatin remodeling. The A and B promoters are subtelomeric and interact with DNA-binding proteins whereas the C interacts with a *var* intron and controls silencing by using a silent information regulator, PfSIR2 (Voss TS et al 2006 *Nature [Lond]* 439:1004).

In *Borrelia hermsii*, a bacterium responsible for tick-borne relapsing fever, unexpressed loci of variant antigens copy into a single expression site at rates determined by extragenic features of silent loci rather than similarity between coding sequences of variants at silent sites and the single expression site. Two elements, in particular, determine switch rates. One set of elements overlaps the 5' ends of the expressed gene and the silent loci; greater sequence identity between elements was associated with a higher switch rate. The second set of elements flanks the expression site on the 3' side and occurs at variable distances downstream from the silent loci; the nearer an element is to a silent locus, the greater the switch rate of that locus into the expression site (Barbour AG et al 2006 *Proc Natl Acad Sci USA* 103:18290).

The bacterium *Neisseria gonorrhoeae* (responsible for a venereal disease—manifested primarily in males but transmitted through both sexes—and for the

various complications affecting both genders) relies on gene conversion for the purpose. ▶**phase variation**, ▶*Borrelia*, ▶*Trypanosoma brucei*, ▶**cassette model** of ▶**yeast**, ▶**gene conversion**, ▶**serotype**, ▶**epigenetic memory**; Barry JD, McCulloch R 2001 *Adv Parasitol* 40:1; Brayton KA et al 2001 *Proc Natl Acad Sci USA* 98:4130.

Antigenome: An antigenome in the replicative form of the viral genetic material it serves as a template for the synthesis of the genome. The term “Antigenome of a pathogen” is used to denote the array of antibody-binding epitope array. ▶**RF**, ▶**epitope**

Antihemophilic Factors: Blood coagulation requires the formation of complexes between serine protease coagulation factors and membrane-bound cofactors. Tissue thromboplastin, an integral membrane glycoprotein (Factor III, encoded at 1p22-p21) and proconvertin (VII, encoded at 13q34) are required to activate Factors IX and X. Mouse embryonic stem cells stimulated by fibroblast growth factor gave some evidence for correction of Factor IX deficiency (Fair JH et al 2005 *Proc Natl Acad Sci USA* 102:2958). Factor VIIa is a trypsin-like serine protease that also plays a key role in blood coagulation after binding γ -carboxyglutamic acid-containing domain. A plasma thromboplastin antecedent (XI, 4q35) activates Factor IX. Blood coagulation factor (VIII, Xq28), a 293-kDa plasma glycoprotein, acts in concert with Factor IXa, a proteolytic enzyme, to activate Factor X (Stuart Factor, 13q34). The latter, in turn, activates prothrombin (II, 11p11-q12) to thrombin that acts on fibrinogen (I, 4q28) to convert it to fibrin (responsible for loose clot). The fibrin-stabilizing factors (XIII, α -chain 6p25-p24; β -chain 1q31-q32.1) then generate the firm clots required for blood clotting. The Hageman factor (XII, 5q33-qter) activates thromboplastin antecedent (XI, 4q35). Accelerin (V, 1q23) stimulates the activation of prothrombin (II, 11p11-q12). In classic recessive X-chromosomal hemophilia, Factor VIII is defective. Factor IX (454 amino acid, Xq27.1-q27.2) deficiency, a partially dominant disorder of hemostasis (arrest of blood flow), is involved in Christmas disease. Blood clotting requires, in addition, calcium and thromboplastin (lipoprotein released into blood from injured tissues). A thromboplastin antecedent (XI, 4q35) deficiency is responsible for hemophilia C. The level of Factor IX increases as a normal condition with the advancing age and may be responsible for the increase in cardiovascular and thrombotic disorders among the aged. Bleeding disorders may be the consequence of mutations at the LMANN1/ERGIC-53 (18q21.3-q22) gene, encoding the lectin, mannose-binding protein, or the simultaneous defects of Factors V and VIII

(2p21-p16.3 and 18q21.3-q22). In the latter case the two proteins may not be folded properly and cannot be moved by the endocytotic vesicles (Zhang B et al 2003 Nature Genet 34:220). A similar condition arises by mutation in MCFD2 (multiple coagulation factor deficiency-2, 2p21p16.3). ▶hemophilia, ▶Hageman trait, ▶PTA deficiency, ▶prothrombin deficiency, ▶Stuart disease, ▶vitamin K-dependent clotting factors, blood clotting pathways, ▶coumarin-like drug resistance, ▶parahemophilia, ▶afibrinogenemia, ▶dysfibrinogenemia, ▶fibrin-stabilizing factor, ▶hypoproconvertinemia, ▶von Willebrand's disease, ▶platelet abnormalities, ▶hemostasis, ▶APC, ▶LINE, ▶tissue factor, ▶anticoagulation, ▶thrombopoietin, ▶warfarin; Bajaj SP et al 2001 J Biol Chem 276:16302; Hockin MF et al 2002 J Biol Chem 277:18322; Tuddenham E 2002 Nature [Lond] 419:23, <http://www.nlm.nih.gov/medlineplus/druginfo/medmaster/a694027.html>.

Antihormones: Antihormones are antagonists of hormones which alter the conformation of the hormones or bind to the hormone receptor sites and thus prevent the attachment of hormones to the hormone responsive elements (HRE) in the DNA and thus block the transcription of the hormone-responsive genes. ▶hormone responsive element, ▶conformation

Anti-Idiotypic Antibody: An anti-idiotypic antibody is a specific antibody that recognizes a particular paratope (idiotype) of an antibody and binds to it rather than to the epitope of the antigen. Homologous anti-idiotypic antibodies are produced within the species, whereas in different species heterologous anti-idiotypic antibodies are produced. The anti-idiotypic antibody may be generated in the laboratory by first exposing the cell to the epitope, an antigen. This specific antibody so obtained may give rise to another antibody, a mimic of the original. Also, other antibodies may arise in a similar manner, which may respond to the original and also to a mutant antigen. These antibodies may be capable of stimulation of B lymphocytes and T cells and thus both humoral and cellular immunity can be generated. Thus, anti-idiotypic vaccine production may become feasible for particular cases, e.g., against the poorly antigenic bacterial polysaccharides or mutant p53 proteins that do not suppress tumor formation. ▶antibody, ▶idiotype, ▶paratope, ▶internal image immunoglobulin, ▶epitope, ▶p53; Birebent B et al 2001 Crit Rev Oncol Hematol 39:117; Bhattacharya-Chatterjee M et al 2001 Curr Opin Mol Ther 3:63.

Antilog: An antilog is the inverse logarithm and it is obtained if the base is raised to the power of the logarithm. The antilogarithm for $\log_{10} x$ is 10^x and for $\ln(x)$ the antilogarithm is e^x . ▶logarithm

Antelope (blackbuck, *Antelope cervicapra*): the male is $2n = 31-33$, the female $2n = 30-32$. ▶antelope

Antimetabolite: Antimetabolite is a compound that binds to an enzyme but is not generally utilized as a substrate, and thus interferes with normal metabolism. ▶metabolism, ▶metabolite

Antimicrobial Peptides (AMP, RAMP): Antimicrobial peptides occur on, or in, animals and plants as a defense system. They can be linear molecules such as *cecropin* (moths, pig, *Drosophila*), making pores by lysis, *magainin* (frog skin) forming pores, or *bactenein* (bovine neutrophils) affecting membrane permeability. They include disulphides: *defensins* (in several organisms, Hoover DM et al 2001 J Biol Chem 276:39021) making pores, *tachyplesins* (in horseshoe crab), affecting potassium efflux, *protegrins* (pig leukocytes). Many of these peptide genes contain attachment sites for transcriptional activators related to NF- κ B, *Rel/Dorsal* oncogene. *Serprocidins* that are high molecular weight protease-like molecules: *protease 3* and *azurocidin* in mammals and *cathepsin G* in human neutrophils that inhibit metabolism. Lipopolysaccharide-binding proteins and bactericidal/permeability-increasing proteins, collectins are components of the mammalian defense system. A defensin-like peptide is expressed exclusively in the epididymis of rats. Plectasin, a defensin family peptide, was discovered in saprophytic ascomycete fungus *Pseudoplectania nigrella* and is highly effective against *Streptococcus pneumoniae* (Mygind PH et al 2005 Nature [Lond] 437:975). Most cells respond to invaders by the mediation of Toll receptors, which initiate and activate the production of antimicrobial peptides against Gram-positive bacterial infection through the peptidoglycan recognition protein (Gobert V et al 2003 Science 302:2126). *Mycobacterium tuberculosis* susceptibility in humans depends on the Toll-like receptor that triggers the upregulation of the vitamin D receptor leading to the induction of the cathelicidine antibacterial peptide (Liu. PT et al 2006 Science 311:1770). A synthetic library of linear peptide-like sequences consisting of alternating acyl chains and cationic amino acids prevents the formation of a stable secondary structure and appears promising as antibiotics (Radzishhevsky IS et al 2007 Nature Biotechnol 25:657). ▶antifungal response, ▶antibiotics, ▶opsonins, ▶nisin, ▶Toll, ▶*Mycobacterium*; Hoffmann JA et al 1999 Science 284:1313; Khush RS, Lemaitre B 2000 Trends Genet 16:442; Zasloff M 2002 Nature [Lond] 415:389; molecular pathways of *Drosophila* immunity: Hoffmann JA 2003 Nature [Lond] 426:33; degradation resistance by folding: Raimondo D et al 2005 Proc Natl Acad Sci USA 102:6309; insect antimicrobial systems: Uvell H, Engström Y 2007

Trends Genet 23:342; defensins database: <http://defensins.bii.a-star.edu.sg/>; http://nar.oxfordjournals.org/cgi/content/full/32/suppl_1/D590.

Antimitotic Agents: Antimitotic agents block or inhibit mitosis through ionizing radiation, radiomimetic chemicals and inhibitors of the cell cycle. ▶[radiation effects](#), ▶[cancer therapy](#), ▶[cytostatic](#)

Antimongolism Chromosome: A chromosome 21 deletion in humans that compensates in some respects for the syndrome accompanied by the trisomy of complete chromosomes 21 (Down's syndrome; by old name mongoloid idiocy). This deletion, G I, causes the formation of large ears, prominent nasal bridges, an antimongoloid slant of the eyelids, long fingers and toes, micro- or dolicephaly and hypo- γ -globulinemia (rather than an excess as in Down's syndrome). ▶[Down's syndrome](#), ▶[dolicephaly](#), ▶[microcephaly](#), ▶[agammaglobulinemia](#)

Antimorph: A (dominant) mutation, which antagonizes the function of the wild type allele (by competing for the substrate). dominant negative, ▶[killer genes](#)

Anti-Müllerian Hormone (AMH/AMS): The anti-Müllerian hormone is produced by the Sertoli cells. It masculinizes XX rodents whereas males deficient in AMH become pseudohermaphrodites. SF-1, SOX9 and WT1 regulate AMH. ▶[Sertoli cells](#), ▶[gonads](#), ▶[pseudohermaphrodite](#), SF-1, ▶[SOX](#), ▶[Wilms tumor](#)

Antimutagen: An antimutagen protects against the mutagenic effect(s) of other agents. Generally, hypoxia-reducing agents (such as dithiothreitol) lower the damaging effects of ionizing radiation. Inhibitors of microsomal mutagen activating enzymes (such as 9-hydroxyellipticine, gallic and tannic acids, carbon monoxide, selenium, etc.) may reduce the mutagenic effectiveness of chemicals. ▶[antimutator](#), ▶[mutagen](#), ▶[caffeic acid](#), ▶[polyphenols](#), ▶[methylguanine-O⁶-methyltransferase](#); Novick A 1955 Brookhaven Symp Biol 8:201.

Antimutator: An antimutator lowers mutation rate. An increased level of nuclease activity (editing function) and all other genetic repair mechanisms may act this way. Compounds that inactivate microsomal enzymes involved in conversion of promutagens into mutagens are also antimutagens, or mutations, which reduce oxidative stress. ▶[AP nucleases](#), ▶[ABC excinucleases](#), ▶[DNA repair](#), ▶[mismatch repair](#), ▶[mutator](#), ▶[proofreading](#); Reha-Kranz LJ 1998 Genetics 148:1551.

Antioncogenes: Antioncogenes are the normal alleles of some genes that, in the mutant state, incite tumors. For example, the cloned normal allele of the human retinoblastoma gene codes for a DNA-binding protein

and the cancer cells transformed by this gene are suppressed in proliferation. ▶[tumor suppressor genes](#)

Antipain: Antipain is a protease inhibitor (1–2 $\mu\text{g/mL}$) and is effective against cathepsin A and B, papain and trypsin protease enzymes.

Antiparallel Pairing: Antiparallel pairing of polynucleotide chains means that at the same end of the double helix one has 5' and the other has 3' ends of the paired nucleotides (see Fig. A98).

Figure A98. Antiparallel

Antiphospholipid Syndrome: Antiphospholipid syndrome is the endocytosis defect which involves greater risk of thrombosis, thrombocytopenia, and recurrent and spontaneous abortions. The antibodies may attack phospholipids, or the protein-phospholipid complex or proteins like $\beta 2\text{q}$ glycoprotein. ▶[endocytosis](#)

Antipodal: Refers to haploid cells (nuclei) located in the plant embryosac at the end opposite to the place of the egg and the micropyle. ▶[embryosac](#)

Antipyretic: An antipyretic is a fever reducing drug.

Antiport: Antiport is the membrane transport of substances in opposite directions. A substance could also be sequestered through the antiport within another compartment. The Na^+/H^+ antiporters in different organisms (bacteria/plants/humans) determine the sodium/proton balance in the cells and are keys to adaptation to high salinity or extreme pH. It is supposed that the ion exchange is regulated by a conformational change elicited by pH at the entry site (Hunte C et al 2005 Nature [Lond] 435:1197)

Antirecombination: Antirecombination prevents recombination between not entirely homologous DNA strands, i.e., between homeologous DNA.

Antidepression: Refers to the situation when transcription factors bound to the DNA upstream of the promoters interfere with the binding of unspecific DNA binding proteins, which normally exert repression. ▶[insulator](#)

Antirestriction Mechanisms: Antirestriction mechanisms are those which prevent the cleavage of the DNA by different mechanisms, e.g., methylation of critical bases (e.g., phages T2, T4, SP β), inhibition of the endonuclease (e.g., T3, T7 phages), enhancing host-encoded methylase (phage λ), carrying hydroxymethyl cytosine in place of cytosine (T-even phages), 5-hydroxymethyluracil substitution for thymine (SPO1, SP8, $\phi 25$), reducing certain vulnerable

restriction sites in their DNA (f29), etc. ▶restriction endonucleases, ▶restriction-methylation; King G, Murray NE 1995 Mol Microbiol 16:769.

Antiridge: ▶ridge

Antirrhinum majus (snapdragon): Is a higher plant of the *Scrophulariaceae* family ($2n = 16$). It is an attractive autogamous flowering plant and a favorite in genetic and cytogenetic studies. A large collection of mutants and transposable elements are available (see Fig. A99). ▶TAM, ▶snapdragon, ▶peloric; <http://www.antirrhinum.net/>; <http://www.mpiz-koeln.mpg.de/english/research/saedlerGroup/schwarzSommer/index.html>.

Figure A99. Antirrhinum

Antisense DNA: library can be used for transformation and isolation of mutations or for other purposes of preventing gene expression. The 25-base oligodeoxyribonucleotide phosphorothioate (TCTTCCTCTC TCTACCCACGCTCTC, Hybridon, Inc., trade name GEM 91) binds to the translation initiation site of the *gag* gene of the HIV-1 pathogen of acquired immunodeficiency and may inhibit the production of new infectious particles because of the defect in packaging. The human L1 (LINE) retrotransposon has two promoters, a sense promoter that directs the transcription of the full-length L1 tract and an antisense promoter that drives in the opposite direction and into adjacent sequences and thus generates chimeric transcripts. Both promoters are situated within the 5' non-translated region of L1 (Nigumann P et al 2002 Genomics 79:628). Antisense transcripts occur not only in tumors but also in normal cells. In the mouse, 72% of the transcriptional units (TU) overlap with some transcripts of the opposite strand. From all Tus, (4520) are full-length sense/antisense pair transcripts. Antisense transcription is different in different chromosomes; it is lower in the X chromosome than in the autosomes (RIKEN 2005 Science 2005 309:1564). Antisense transcripts have a regulatory and evolutionary role to play and do not appear to be due to accidental leakage (Dahary D et al 2005 Genome Res 15:364). ▶OL(1)p53, ▶Bcl, ▶antisense RNA, ▶aptamer, ▶peptide nucleic acid, ▶antisense technologies, ▶cancer gene therapy, ▶G3139, ▶acquired immunodeficiency, ▶HIV,

Antisense Oligodeoxynucleotide (AS ODN): ▶antisense DNA, ▶antisense RNA, ▶selection and design: <http://www.bioit.org.cn/ao/aobase/>.

Antisense RNA: Is a transcript of a gene or transposon that may inhibit translation by pairing with the 5' end of the correct (sense) mRNA and thus prevent its ribosome binding and expression. In several bacterial plasmids, by inhibiting the synthesis of the replication initiator protein, the antisense RNA limits copy number. Some synthetic oligonucleotide analogs may block replication and transcription, interfere with splicing of exons, disrupt RNA structure, destabilize mRNA by interfering with 5' capping of mRNA, inhibit polyadenylation, activate ribonuclease H. When coupled to alkylating agents they can cross-link nucleic acids at the recognized sequences, can be used as vehicles for targeted DNA cleavage, may inhibit receptors, etc. The various functions require a large variety of specific antisense constructs. Usually, the antisense oligonucleotides are 12–50-nucleotide long. According to calculations in the human genome, any 17-base sequence occurs only once, and in the mRNA populations, 13mer residues are unique. Shorter sequences do not have sufficient specificity. Long antisense sequences may have self-binding tracts that may cause lowered affinity for their target. Natural antisense RNA transcripts (NATs) occur in all types of biological systems, from viruses to higher eukaryotes. This fact indicates that in eukaryotes both strands of the DNA may be transcribed. In the human genome, 2,667 loci were reported as showing transcripts of the complementary strands (Yelin R et al 2003 Nature Biotechnol 21:379). In *Arabidopsis* ~30% of the annotated genes displayed significant antisense RNA expression (Yamada K et al 2003 Science 302:842). The cis-NATs are transcribed at the same locus but from the opposite strand of the DNA. The trans-NATs are transcribed at sites different from that where encoding of the sense transcript takes place. The trans-NATs can regulate the expression of several genes like the microRNAs (Wang, X.-J. et al. 2005 Genome Biol 6: R30). Among five species of fungi, the number of genes involved with antisense transcripts is variable (Steigle S, Nieselt K 2005 Nucleic Acids Res 33:5034).

Antisense RNA (or DNA) was expected to become an important therapeutic tool for fighting infections and cancer. This technology is still under development for finding cures against cytomegaloviruses, HIV1, Papilloma virus, autoimmune diseases (arthritis, etc.), leukemia (CMV) and blocking the immune

A

system in case of organ transplants. Surprisingly, the antisense RNA may trigger an immune reaction because the CpG blocks are unmethylated and the animal immune system responds to them as to bacterial molecules. In bacteria these bases are largely unmethylated in contrast to eukaryotes where a substantial fraction of the DNA is methylated. The phosphorothioate oligodeoxynucleotides or oligoribonucleotides are taken up by a variety of cell types, including some prokaryotes (*Vibrio*), and bind either to DNA, RNA or protein. Phosphorothioate LD₅₀ is about 750 mg/kg. Antisense RNAs may block embryonic development and can be used to inhibit gene expression at defined stages. Although antisense RNA is supposed to be very specifically for the intended target, it may affect several genes that have short or long sequences homologous to the target. A deletion in the hemoglobin gene cluster juxtaposes another gene (LUC7L, an U1Snrp component) to the HBA2 gene, which normally is situated 335–337 bp downstream from the polyA addition site of HBA2 and transcribed in the opposite direction of the hemoglobin gene. The LUC7L is also truncated by the deletion and thus lacks the termination signals and consequently its transcript fuses with the CpG island of HBA2. This condition generates an antisense RNA, which causes complete methylation of the island and silencing of the intact HBA2 and thereby α -thalassemia (Tufarelli C et al 2003 Nature Genet 34:157). In addition, the antisense RNA may bind and affect different proteins as an aptamer. Furthermore, the nucleic acid degradation products concomitant or following the administration of the antisense RNA may also result in unspecific inhibition in the cells.

Antisense Strand of DNA: An antisense DNA strand is the template strand of DNA from which the mRNA or other functional, natural RNAs, are replicated as complementary copies. ►antisense RNA

Antisense Technologies: Use RNA and DNA targets for the suppression or modification of gene expression. The antisense molecule then blocks the synthesis of RNA and protein (see Fig. A100). Various forms of antisense molecules have been used (see antisense RNA); for antisense DNA technology, the nucleotides are ligated, for example, e.g., by phosphorothioate linkage and not by the normal phosphodiesterase linkage in order to protect the antisense strand from nuclease attack. For the production of antisense nucleic acids, the oligonucleotides are modified either in the base of the sugar or through changes in the sugar phosphate background. The good antisense molecules are expected to allow for RNase H activity to remove the natural target (preventing its translation) and then bind stably to DNA, blocking protein synthesis. The modification usually prevents enzymatic disposal of the antisense constructs. The antisense sequences may have side effects. Guanine-rich antisense sequences may have an undesirable affect on the telomerase enzyme, may form quadruplex structures, interfere with replication of the chromosomes, and may bind to proteins and may modify their function. In order to minimize these deleterious consequences various alterations have been attempted. The number of phosphorothioates is reduced or in a five base sequence the terminals (“wings”) are modified whereas, in-between, an RNase H-competent 2'-deoxy-oligodeoxynucleotide “window” is preserved. This approach basically is the generation of an “artificial restriction endonuclease” site. Another possibility involves targeting a mutant, activated oncogene by a single mismatch antisense RNA. The mismatch is expected to reduce the chance of cleavage at the heteroduplex site, but increase the chance of cleavage by RNase H at the oncogenic mutation and the perfectly matched mutant mRNA,

Figure A100. Antisense technologies

thus achieving suppression of malignancy. Antisense oligonucleotides also have therapeutic applications by correcting for defects in mRNA splicing, to induce exon skipping and restoring normal reading frames in cases when deletion or nonsense mutation cause the disease (Aartsma-Rus A et al 2004 *Am J Hum Genet* 74:74). A two exon skipping may change the more serious symptoms of Duchenne muscular dystrophy to the milder Becker type. Besides these changes, good uptake should be secured, e.g., by the use of cationic lipids and by assuring membrane permeabilization with the stability of the internalized oligonucleotides. The nerve cells apparently take up oligonucleotides more readily than other type of tissues if introduced by injection. There however is a blood/neuron barrier after intravenous or intraperitoneal applications. Antisense constructs readily target the liver and kidneys, but the degradation and excretion are most rapid in and from these tissues. Endocytosis and pinocytosis can take up antisense oligonucleotides but then they are usually locked up in the vesicles within the cells. When injection or electroporation introduces the antisense molecules, they may reach the nucleus. The half-life may be less than 5 min and within 10 h half the antisense oligonucleotides are lost. The antisense construct may have a variety of effects on the cells and the observed consequences may be the result of non-antisense type of action. The antisense DNA oligonucleotides usually target the AUG initiator codon, the 5' cap, the first splice acceptor, the polyadenylation, or the translocation breakage point site in cancer. The actively transcribed RNA is a superior target. At the proper dosage the AO have minimal or no effect on normal cells but may be quite effective. (►antisense RNA, ►fruit ripening, ►peptide nucleic acid, ►triple helix formation, ►methylphosphonates, ►phosphoramidate, ►phosphorothioates, ►cancer gene therapy, ►ribonuclease H, ►TFD, ►PKA, ►mixed backbone oligonucleotides, ►aptamer, ►G3139, ►BCL, ►fomivirsen, ►cationic lipid, ►tricyclo-DNA, ►muscular dystrophy; Galderisi U et al 1999 *J Cell Physiol* 181:251; Cotter FE et al 1999 *Biochim Biophys Acta* 1489:97; Kushner DM, Silverman RH 2000 *Curr Oncol Rep* 21:23; Astriab Fisher A et al 2002 *J Biol Chem* 277:22980; Fu C et al 2002 *Anal Biochem* 306:135; Sazani P et al 2002 *Nature Biotechnol* 20:1228.

Antisense Transcript: ►antisense RNA

Antiserum: An antiserum is a blood serum that contains specific antibodies obtained from an animal after natural or artificial exposure to an antigen. Antisera are collected from the blood of fasted animals by centrifugation and allowed to clot at room temperature. The clot is then discarded and the straw-colored

serum may be preserved either by lyophilization and stored at room temperature or at 4° with 0.02% sodium azide or deep frozen at -20° to -70°C. The antisera generally contain polyclonal antibodies.

►antibody polyclonal, ►monoclonal antibody

Antiserum Purification: Of polyclonal antibodies by affinity chromatography on protein A-Sepharose columns. Protein A binds the Fc domain of IgG of various sources but not with equal intensity. Further purification may be obtained by affinity chromatography with an immobilized antigen of high purity. ►antibody purification, ►antibody, ►immunoglobulins

Anti-Shine-Dalgarno Sequence: CCUCC is complementary to the GGAGG Shine-Dalgarno consensus near the 3'-end of the 16S rRNA molecule. ►Shine-Dalgarno

Antisuppression: Inactivates suppressor genes. ►suppressor gene, ►suppressor tRNA

Antitermination: Antitermination permits the RNA polymerase to ignore transcription termination instructions such as bacterial rho and thus proceed through the termination signal. In phage λ , after the transcription of two *immediate early genes*, the RNA polymerase should stop. The switch to transcribe the next set of genes is controlled by gene N, transcribed from the left promoter (PL) and terminated by the rho-dependent tL1 terminator and cro, transcribed from the right promoter (PR) and terminated by the rho-dependent tR1 terminator. The product of the N gene is protein N (pN), an antiterminator that permits readthrough to the delayed early genes in both tL1 and tR1. Although pN has a half-life of about 5 min, transcription is maintained because N is part of the delayed early transcript. Gene Q is also part of the delayed early transcript and its product pQ is also an antitermination protein that allows, by readthrough, the transcription at the late promoter PR. The recognition site for pN is upstream at the N utilization sites, NutL and NutR; the former is near the promoter but the latter is near the terminator. pN can act on both rho-dependent and rho-independent systems. Different phages have different nut sites, yet all these work in a similar manner. The nut elements include boxA and boxB; the former is required for binding the bacterial antitermination proteins, used by phages as well as by bacteria. The boxB is a phage-specific element.

Mutations in bacteria (rpoB) interact with pN. The nus loci (A, B, G) are involved with transcription termination; nus E codes for a protein in the 30S ribosomal subunit (p10). The product of nusA is a general transcription factor interacting with p10 and it affects termination by binding to boxA. Gene nusG organizes the various Nus proteins that together

A

control rho-dependent termination, whereas the nusA product combined with pN may interfere with termination where it normally is supposed to take place. In *E. coli* antitermination involves also the ribosomal *rm* genes. This operon has in its leader sequence a boxA where the NusB-S10 protein dimer binds to the RNA polymerase as it passes through. This binding enables pol to continue transcription through the rho-dependent terminators of the transcript. Protein NusA does not bind to the bacterial RNA polymerase when it is associated with the σ factor but after pol attaches to the promoter, σ may be released and that provides an opportunity for transcription and for the formation of the core polymerase-Nus complex. After termination of transcription the pol complex is released from the DNA and the separation of Nus from pol takes place. Thus, the polymerase core enzyme may be in two alternative states, one with σ for transcription and another with Nus with the potential for termination of transcription. Antitermination may then be mediated through pN after the polymerase binds Nus. Gene Q of phage λ also has a role to play in antitermination by permitting, through its product, the passage over the terminator signals. Transcription is modulated by preventing termination of transcription at T-rich sequences that occur at random within the gene, but they dissociate the RNA polymerase from the DNA when it arrives at the T-rich region at the end of the gene and where termination of transcription is expected. Other antitermination (attenuation) proteins act in the amino acid operons of bacteria, and allow the expression of the operon only after the protein that mediates attenuation of transcription is made. Thus, attenuation is not always dependent on the presence of an excess of charged specific tRNAs that slow down transcription when the supply of this particular amino acid is sufficient. In eukaryotes the Pol II-transcribed U1-RNA is involved in proper processing of the 3'-ends of the RNA used for reinitiation of transcript elongation. ▶attenuation, ▶RNA polymerases, ▶rho, ▶lambda phage, ▶half-life, ▶rm, ▶transcription, ▶ σ transcription termination in prokaryotes, ▶T box, ▶terminator, ▶transcription termination in eukaryotes, ▶rho factors, ▶tryptophan operon, ▶hut ▶operon; Mason SW, Greenblatt 1992 J Biol Chem 267:19418; Yarnell WS, Roberts JW 1999 Science 284:611, Grundy FJ et al 2002 Proc Natl Acad Sci USA 99:11121.

Antithrombin (AT-III, 1q23-q25): Is an α -globulin, neutralizing the blood clotting contribution of thrombin. Antithrombin—especially when cleaved at the COOH-terminal loop—blocks angiogenesis and tumor development. ▶thrombin, ▶blood clotting pathways, ▶antihemophilic factors, ▶protein C,

▶protein S, ▶dysfibrinogenemia, ▶angiogenesis, ▶anticoagulation

Antitoxin: ▶immunization

Antitrypsin Gene (AAT or PI): In the human chromosome 14q32.1 prevents the activity of the protease trypsin and elastase. The α -antitrypsin gene is supposed to be involved in pulmonary emphysema (increase of lung size because dilatation of the alveoli [the small sacs] of the lung) and liver disease. Different mutations may lead to one or the other, or to both of these diseases. The so-called Z mutant group prevents the exit of the AAT protein from the liver, where it is synthesized, and as a consequence the liver disease (cirrhosis) appears. Smoking may increase the chances of the development of cirrhosis in the individuals of ZZ genotype by 3 orders of magnitude. The incidence of AAT deficiency is about 8×10^{-4} in the white population of the USA. The total length of the α -antitrypsin gene is 10.2 kb with coding sequences of 1,434 bp. Oral administration of 4-phenylbutyric acid facilitates the release of AAT from the endoplasmic reticulum and as a “chemical chaperone,” may prevent the injuries resulting from AAT deficiency. The 14q32 chromosomal site includes the serpin gene encoding the corticosteroid-binding globulin (CBG) and a DNase-1 hypersensitive site. The AAT gene can be inserted into sheep eggs and under favorable conditions the milk may contain the protein it encodes. ▶emphysema, ▶cirrhosis of the liver, ▶liver cancer, ▶endoplasmic reticulum, ▶serpin, ▶corticosteroid, ▶DNase hypersensitive site, ▶acquired immunodeficiency; Crystal RG 1989 Trends Genet 5:411; Brigham KL et al 2000 Hum Gene Ther 11:1023.

Antivector Cellular Immunity: Antivector cellular immunity in a vaccination may cause a serious problem if the vector, e.g., adenovirus, occurs in the population and if the animal/human cells have already developed antibodies against a particular serotype, thereby diminishing the effectiveness of such a vector. Antivector immunity can be circumvented by the use of a chimeric vector. In a novel vector the hypervariable region of the rare adenovirus serotype Ad48 replaced, in a rAd5 adenovirus-derived vector, the seven short hypervariable regions of the Ad5 hexon protein. The engineered vector expressed well the simian HIV Gag protein in naïve mice and rhesus monkeys and it did not show neutralizing suppression. Such a construct may open a new approach to vaccination and gene therapy (Roberts DM et al 2006 Nature [Lond] 441:239). ▶human gene transfer, ▶gene therapy, ▶HIV, ▶acquired immunodeficiency, ▶hexon

Antiviral Antibodies: Result when immunization against some viral diseases is not fully successful. Monoclonal (or enriched polyclonal) antibody therapies have been considered against human respiratory syncytial virus (RSV), rabies, hepatitis B and C, herpes simplex viruses, cytomegalovirus and acquired human immunodeficiency (HIV). These preparations may be administered intramuscularly. ► **monoclonal antibody therapies**

Antiviral Protein: Zinc-finger anti-viral protein (ZAP) is a host antiviral factor that specifically inhibits the infection of cells by Moloney murine leukemia and multiple members of the alphavirus family, including Sindbis virus (SIN). An overexpression of ZAP prevents the accumulation of the viral RNA in the cytoplasm. The N terminus of ZAP contains four CCCH-type zinc-finger motifs. ZAP binds directly to specific viral RNA sequences through these zinc-finger motifs. The target sequence of ZAP in MLV was mapped to the 3'-LTR, and the target sequences in SIN were mapped to multiple fragments, but no obvious common motifs have been found in these sequences yet. Particularly, ZAP does not target ARE-containing mRNAs. Despite the lack of primary sequence homology, ZAP shares considerable similarities with tristetraproline (TTP). Both ZAP and TTP directly bind to their cognate target RNAs, and the zinc-finger motifs are required for the binding. ZAP directly interacts with the exosome, and it seems that ZAP destabilizes RNA by directly binding to the target RNA and recruiting the exosome to degrade the target RNA. Type I interferons (IFNs) play an essential role in the host response to viral infection through the induction of numerous IFN-stimulated genes. IFN-stimulated gene 15 (ISG15) is an ubiquitin homolog that is rapidly up-regulated after viral infection, and it conjugates to a wide array of host proteins. It appears to be a novel antiviral molecule with activity against both RNA and DNA viruses and can provide a target for the development of therapies against important human pathogens

(Lenschow DJ et al 2007 Proc Natl Acad Sci USA 104:1371). ARE, ► **exosome**, ► **tristetraproline**, ► **zinc finger**; (Guo X et al 2007 Proc Natl Acad Sci USA 104:151).

Antizymes: Antizymes are proteins that bind to enzymes and direct their degradation by proteasomes without ubiquitin (see Fig. A101). The proximal or distal products of the enzymes they inhibit induce their synthesis. Antizymes regulate polyamine enzymes such as ornithine decarboxylase. Antizyme (AZ) ornithine decarboxylase (ODC) fusion proteins provide the means of targeted protein destruction by proteasomes without prior ubiquitination (Matsuzawa S-i et al 2005 Proc Natl Acad Sci USA 102:14982; see diagram redrawn). ► **proteasome**, ► **polyamines**, ► **ubiquitin**; Coffino P 2000 Proc Natl Acad Sci USA 97:4421; Chattopadhyay MK et al 2001 J Biol Chem 276:21235.

Antley-Bixler Syndrome (trapezoidocephaly-synostosis syndrome): Is a defect in bone formation, abnormality of the face and other developmental anomalies due to mutation in the fibroblast growth factor receptor 2 (FGFR2) gene. ► **craniosynostosis syndromes**, ► **fibroblast growth factor**, ► **Apert or Apert-Crouzon syndrome**

AP: ►amino purine, ►base analog mutagen

AP1, AP2, AP3, AP4, AP5 (activated protein): Is a group of transcription factors. AP1 is similar to the one coded for by the chicken virus, oncogene *v-jun*. The human gene at chromosomal location 1p32-p31 shows 80% homology to the avian viral protein gene; their binding is greatly enhanced by the *fos* oncogene. AP1 generally appears as a heterodimer of Jun and FOS and Fra1n yeast AP1 has a homolog, GCN4, and the mammalian homolog is TFIID. The yeast and their mammalian factors can substitute for each other. This family of genes encodes the AP transcription factors where the binding motif is well conserved but other sequences may vary. These proteins bind to 5'-TGANTCA-3' consensus in DNA. AP2 binds only to TC-II but not to TC-I of the two identical and adjacent TC motifs (5'-TCCCCAG-3') upstream in the promoter of eukaryotic genes. AP2 binding affects enhancer activity. AP2 is an essential morphogenetic factor; in its deficiency head development is impaired. AP2 seems to have negative control on the cell cycle possibly by activation of p21 protein. AP3 binds to TC-II and to the adjacent GT-I motif (5'-G[C/G]TGTGGA[A/T]TGT-3') and also to the so-called core enhancer sequence (5' -GTGG[A/T][A/T][A/T]G-3') that is similar to parts of viral and prokaryotic enhancers but does not function by itself alone. AP4 binds to the 5'-CAGCTGTGG sequence that partially overlaps the GT-II motif (that is identical to GT-I, except two bases). AP5 binds to GT-II and adjacent sequences (5'-CTGTGGAATGT-3') and it is present in some cell types but not in others. The mouse Jun genes (chromosomes 4 and 8) are inducible by serum and the phorbol ester, 12-o-tetradecanoyl phorbol 13-acetate (TPA). The AP loci of *Arabidopsis* are completely different and mean apetala, a defective flower type.

AP180 (assembly protein): Mediates the assembly of clathrin for endocytosis. It is built of four adaptin proteins (100, 100, 50, 25 kDa, respectively).
 ►endocytosis

AP Endonucleases (APE): APE are basically repair enzymes, in both prokaryotes (2 enzymes) and eukaryotes (encoded in humans by HAP1m BAP1, APE/APEX) that cut DNA 5' or 3' to modified (alkylated or otherwise mutated) DNA bases or at apurinic and apyrimidinic sites from where

glycosylases have already removed damaged purines or pyrimidines. Usually the first step is the recognition of the altered bases and the DNA sequence is cut in the vicinity. Then the exonuclease activity removes the damaged section and creates a gap. After that a repair synthesis adds the correct bases to the 3'-OH ends, using the undamaged strand of the double helix as a template. Ligation by covalent bonds restores the integrity of the DNA. The glycosylases have some specificity for deaminated cytosine residues; the uracil-*N*-glycosylase removes uracil residues and the hypoxanthine-*N*-glycosylase removes hypoxanthines formed by deamination of adenine. These endonucleases have thus antimutator activities. The eukaryotic DNA uses pol β or pol δ and pol ϵ for filling the gap. ►antimutator, ►DNA repair, ►glycosylases, ►DNA polymerases, ►AP site; Sobol RW, Wilson SH 2001 Progr Nucleic Acid Res Mol Biol 68:57.

AP lyase: Releases apurinic and apyrimidinic sites from the DNA. ►apurinic site, ►apyrimidinic site, ►DNA repair

AP Site: ►apurinic site, ►apyrimidinic site

Apaf-1 (apoptotic protease activating factor/CED4): Interacts with caspase-9 after being activated by a cytochrome c and dATP. Then caspase-3 triggers the process of apoptosis. Somehow, the caspase-3 is linked to an endonuclease that cuts up chromosomal DNA in the cells destined for apoptosis. The Apaf gene (and some others) may be disabled by methylation and then apoptosis is interfered with and the road opens up to carcinogenesis, as it happens in chemotherapy-resistant metastatic melanoma. ►caspase, ►apoptosis, ►AIF, ►melanoma, ►Crohn disease, ►Huntington's disease; Bratton SB et al 2001 EMBO J 20:998; Soengas MS et al 2001 Nature [Lond] 409:207; molecular structure; Riedl SJ et al 2005 Nature [Lond] 434:926.

Apandry: Is the development of a diploid fruiting body of fungi by the fusion of two female nuclei, without the involvement of any male gamete.

APC: ►antigen presenting cell, ►Gardner syndrome, ASE1

APC: (anaphase-promoting complex; also called cyclo-some): It is a ~13-subunit, ~1700-kDa ubiquitin ligase protein complex containing CDC27, CDC16, CDC23, CDC26, Apc1p, Apc2p, Apc4p, Apc5p, APC9, APC10/DOC, Apc11p, Apc13 and bimE. APC is required for the progression from metaphase to anaphase. It is regulated by CDC20 and CDH1 in humans, *fzy* and *fzr* in *Drosophila* and the APC complex mediates ubiquitination of the superfluous cyclins and anaphase-inhibitory proteins such as

securin. Securin is required for the prevention of the separation of sister-chromatids until there is a firm association with the mitotic spindle fibers. Premature separation may result in aneuploidy. Protein Rael–Nup98 complex regulates securing degradation (Jeganathan KB et al 2005 Nature [Lond] 438:1036). This degradation is a requisite for exiting from each phase of the cell cycle and for entry into the next one. APC recognizes a 9 amino acid destruction box at the N-terminus of cyclins and some other proteins such as Pds1p/Cut2p anaphase inhibitors of yeasts or the spindle protein Ase1. ▶cell cycle, ▶CDCs, ▶bimE, ▶CDC20, ▶CDH1, ▶PDS, ▶ubiquitin, ▶E2, ▶Rbx1, ▶mitotic exit, ▶SCF, ▶tetra-trico sequences, ▶cullin, ▶SIC1, ▶PDS, ▶CDH, ▶D box, ▶sister chromatid cohesion, ▶securin, ▶separin, ▶nucleoporin, ▶Mnd2, ▶MPF, ▶substrate ordering, ▶Evi oncogene; Page AM, Hieter P 1999 Annu Rev Biochem 68:583; Schwab M et al 2001 EMBO J 20:5165; Peters J-M 2002 Mol Cell 9:931; Burton JL et al 2005 Mol Cell 18:533.

APC (activated protein C): Mediates cleavage and inactivation of antihemophilic factors Va and VIIIa with the cooperation of protein S. Its mutation which conveys resistance to blood coagulation may increase the risk of thrombosis by 5–10 fold and is the most common genetic cause of thrombosis. ▶protein C, ▶protein S, ▶antihemophilic factors, ▶thrombosis

APC: ▶adenomatous polyposis coli

APE: A apurinic/apyrimidinic endonuclease which recognizes these sites and cleaves the nucleic acid backbone as part of the repair function. APE activity is essential for cellular viability (Fung H, Demple B 2005 Mol Cell 17:463). ▶excision repair; Gros L et al 2004 Nucleic Acids Res 32:73.

APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy): Is a human autoimmunity syndrome involving a Zn-finger-like protein (a transcription factor) encoded in chromosome 21q22.3 by the gene called AIRE (autoimmune regulator). It also affects diabetes. ▶autoimmune disease, ▶Zinc fingers

Aperiodic Crystal: Is the term used for the chromosome by the physicist Erwin Schrödinger in 1944. (See Stent GS 1995 Ann NY Acad Sci 758:25)

Apert or Apert-Crouzon Syndrome: Involves acrocephaly (top of the head pointed), syndactyly (fingers fused) and mental retardation, although some individuals have near normal intelligence (see Fig. A102). The symptoms vary. Many of the cases are sporadic, in others, autosomal dominant inheritance is most likely; chromosomal rearrangement may also

Figure A102. Syndactyly. (From Bergsma, D. 1973 Birth Defects. By permission of the March of Dimes Foundation)

be present in some cases. This condition may also be caused by a defect in FGFR2 (fibroblast growth factor receptor), a protein tyrosine kinase, encoded at 10q25-q26. An insertion of an Alu element in the gene results in an alternately spliced keratinocyte growth factor receptor (KGFR). It is allelic to the Crouzon and Pfeiffer syndromes. ▶syndactyly, ▶mental retardation, ▶craniosynostosis syndromes, ▶Crouzon syndrome, ▶Pfeiffer syndrome, ▶Jackson-Weiss syndrome, ▶tyrosine kinase receptor

Apes: Closest to humans among animals. The human non-repetitive DNA sequences appear 98.7% identical to that of chimpanzees and 98.38% to that of gorillas. ▶primates, ▶chimpanzee; Hacia JG 2001 Trends Genet 17:637.

Apex: Refers to the top part of a cell, organ or any structure. The shoot apex of plants gives rise to the leaves, stem and inflorescence. The topless (*tpl-1*) dominant negative mutation of *Arabidopsis* transforms the apex into a root pole by suppressing transcription (Long JA et al 2006 Science 312:1520). ▶apical, ▶meristem

Apex: ▶arrayed primer extension

APH: Aminoglycoside phosphotransferases are enzymes phosphorylating aminoglycoside antibiotics, resulting in resistance to the antibiotics when the enzyme is present (introduced by transformation). ▶APH[3']II, ▶antibiotics, ▶aminoglycosides

APH(3')II: The aminoglycoside phosphotransferase enzyme inactivates kanamycin, neomycin and geneticin, commonly used antibiotic resistance markers for

A

transformation in tissue culture; synonymous with NPTII. ►aminoglycoside, ►antibiotics

Aphakia: A rare abnormality of the development of the embryonal lens caused by homozygosity of the human gene (1p32) FOXE3 (Valleix S et al 2006 Amer J Hum Genet 79:358). ►eye diseases

Aphasia: Aphasia is a form of brain injury resulting in the partial or complete inability to speak/understand language. About two-dozen human gene loci in several chromosomes may be responsible for aphasia. ►MASA syndrome

Apheresis: The separation of certain component(s) of a patient's blood and reinfusion of the remainder.

Aphidicolin: A tetracyclic diterpene of fungal (*Cephalosporium*) origin capable of blocking cell division and of antiviral activity; it is an inhibitor of DNA polymerase α , δ and ϵ (see Fig. A103) (Wright GE et al 1994 FEBS Lett 341:128). ►pol, ►terpenes

Figure A103. Aphidicolin

Aphids (*Aphididae*, homoptera): Aphids are small sucking insects and parasites of almost all plant species (see Fig. A104). At the site of the infestation the plants secrete honeydew that may attract other types of insects. They reproduce sexually at the end of the growing season after the males have differentiated. During the rest of the year only the females are found. The females reproduce parthenogenetically and their ca. 20 generations produce daily three to seven nymphs. Thus, the progeny of a single individual may run into billions during the year. Besides the direct damage by sucking, they spread viral diseases of plants. They can be controlled by contact or systemic insecticides. Aphids harbor 60–80 large cells (bacteriocytes), which contain the symbiotic *Buchnera* bacteria with ~100 copies of a genome of 640,681 bp. The bacteria supply essential amino acids to the aphids and rely on the host for cell-surface molecules, regulator genes and defense. The genotype of the symbiotic bacterium *Hamiltonella defensa* determines the degree of resistance of pea aphids (*Acyrtosiphon pisum*) to parasitoid wasp *Aphidius ervi* (Oliver KM et al 2005 Proc Natl Acad Sci USA 102:12795). In addition to the most common *Buchnera*, several other

bacterial species may cohabit with aphids and some are transmitted to the female by copulation and subsequently transmitted by the females during parthenogenetic reproduction (Moran NA, Dunbar HE 2006 Proc Natl Acad Sci USA 103:12803). ►parthenogenesis, ►parasitoid, ►biological control; Abbot P et al 2001 Proc Natl Acad Sci USA 98:12068.

Figure A104. Aphids

Aphrodisiac: Aphrodisiacs are compounds that stimulate sexual interest. ►yohimbine

Apical: Indicates top position. ►apex

Apical Dominance: Apical dominance is the phenomenon whereby the main central stem of the plant is dominant over (i.e., grows more strongly than) other side stems, and on a branch, the main stem of the branch is further dominant over its own side branchlets. The terminal bud of the main stem of a plant prevents or suppresses the formation of lateral buds or branches by auxin although auxin does not enter the lateral bud. In *Arabidopsis* the flavonoid pathway represses lateral outgrowth by diminishing the expression of auxin transporters in the stem and bud (Lazar G, Goodman HM 2006 Proc Natl Acad Sci USA 103:472).

Apical Ectodermal Ridge (AER): AER refers to the group of cells at the tip of the limb bud, involved in the differentiation of the limbs of animals. ►ZPA, ►morphogenesis, ►organizer

Apicomplexan Plastid: ►apicoplast

Apicoplast (apicomplexan plastid): An apicoplast is an acquired ~35 kb DNA-containing plastid type body (from endosymbiosis by green algae) in several parasites (e.g., *Toxoplasma*, *Plasmodium*). The *Plasmodium falciparum* apicoplast contains about 466 proteins, which are mainly nuclear encoded and imported with the aid of signal peptides and transit peptides. The apicoplast has an as yet undefined essential role in the survival of the parasite and can be targeted by antibiotics as a measure of defense. The 9.1 Mbp *Cryptosporidium parvum* genome (3,807 genes) has been sequenced. This intestinal parasite

has no apicoplast and its degenerate mitochondria has lost its genome (Abrahamsen MS et al 2004 Science 304:441). ▶[signal peptide](#), ▶[transit peptide](#), ▶[toxoplasmosis](#), ▶[microneme](#), ▶[rhoptry](#); Wilson RJM 2002 J Mol Biol 319:257; Foth BJ et al 2003 Science 299:705; Ross DS 2005 Science 309:72. *Cryptosporidium*, *Plasmodium* and *Toxoplasma* database: <http://ApiDB.org>.

Apigenin: A flavone plant pigment.

Apis mellifera (honeybee): The *Apis mellifera* refers to social insects with three types of individuals: diploid egg-laying queen ($2n = 32$), haploid drones, and sexually undifferentiated diploid workers. The drones hatch from unfertilized eggs. The difference between the queen and the workers is due to different nutrition of the larvae. ▶[arrhenotoky](#), ▶[honey bee](#); Robinson GE et al 1997 Bioessays 19:1099; mapping: Solignac M et al 2007 Genome Biol 8(4):R66; HGS 2006 Nature [Lond] 443:931.

Aplasia: Failure of the development of an organ or a type of tissue.

Aplastic Anemia: Aplastic anemia is a condition of several blood diseases where the bone marrow may not produce the cellular elements of the blood. ▶[anemia](#), ▶[Duncan syndrome](#)

Aplysia: Refers to a sea mollusc, an invertebrate small animal, frequently used for behavioral and memory studies. Hawkins RD et al 2006 Biol Bull 210:174.

APM: Affected—pedigree-member or APM is used in determining identity by descent and as a non-parametric method to detect linkage. ▶[IBD](#)

Apnea (familial obstructive sleep, snoring): Apnea is a breathing disorder of any age; it is also responsible for sudden infant death. The genetic basis for apnea is unclear. The composer Johannes Brahms might have been afflicted by it. ▶[narcolepsy](#); Palmer LJ et al 2003 Am J Hum Genet 72:340.

AP01: ▶[Fas](#)

Apo-2: ▶[TRAIL](#)

Apoaequorin: ▶[aequorin](#)

ApoBec1: Developmentally active, tissue-specifically distributed deaminase of 5-methyl-cytosine into uracil. ▶[AID](#)

APOBEC (apolipoprotein B mRNA-editing complex, CEM15): A cellular protein in defense against infection by single-strand RNA viruses (HIV, MLV, etc.). The eight genes are in human chromosome 22q12-q13. The protein packaged into the virion has a deaminase activity and changes the viral code

by converting C residues to U during reverse transcription. It also increases mutation of C/G → T/A (Schumacher AJ et al 2005 Proc Natl Acad Sci USA 102:9854). HIV fights this defense by suppressing its synthesis with the help of the Vif viral proteins. APOBEC3G deaminase is encapsulated by the HIV virion and facilitates restriction of HIV-1 infection in T cells (see Fig. A105). It binds at random to single-strand DNA and then jumps and slides processively to deaminate the CCC target motif. Sliding is lost when it encounters double-strand DNA but it continues jumping. Deamination is mainly in 3'→5' direction (Chelico L et al 2006 Nature Struct Mol Biol 13:392). Apobec also inhibits retrotransposition of endogenous retroviruses, LINE-1 elements and Alu sequences, which would still have the ability to move in the mouse genome (Esnault C et al 2005 Nature [Lond] 433:430; Bogerd HP et al 2006 Proc Natl Acad Sci USA 103:8780). The crystal structure of APOBEC-2 has been determined (Prochnow C et al 2007 Nature [Lond] 445:447). ▶[HIV](#), ▶[MLV](#), ▶[reverse transcription](#), ▶[retroviruses](#), ▶[LINE](#), ▶[retroviral restriction factors](#), ▶[AID](#); Gu Y, Sundquist WI 2003 Nature [Lond] 424:21; Zhang H et al 2003 Nature [Lond] 424:94; Harris RS, Liddament MT 2004 Nature Rev Immunol 4:868; Ribeiro AC et al 2005 J Virol 79:823; Turelli P, Trono D 2005 Science 307:1061.

Figure A105. APOBEC3G jumping and sliding during deamination

Apocrine Gland: The tip of the secreting organ is cast off with the secretion.

Apocytochrome B Gene (cob): Located in mitochondrial DNA of yeast; cytochromes are heme-containing proteins involved in electron transport. ▶[mitochondrial genetics](#), ▶[mtDNA](#)

ApoE: ▶[apolipoprotein](#)

Apoenzyme: The enzyme protein without the co-factors required for activity.

A

Apoferritin: The protein part (M_r 460,000) of ferritin, it contains ferric hydroxide clusters. About 20–24% of it is iron. Ferritin is the most readily available iron storage facility in the body. ► [ferritin](#)

Apogamety (apogamy): Embryo formation without fertilization from a cell of the embryo sac, other than the egg cell. ► [apomixis](#)

Apoinducer: DNA binding protein that stimulates transcription. ► [transcription](#)

Apolar: Molecules are generally insoluble in water because they do not have symmetrical positive and negative charges.

Apolipoproteins: Lipid-binding proteins in the blood that transport triglycerols, phospholipids, cholesterol and cholesteryl esters within the body. Apolipoproteins are not only the most important parts of the high-density lipoprotein (HDL), but are also preferred in order to lower the risk of coronary heart disease. Different classes are distinguished (APOA1, human chromosome 11q23.2-qter and mouse chromosome 9), APOA2 (1q21-q23), APOC2 (19q13.2), APOC3 and APOA4 are in the same region. APOA1 protects against cardiovascular disease by combination with high-density lipoproteins. Its crystal structure is known (Ajee AA et al 2006 Proc Natl Acad Sci USA 103:2126). Apolipoprotein B (human chromosome 2p24) exists in two lengths due to different editing of the transcript. APOC cluster is in human chromosome 19q13.2 and APOE appears to be linked to it. APOE deficiency causes hyperlipidemia and atherosclerosis. APOE isoform E4 is involved in dementia associated with HIV infection and Alzheimer's disease. ApoE ϵ 4 allele increases the risk of Alzheimer's disease whereas allele ϵ 2 lowers the risk (Dodart J-C et al 2005 Proc Natl Acad Sci USA 102:1211). Some other apolipoproteins are genetically less well defined. Apolipoprotein A-IV may protect against atherosclerosis without an increase of HDL levels. Apolipoprotein B deficiency lowers male fertility in knockout mice. Apolipoprotein L-1 is a high-density apolipoprotein bound particle that kills *Trypanosoma brucei brucei*, except subspecies *T. b. rhodesiense* and *T. b. gambiense*. Its killing effect is based on M60-W265 region, which is homologous to bacterial colicins and it lyses holes in lysosomal membranes (Pérez-Morgan D et al 2005 Science 309:469). ► [cholesterols](#), ► [fatty acids](#), ► [atherosclerosis](#), ► [arteriosclerosis](#), ► [HDL](#), ► [hyperlipidemia](#), ► [hypobetalipoproteinemia](#), ► [hyperlipoproteinemia](#), ► [abetalipoproteinemia](#), ► [lipoprotein lipase](#), ► [cholesterol](#), ► [megalin](#), ► [Alzheimer's disease](#), ► [AIDS](#), ► [Tangier disease](#), ► [hypo- \$\alpha\$ -lipoproteinemia](#), ► [Trypanosomatids](#); Mahley RW, Rall SC Jr 2000 Annu Rev Genomics Hum Genet 1:507;

Pennachio LA et al 2001 Science 294:169; Davidson WS, Thompson TB 2007 J Biol Chem 282:22249.

Apomeiosis: Gamete development without a meiotic process. ► [meiosis](#), ► [apomixis](#)

Apomict: A plant which reproduces by apomixis. ► [apomixis](#), ► [Rosa canina](#)

Apomixia: Parthenogenesis, common in *Caenorhabditis elegans*, bees, wasps, aphids, in some crustacea, lizards, isopoda, lepidoptera, etc.; it does not occur in humans. ► [parthenogenesis](#), ► [apomixis](#)

Apomixis: Embryo (zygote) development without fertilization in plants and fungi. It occurs regularly in certain species, e.g., in the polyploid *Festuca*, hawkweeds (*Hieracium*), etc. Some apomicts reproduce sexually after doubling the chromosome number. Apomicts may make possible the fixation of heterozygous condition. Apomixis may be genetically very different from somatic embryogenesis. If apomixis is preceded by meiosis, and the egg parent was heterozygous, segregation may occur among the apomictic progeny. In aposporous apomixes, the megagametophyte develops from a somatic cell of the ovule. ► [parthenogenesis](#), ► [apomixia](#), ► [apogamety](#), ► [agamospermy](#), ► [androgenesis](#), ► [Hieracium](#); Koltunov AM 1993 Plant Cell 5:1425; van Dijk O, van Damme J 2000 Trends Plant Sci 5:81; Grimanelli D et al 2001 Trends Genet 17:597.

Apomorphic: A species trait evolved from a more primitive state of the same. ► [plesiomorphic](#), ► [symplesiomorphic](#), ► [synapomorphic](#), ► [autapomorphy](#)

Apopain (caspase 3, human chromosome 4q35): ► [apoptosis](#)

Apoplast: Intercellular material of plants. (Sattelmacher B, Horst W (eds) 2007 Springer Berlin, D.)

Apoptosis (programmed cell death, PCD): The cells and the nuclei shrink and are generally absorbed after fragmentation. Apoptosis is an indispensable process for the majority of organisms. Unneeded cells are disposed of, room is made for differentiated cells and it is a safeguard against cancerous growth. A generalized outline of the apoptotic cell death pathway is presented here. Ceramide is one of the regulatory molecules of the process. Tumor necrosis factor (TNF) is an inducer of apoptosis. The metabolites of ceramides, sphingosine and sphingosine-1-phosphate prevent the symptoms of apoptosis. These two molecules are supposedly second messengers for cell proliferation mediated by platelet-derived growth factor. The activation of protein kinase C brought about by sphingosine kinase and the increase of the level of sphingosine-1-phosphate inhibits the ceramide-mediated apoptosis. The latter molecules also stimulate the ERK-controlled

reactions and inhibit the stress-activated kinases SAPK/JNK. In *Caenorhabditis* more than a dozen *ced* (cell death) genes have been identified. Ced3 protein is an interleukin-1 converting (ICE) cysteine protease enzyme, involved in ceramide production. Ced9 is a suppressor of cell death and EGL-1 releases the suppression and CED-tetramer facilitates the conversion of the CED-3 zymogen (enzyme precursor) to an active CED-3, which brings about cell death. The apoptotic pathway mediated by CED-3 is illustrated after Yan N et al 2005 Nature [Lond] 437:831. CED-9 has 23% identity to the human oncogene BCL-2, controlling follicular lymphoma. If this human gene is transfected to the nematode it suppresses apoptosis, indicating that the same function is controlled over a wide evolutionary range (see Fig. A106).

Figure A106. Death pathway CED-3

The *reaper* gene (*rpr*) of *Drosophila* is an activator of apoptosis and it is homologous to *ced-3* of *Caenorhabditis*. Another *Drosophila* gene, *hid* (*head-involution defective*), is linked to *reaper*. The 65-amino acid RPR protein has similarity to the “death domain” of the tumor necrosis factor receptor (TNFR) family. TNFR1 and Fas induce cell death when activated by ligand binding or when over-expressed. Other death receptors are DR3 (Ws1, Apo3, TRAMP, Lard) and Dr4. They may directly connect to the Fas-associated death domain (FADD/MORT1) or to the tumor necrosis factor-associated death domain receptor (TRADD). FADD recruits procaspase 8. TRAIL is another killer protein for which DR3 and Dr4 serve as receptors. Curiously, the latter receptors are present in non-apoptotic cells. The lack of killing effect in these cells is explained by other TRAIL receptors TRID (TRAIL receptor without an intracellular domain) or DcR1 (decoy receptor 1). These receptors have glycopospholipid anchored cell surface portions that trap TRAIL but do not allow the transfer of the death signal to FADD and actually function as a decoy preventing the death signal transduction even for Dra3 and Dra4. The dead cells are disposed of generally by the macrophages without producing inflammation in the tissue. The

apoptotic cells are recognized generally by the altered sugar groups or phosphatidylserine on their surface. The phagocytes recognize apoptotic cells by their phosphatidylserine receptors (PSR). The absence of PSR during early mammalian organogenesis results in respiratory and brain anomalies (Li MO et al 2003 Science 302:1569; Wang X et al 2003 Science 302:1563). The macrophage secretes an extracellular protein, thrombospondin, which recognizes apoptotic cells. The *Alg-2* (apoptosis-linked gene) encodes a Ca^{2+} -binding protein that is required for T cell receptor-, Fas- and glucocorticoid-induced apoptosis. *Alg-3* is a homolog of Alzheimer’s disease gene, which is basically a senescence gene. Apoptosis may be a very natural response of the cells to be disposed when no longer needed. In some cancers the proliferation is not under control because regulators of the process go awry. The baculovirus apoptosis inhibitor proteins (Cp-IAP and Op-IAP) as well as neuronal apoptosis inhibitor proteins (NAIP), located in human chromosome 5q13.1, are defective or deleted in spinal muscular atrophy. BAX is a heterodimeric protein that works in the opposite direction as BCL2 (chronic lymphocytic leukemia, B cell). The gain of function BAX mutations, knockouts were viable but in the lymphocyte cell lineages apoptosis was induced. In other cell lineages hyperplasia was observed. Thus, the BAX expression depends on the cellular context. The wild type BCL2 gene functions similarly to *Ced-9* of *Caenorhabditis*, i.e., it suppresses apoptosis. The enzyme apopain, cleaving poly(ADP-ribose) polymerase (PAR) is also necessary for apoptosis to proceed. Apopain is generated from the proenzyme called CPP32, a protein related to ICE and CED-3. Lymphocyte apoptosis may be mediated by Type 3 inositol 1,4,5-trisphosphate receptor in the plasma membrane by promoting the influx of calcium. Apoptosis of neurons is mediated by the activation of JNK (JUN [oncogene] NH2-terminal kinase) in a process opposing the effect ERK (extracellular signal-activated kinase) in the absence of the nerve growth factor (NGF). The p35 protein of the baculovirus *Autographa californica* has similar antiapoptotic property for insects as well as for mammals as the *Ced-9* gene product of *Caenorhabditis*. *Ced-9/Bcl-2* gene product inhibits both the apoptosis promoting and protecting effects of the *Ced-4/Apaf-1* products. CED-4 interacts with CED-3 and they oligomerize. Their oligomers may associate with BCL and this results in processing (in the presence of ATP) of CED-3 leading to cell death. In order to activate the death pathway the EGL-1 protein stops the interaction of CED4-CED3 with BCL. CED-10/RAC1 mediates the removal of apoptosed cells through actin reorganization (see Fig. A107). (Kinchin JM et al 2005 Nature [Lond] 434:93).

A

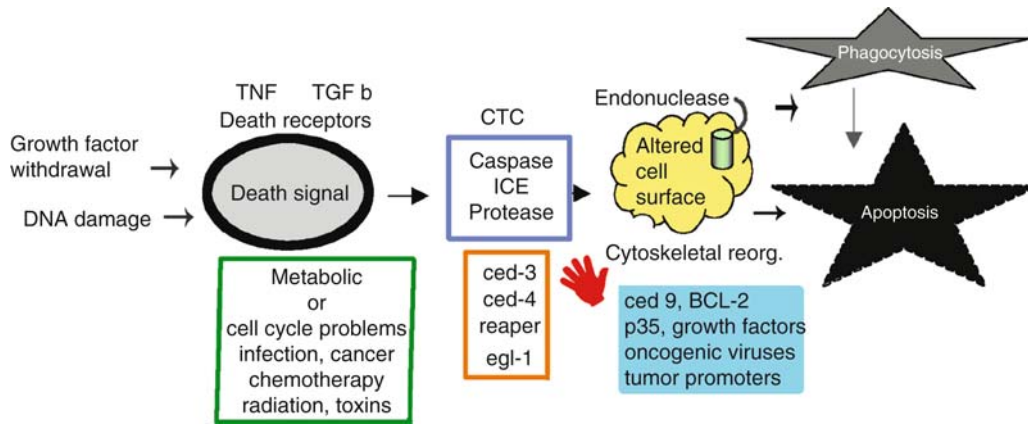

Figure A107. Pathway to apoptosis and its inhibition

Ced-9 is homologous to the mammalian BCL-2. *Ced-3* and *Ced-4* are considered to be promoters of apoptosis. Actually, *Ced-4* has two transcripts; the short transcript promotes apoptosis whereas the long transcript is somewhat protective. Excessive manifestation of *ced-4L* can actually prevent programmed cell death. It is interesting to note that the structurally unrelated *BCL-x* and *Ich-1* genes are also involved in apoptosis, similarly to *Ced-4*, all have two alternative transcripts. This indicates that RNA splicing may have an important role in programmed cell death.

Before caspase could be fully functional *ced-4* moves from the mitochondrion to a perinuclear location. The basic leucine zipper proteins (bZIP) PAR (proline and acid rich) and other members of the protein family can also control apoptosis. PAR mediates cytochrome c release during apoptosis by remodeling mitochondrial cristae with the aid of the dynamin-related protein OPA1 (Cipolat S et al 2006 Cell 126:163; Frezza C et al 2006 Cell 126:177).

Inappropriate activation of apoptosis may be involved in diseases such as AIDS, degeneration of the nervous system (Alzheimer's disease, amyotrophic lateral sclerosis, Parkinson's disease, retinitis pigmentosa), constriction or obstruction of the blood vessels (ischemic stroke), anemias, liver diseases, autoimmune diseases, etc. The diagram given here is modified after Thompson CB 1995 Science 267:1456.

Recently, the generic name CASPASE has been suggested (c for cysteine protease, aspase for cleaving at aspartate) for the ICE-*ced* protease enzyme system. The individual enzymes would also be designated by numbers. After the initiation of the apoptotic pathway cytochrome c is released from the mitochondria by the action of the BAX protein and this in turn leads to the activation of the caspases by Apaf-1. The mitochondrial route of apoptosis is initiated by the facilitation of the permeability of the outer membrane of the mitochondria. The permeability enables the

leakage of mitochondrial proteins involved in the activation of caspases (Green DR, Kroemer G 2004 Science 305:626). According to some, there are two pathways of apoptosis, one through the Fas and another through the Apaf/mitochondrial route. Protein BAR (member of the BCL family) may coordinate these two pathways. BCL-2/CED-9 protein blocks caspase activation. "BH-Only" proteins of the Bcl family (Bad, Bil Blk, Hrk/Dp5, Bid, Bim, Noxa, EGL-1) share 9–6 amino acids and are initiators of apoptosis. The X-chromosome-linked IAP (inhibitor of apoptosis) directly inhibits caspase-3 and 7 proteases. Another protease inhibitor is known by the synonyms FLIP, Casper, Flame, Cash and I-FLICE. The CED-3 enzymes are cysteine proteases, accompanied by nucleases that cut the DNA to approximately 180–200 bp fragments, the size of a nucleosomal unit (hence the name caspase-activated DNase [CAD]). There is a closely associated other protein inhibitor of CAD (ICAD or DFF45 in humans). ICAD releases CAD after caspase-3 cut and its role is that of a chaperone. CAD is produced as a complex with ICAD and the action of caspase-3 permits CAD to move into the nucleus from the cytoplasm. The site of cutting is between two nucleosomes by the 343 amino acid nuclease, a basic protein. Actually the whole complex process involves a number of other proteins that interact and affect the outcome of cell death or proliferation (see Fig. A108).

Apoptosis is used for multiple purposes besides aging. Differentiation, homeostasis, cellular defense mandate this process of suicide for damaged or unnecessary cells. The purpose of the apoptotic process is to free the system from unwanted cells and stop proliferation (e.g., prevent cancer and autoimmune disease) and maintain healthy conditions. Glucocorticoids are effective stimulators of apoptosis. After a stroke or Alzheimer's disease overactive

Figure A108. Apoptosis can be imaged by introducing into the cell the firefly luciferase gene (*Luc*) attached to the regulatory domain of a silencer estrogen receptor (ER) domain. In between *Luc* and ER there is A DEVD cleavage site for caspase-3. When caspase is activated at apoptosis the DEVD link is severed and the silencing effect of ER is removed and luciferase is expressed. This is a non-invasive real-time monitoring procedure. (Modified after Laxman B et al 2002 Proc Natl Acad Sci USA 99:16551)

apoptosis may, however, damage the brain. Low level of apoptosis may be the cause of follicular B cell lymphoma. Tumor formation may be caused by the overexpression of *Bcl-2* suppressor of apoptosis. The suppression of *Bcl-2* may, however, promote apoptotic death of cancer cells. The suppression of survivin, an apoptosis inhibitor may also cause death of cancer cells. TRAIL, caspases and caspase inhibitors, respectively have also been considered for cancer therapy. p53 tumor suppressor may channel damaged cells to an apoptotic path.

It has been estimated that in the human body 10 billion cells suffer apoptosis daily and about the same number of cells arise again by mitosis. Humans have more than 200 genes that are involved with apoptosis and their manipulation has therapeutic significance (Schwerk C, Schultze-Osthoff K 2005 Mol Cell 19:1).

Programmed cell death also occurs in plants during the differentiation of the vascular system (xylem), fruit ripening and senescence, the hypersensitive defense reaction against pathogens. Although plants do not have caspases, the vacuolar processing enzyme, a protease has a similar function in controlling virus infection by hypersensitive reaction (Htsugai N et al 2004 Science 305:855).

Apoptosis Inhibitors: These are viral (baculovirus) proteins aimed at overcoming the host defense against viral infection by cell death. Similar proteins targeting primarily caspase-9 and apoptotic mitochondrial cytochrome c occur in insects, mammals as well as in humans.

Apoptosome: A complex of apoptosis proteins including caspases, Apaf, etc. ►apoptosis, ►caspase, ►Apaf; Acehan D et al 2002 Mol Cell 9:423; review: Schafer ZT, Kornbluth S 2006 Developmental Cell 10:549.

Aporepressor: Repressor proteins that require another molecule, the co-repressor (frequently a late product of the metabolic pathway) to be active in controlling transcription. ►transcription, ►tryptophan operon, ►tryptophan repressor

Aposematic Coloration: Warning display of animals and plants against invaders, e.g., bright color of poisonous snakes or poisonous mushrooms or plants. ►Batesian mimicry, ►Müllerian mimicry; Brodie ED III, Agrawal AF 2001 Proc Natl Acad Sci USA 98:7884.

Apospory: Seed formation without fertilization from diploid cells of the nucellus or integumentum. ►apomixis, ►agamospermy diplosperry, ►adventitious embryo, ►amixia

Apostatic Selection: Predators often prefer the most abundant types of prey and thus maintain the polymorphism of the prey population. Polymorphism in populations is maintained by frequency-dependent selection that seems to be paradoxical to the principle of natural selection but under experimental conditions some rare phenotypes have the unexpected advantage of survival (Olendorf R et al 2006 Nature

A

[Lond] 441:6330; ►selection types, ►frequency-dependent selection; Bond AB, Kamil AC 2002 Nature [Lond] 415:609.

Aposymbiotic: An organism cured from the symbiotic partner. ►symbionts

Apothecium: An open fruiting body of fungi on which the asci develop; it is similar to perithecium but the latter is a closed fruiting body. Among the genetically widely used organisms *Ascobolus* develops apothecia (see Fig. A109). ►perithecium

Figure A109. Apothecium. (After Weier TE et al 1973 Botany. Wiley & Sons, New York)

Apotransferrin: A transport protein without its ligand. ►transporters, ►ligand

apo-VLDL: ►apolipoprotein

AP-PCR: Arbitrarily primed PCR. ►polymerase chain reaction, ►methylation-specific PCR

APP (amyloid precursor protein): ►Alzheimer's disease, ►amyloids, ►secretase, ►memory

Apple (*Malus* spp.): About 25 species all with $x = 17$, most of them are diploid although tetraploid and triploid varieties also occur. Apples are frequently self-incompatible but cross-fertilize with other apples. They do not easily hybridize with pears (*Pyrus*), but they hybridize with *Sorbus* (mountain ash). ►pears

Application Programs (computer): Programs serving special purposes such as word processing, graphics, telecommunication, DNA sequencing, data management, etc.

Appressor: Cylindrical or globular fungal organs at the end of the hyphae with a rigid wall. It serves for infection by rupturing the cell wall of plants and invasion of the tissues with the aid of the penetration peg. The process may rely on cutinase, cellulase and other enzymes but it may utilize high turgor mechanical pressure.

Appressorium: An enlarged fungal structure at the point of invasion of the host tissue (see Fig. A110).

Figure A110. Appressorium

APRF (acute-phase response factor, 17q21): A transcription factor related to the p91 subunit of the interferon-stimulated gene factor-3 α (ISGF-3 α). It is phosphorylated by the mediation of cytokines, and along with Jak1 kinase, it is associated with gp130. Interleukin-6, leukemia inhibitory factor (LIF), oncostatin M (OSM, 252 amino acids, encoded at human chromosome 22q12.1-q12.2 at the same general location as LIF) and ciliary neurotrophic factor (CNTF, 11q12.2), cytokines, neurokines and neuronal differentiation factors are also involved. LIF and OSM may promote atherosclerosis by inhibiting the replacement of defective endothelial cells. ►gp130, ►signal ►transduction, ►cytokines, ►embryogenesis, ►leukemia inhibitory factor, ►ciliary neurotrophic factor, ►atherosclerosis

Apricot (*Prunus armeniaca*): $x = 7$; 2x and 3x forms are known.

APRIL (a proliferation-inducing ligand): A member of the TNF ligand family with homology to CD95. The tumor necrosis factor ligand 13B (encoded at 13q32-q34) is also called TNFSF-13B and April. ►TNF, ►CD95, ►BAFF; Stein JV et al 2002 J Clin Invest 109:1587.

Aprotinin: Inhibitor (at concentrations 1–2 mg/mL) of proteases kallikrein, trypsin, chymotrypsin, plasmin but not of papain. ►protease, ►kallikrein, ►trypsin, ►chymotrypsin, ►plasmin, ►papain

APSES (present in ASM-1-Phd1-StuA-EFGTF1-Sok2 proteins [among others]): A helix-loop-helix-like structure regulating developmental processes. ►DNA binding protein domains

Aptamer: An oligo-RNA, oligo-DNA or a protein—oligo-RNA complex that can bind specifically a particular protein or other molecule (see Fig. A111). E. G., a thrombin-binding aptamer inhibits the action of thrombin in blood clotting and thus prevents the formation of blood clots. Human neutrophil elastase, fibroblast growth factors, vascular endothelial growth factor, selectin, antibodies have been successfully

isolated by the SELEX procedure. Short RNA aptamers inserted into the 5' untranslated region of a mRNA may bind various ligands including (fluorescent malachite green) and may facilitate the control of translation behind it. Cancer cell-specific aptamers can distinguish normal cells from cancer cells and may facilitate fast and effective early diagnosis (Shangguan D et al 2006 Proc Natl Acad Sci USA 103:11838). ▶antisense ▶RNA, ▶SELEX, ▶elastase, ▶FGF, ▶riboswitch, ▶selectin, ▶antibody, ▶mRNA ▶display; Hermann T, Patel DJ 2000 Science 287:820; Cerchia L et al 2002 FEBS Lett 528:12; Famulok M 2004 Nature [Lond] 430:976.

Figure A111. RNA aptamer of ATP

Aptazyme: A ribozyme with an aptamer. ▶ribozyme, ▶aptamer

Apurinic Endonuclease: ▶AP ▶endonucleases

Apurinic Site (AP): A site from where a purine has been removed from the nucleic acid. It has been estimated that mammalian cells lose about ten thousand purines daily. The apurinic sites are removed by excision repair and deoxycytidyltransferase can include deoxycytidine across the apurinic site and DNA polymerase ζ makes further repair. ▶glycosylases, ▶abasic ▶sites, ▶depurination, ▶excision repair; Lindahl T, Nyberg B 1972 Biochemistry 11:3610; Haracska L et al 2001 J Biol Chem 276:6861.

Apyrase: An acid tri- and diphosphatase enzyme that also degrades nucleotides.

Apyrimidinic Endonuclease: ▶AP endonucleases

Apyrimidinic Site: A site from where a pyrimidine has been removed from a nucleic acid.

Aquaporin (AQP2, 12q13, APQ4, 18q11.2-q12.1): Six transmembrane domain proteins (M_r 28K) and water channel in fluid absorbing and fluid secreting cells. The AQP1 monomer contains 269 amino acids, forming two tandem repeats of three membrane-spanning domains and amino and carboxy termini located on the cytoplasmic side of the membrane. The AQP family includes proteins with wide distribution in diverse species across the plant, animal and microbial world. The aquaporin channel of plants is

closed when two conserved serine residues are dephosphorylated or when a conserved histidine is protonated during anoxia by flooding. In closed conformation a D loop caps the channel from the cytoplasm. In open conformation the D loop is displaced and removes the blockade of the entrance of the channel from the cytoplasm (Törnroth-Horsfield S et al 2006 Nature [Lond] 439:688). cAMP-dependent mechanisms or PKA activate the aquaporin channel. It is important for various types of cells, diabetes, kidney function, *Drosophila* neural development, nematodal infestation of plants, etc. Aquaporin 7 deficiency activates adipose glycerol kinase and may lead to obesity (Hibuse T et al 2005 Proc Natl Acad Sci USA 102:10993). The deletion of aquaporin-4 in mice reduces brain edema. The disruption of the rodent aquaporin-1 gene (*AQP1*) impairs angiogenesis and cell migration and thus reduces tumor growth (Saadoun S et al 2005 Nature [Lond] 432:786). ▶CHIP, ▶forskolin, ▶cAMP, ▶PKA, ▶cell ▶membranes, ▶ion ▶channels; Borgnia M et al 1999 Annu Rev Biochem 68:425; Murata K et al 2000 Nature [Lond] 407:599; Sui H et al 2001 Nature [Lond] 414:872; Uehlein N et al 2003 Nature [Lond] 425:734; King LS et al 2004 Nature Rev Mol Cell Biol 5:687.

Aquaretic: Secreting bloody fluids.

Aqueous: Prepared with water (e.g., a solution) or watery in appearance.

Aquifex aeolicus: A chemolithoautotroph bacterium capable of growth at 95 °C. Its completely sequenced DNA genome is 1,551,335 bp. ▶chemolithoautotroph

Aquilegia (Columbine): 700 species have a genome size of ~400 Mb; under development for ecological and evolutionary genetic studies (see Fig. A112).

Figure A112. Columbine

Arabidopsis Mutagen Assays: In the mature embryo of plants two diploid cells represent the inflorescence. Therefore, if the seeds are exposed at such a stage to a mutagen, in the progeny of the emerging plants the

A

segregation is about 7:1 for recessive mutations. This also indicates that one of the two apical cells became heterozygous for the new mutation induced. For mutagen assays it is sufficient to open up the immature fruits of the plants before the seed coat becomes opaque (about 10–14 days after fertilization) and albina or other color mutations in the cotyledons or embryo defects can be determined. Within a single fruit the segregation for recessives is 3:1 (see above). The fruits on the plants emerging from the treated seed already contain the F_2 generation. Generally, two opposite fruits next to each other are examined because the phyllotaxy index assures that these are sufficient for complete sampling. Such a test permits the identification of about 80% of the spectrum of visible mutations. Since the plants are diploid and the “germline” consists of two cells, the mutation rate on genome basis is calculated by counting all independent mutational events and dividing it by the total number of plants tested $\times 4$. *Arabidopsis* can activate many types of promutagens and therefore provides an efficient and low cost method for assessing the genotoxic effects of a wide variety of agents in a single culture (see Fig. A113). ►bioassays for genetic toxicology, ►*Arabidopsis thaliana*, ►phyllotaxy; Rédei GP, Koncz C 1992 In: Koncz C et al (eds) *Methods in Arabidopsis Research*, World Scientific, Singapore, p 16; Hays JB 2002 *DNA Repair* 1:579.

Figure A113. *Arabidopsis*.

Figure A114. Open *Arabidopsis* fruit.

***Arabidopsis thaliana*:** An autogamous plant of the crucifer family, $2n = 10$, the genome size has been estimated to be 9×10^7 to 1.5×10^8 bp (the current best estimate is ~ 121 – 125 Mbp). Its life cycle may be as short as 5–6 weeks. Its seed output may exceed

50,000 per plant. Its mitochondrial DNA is 366,924 bp, 10% duplicated, and apparently codes for 58 genes. Because of its small size thousands of individuals may be screened even on a Petri plate or grown for the entire life cycle in test tubes where the plants may produce more than 100 seeds. Its plastid DNA is approximately 154 kbp encoding 79 proteins and 17% is duplicated. It is the first higher plant with the genome completely mapped and sequenced in 2000. Transposons constitute 14% of the nuclear DNA and 4% of the mitochondria; the plastids appear free of moving elements. Chromosome 2 and 4 sequences became available by late (1999) (Nature [Lond] 402:761 and 769).

The initial data indicate higher gene number than in *Drosophila* or *Caenorhabditis*. At present the predicted gene number of *Arabidopsis* is $\sim 30,700$ from which $\sim 25,540$ have been annotated as protein-coding whereas the remaining are pseudogenes or partial genes (Yamada K et al 2003 *Science* 302:842). Interestingly, more than two decades ago, on the basis of mutation frequency in *Arabidopsis*, the total number of genes was estimated to be about 28,000 (Rédei GP et al 1984 In: Chu EHY, Generoso WM (eds) *Mutation, Cancer, and Malformation*. Plenum, p. 306). All chromosomes display on an average ca. 60% duplication. Although many of the genes show homologies to those of other organisms, there is 38.9% identity with the human breast cancer gene (BRC2), Werner syndrome (37.4%) and the Niemann-Pick disease (42.7%). Interestingly, many genes with apparently so far unidentified function and specific for plants were revealed by the sequences.

Annotation of the full-length cDNA: Seki M et al 2002 *Science* 296:141. A global gene expression map is available including from embryogenesis to seed development and senescence. The expression pattern of large gene families indicates that many families are co-opted for specific developmental processes. (Schmid M et al 2005 *Nature Genet* 37:501).

Arabinose Operon: Consists of three juxtapositioned structural genes *araB* (l-ribulokinase), *araA* (L-arabinose isomerase) and *araD* (L-ribulose-4-epimerase) transcribed in this order into a polycistronic *araBAD* mRNA starting at the O^{BAD} operator and

A

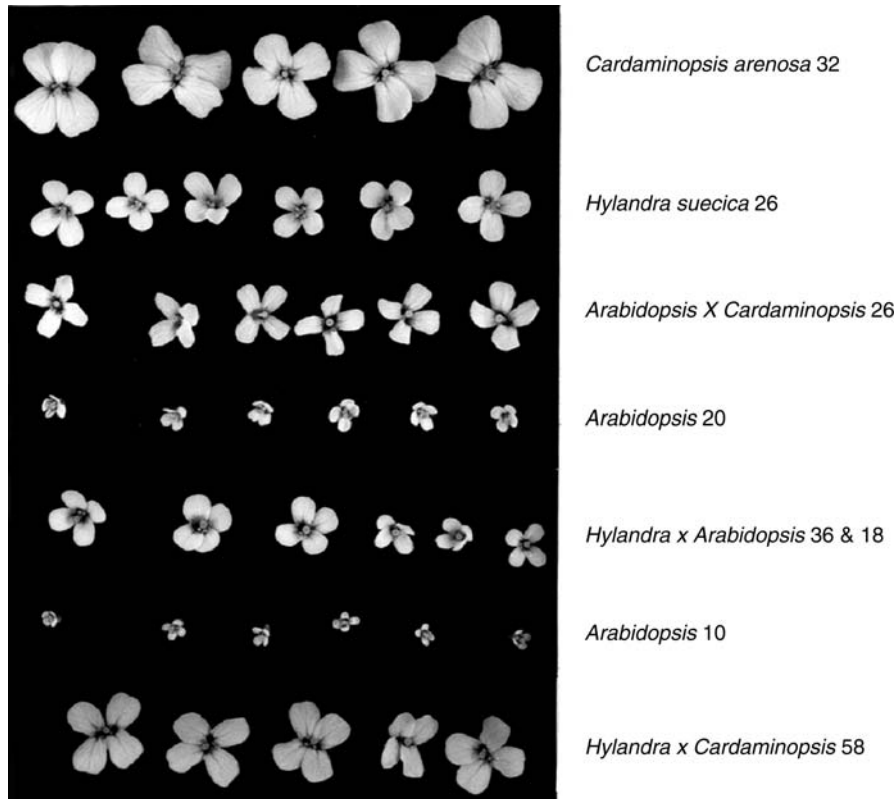

Figure A119 *Arabidopsis*, related species and hybrids with somatic chromosome numbers. (Rédei GP 1960 unpublished)

initiated by the P^{BAD} promoter. The repressor-activator site functions by positive or negative control and it is transcribed in the opposite direction from the O_C operator and uses the P_C promoter. These genes are near the beginning of the *E. coli* map, while another gene *araF* is located near map position 45. They form a common regulatory system: a regulon. The activation of the *ara* operon not only requires the presence of the substrate arabinose, but also that the catabolite activating protein cyclic adenosine monophosphate complex be attached to the promoter. This operon is subject to catabolite suppression and as long as glucose is present in the medium (even when arabinose is also available) its transcription cannot begin. ▶operon, ▶polycistronic, ▶operator, ▶catabolite activating protein, ▶cAMP, ▶negative control; Schleif R 2000 Trends Genet 16:559.

Arabinosuria: An early name of pentosuria but it was subsequently found that L-xylulose was misidentified as arabinose; the current name of the recessive disorder is (essential) pentosuria. ▶pentosuria, ▶xylulose

Arachidonic Acid (arachidate): An unsaturated fatty acid, which, is known as arachidonate when there are four double bonds in the molecule (it is synonymous with eicosatetraenoate). It occurs in lipids and plays a role in mediating signal transduction. Cyclooxygenase

mediates the formation of prostaglandins, prostacyclins and thromboxanes whereas lipoxxygenase catalyzes the synthesis of leukotrienes from arachidonic acid.

▶fatty acids, ▶cyclooxygenase, ▶lipoxxygenase signal transduction, ▶atherosclerosis

Arachnodactyly (5q23-q31): A characteristic of the Marfan syndrome involving unusually long fingers and toes. Unlike the Marfan syndrome (FBN1), here the mutation involves the fibrillin gene FBN2 (see Fig. A120 for a photograph). ▶Marfan syndrome, ▶fibrillin; Belleh S et al 2000 Am J Med Genet 92:7.

Figure A120. Arachnodactyly

Aracne (algorithm for the reconstruction of accurate cellular networks): From phenotypic and biochemical information scale-free networks of interconnected gene hubs are determined (Basso K et al 2005 Nature Genet 37:382). ▶networks, ▶genetic networks

ARAF Oncogenes: Have been assigned to the mouse X-chromosome whereas in humans ARAF 1 is in chromosome Xp11-p11-2 and ARAF 2 was localized to either 7p11.4-q21 or 7p12-q11.21. These oncogenes are homologous to the RAF1 oncogene and are supposed to encode a serine/threonine kinase. ►**RAF1**

Aragorn: A computer program for the detection of tRNA and tmRNA genes. (Laslett D, Canback B 2004 Nucleic Acids Res 32:11)

Arboviruses: Parasites of blood-sucking insects and vertebrates, their genetic material is RNA.

Arbuscular Mycorrhiza: The hyphae of the fungus actually penetrate the roots of the plants and form their branching structures. ►**mycorrhiza**

ARC: ►**DRIP**

Archaea: The third major group of living systems besides bacteria and eukarya. *Methanococcus jannaschii* DNA (1.66 megabase) has been sequenced in (1996) and 1,738 predicted protein-coding genes have been identified. The organism has two, 58-kb and 16-kb, extrachromosomal elements. Only 38% of its genes appear similar to genes (by nucleotide sequences) of other fully sequenced bacteria or budding yeast. The metabolic genes bear similarities to bacterial genes whereas its genes involved in transcription, translation and replication bear greater resemblance to eukaryotic genes. Their genome displays nucleosomal structures. For a complete nucleotide sequence see World Wide Web at <http://www.tigr.org/tdb>. In halobacteria the genes are in linkage equilibrium, which is an indication of frequent genetic recombination (Papke RT et al 2004 Science 306:1928). Archaea in the rhizosphere of rice plants are responsible for an estimated 10 to 25% of the global methane emission. The genome of 3,179,916 bp of the methanogenic strains contains 3,103 coding sequences (Erkel C et al 2006 Science 313:370). ►**life form domains**, ►**evolution of eukaryotes**, ►**linkage disequilibrium**; Whitman WB et al 1999 Genetics 152:1245; Podani J et al 2001 Nature Genet 29:54.

Archaeobacteria: Groups of prokaryotes that appear to have some similarities to eukaryotes in as much as displaying nucleosome-like structures in their DNA, introns in their genes, unlinked 5S RNA genes and their transcriptase enzyme are somewhat related antigenically to similar enzymes in lower eukaryotes. ►**archaea**

Archaeogenetics: Studies the descent of humans mainly on the basis of mitochondrial and Y-chromosomal population information.

Archegonium: Female sexual organ (gametangium) of lower plants where the eggs develop.

Archeogenetics: The application of molecular genetics techniques to ancient populations, their bone remains or otherwise preserved biological samples and their evolving descendants. The studies are based on mitochondrial DNA that can reveal the pattern(s) of human/animal evolution and migration of females and the analysis of Y chromosomal makeup provides comparable information on the male lineages. ►**Eve foremother of mtDNA**, ►**Y chromosome**

Archeozoic: Geological period 400 to 100 million years ago when protists (unicellular organisms) evolved.

Archespore: The ancestral, enlarged cell that develops into the megasporocyte (megaspore mother cell) in plants. ►**megagametophyte**

Archezoa: ►**microsporidia**

Architectural Editing: Proteins from the endoplasmic reticulum are selectively transported. The new proteins are retained until properly folded and the misfolded chains are degraded. ►**endoplasmic reticulum**

Architectural Proteins: Modulate DNA structure in such a way that transcription factors gain better access to the promoter area. ►**UBF**, ►**high-mobility group proteins**

Archival DNA: Stored in museum, herbarium or other preserved samples of long dead cells; can be amplified with PCR techniques for analysis and for obtaining information on old populations or on extinct species. ►**PCR**, ►**ancient DNA**

Archtype: A hypothetical ancestral form in evolution.

Arcsine: The inverse of sine (\sin^{-1}), it denotes the angle of whose sine is given. ►**sine**

Arcsine Transformation: ►**angular transformation**

ARE (anoxia response element): DNA sequences regulating responses to anaerobiosis. ARE responding genes represent detoxification and antioxidant defense. ►**anoxia**; Li J et al 2002 Physiol Genomics 9:137.

ARE: AU-rich elements in the 3'-untranslated region of RNA involved in the regulation of translation Cheong C-G, Tanaka-Hall TM 2006 Proc Natl Acad Sci USA 103:13635; Vasudevan S, Steitz JA 2007 Cell 128:1105; ►**AMD**, ►**HuR** [human AUY-rich elements], <http://rc.kfshrc.edu.sa/ared/>.

α-Repeat: A 171 bp abundant (up to 1,000,000) repeat in the human genome, localized primarily in the centromeric regions of the chromosomes. This and

A

the Alu repeats constitute 5–10% of the human genome. ►Alu family

ARF (ADP-ribosylation factor, p14^{ARF} [human]/p19^{ARF}[mouse]): A GTP-binding protein of the monomeric Raf family of G proteins involved in the transport between the endoplasmic reticulum and the Golgi apparatus and within the Golgi complex. The ARF alters the membrane lipid composition. It is also required for the physiological effect of cholera and pertussis toxins. p^{ARF} regulates tumor suppressors p53 and RB through the E2F-1 transcription factor. A novel nuclear protein NIAM (nuclear interactor of ARF and MDM2) binds both the ARF and the p53 antagonist MDM2). NIAM protein is normally expressed at low to undetectable levels in cells partly because of, MDM2-mediated ubiquitination and proteasomal degradation. When reintroduced into cells, NIAM activated p53, caused a G1 phase cell cycle arrest, and collaborated with the ARF in an additive fashion to suppress proliferation. Notably, NIAM retains growth inhibitory activity in cells lacking ARF and/or p53, and knockdown experiments revealed that it is not essential for ARF-mediated growth inhibition. Thus, NIAM and ARF act in separate anti-proliferative pathways that intersect mechanistically and suppress growth more effectively when jointly activated. Intriguingly, silencing of *NIAM* accelerated chromosomal instability, and microarray analyses revealed reduced *NIAM* mRNA expression in numerous primary human tumors (Tompkins VS et al 2007 J Biol Chem 282:1322).

When c-Myc oncoprotein level increases, the ARF blocks c-Myc and its ability to induce hyperproliferation. Also, the ARF does not affect the transcription of Myc and enhances apoptosis independently from p53 (Qi Y et al 2004 Nature [Lond] 431:712). The short mitochondrial form of p19^{ARF} induces autophagy and caspase-independent cell death (Reef S et al Mol Cell 22:463). The ARF is turned on by Sec7 guanine nucleotide exchange factor domain proteins, which are inhibited by brefeldin. ►signal transduction, ►cholera toxin, ►pertussis toxin, ►GTPase, ►SecA, ►SecB, ►translocase, ►translocon, ►ARNO, ►Golgi, ►G proteins, ►raf, ►tumor suppressor, ►p53, ►retinoblastoma, ►E2F1, ►p16^{INK4}, ►guanine nucleotide exchange factor, ►brefeldin, ►cytohesins, ►MDM2, ►Myc, ►Sirtuin, ►RNAs polymerase III, ►Pokemon, ►MDM2, ►ABA; Sherr CJ 1998 Genes Dev 12:2984; Randle DH et al 2001 Proc Natl Acad Sci USA 98:9654.

ARF1: A GTPase protein activating phospholipase D. It is activated by PtdIns (phosphatidyl inositol), and participates in the recruitment of coatomer and trans-Golgi network (TGN) clathrin. ►coatomer,

►phosphoinositols, ►trans-Golgi network, ►clathrin, ►GEF, ►Sec, ►Ypt, ►COP ►transport ►vehicles

ARF1 (auxin response factor): Modulates the action of auxin response elements (AuxRE, TGTCTC) in combination with transcription factors. auxins, ►plant ►hormones

Arfaptin: An adaptor mediating cross-talk between the ARF and small G-proteins Rac, RHO and RAS in signal transduction. signal ►transduction, ►ARF, ►cross-►talk, ►G-proteins; Peters PJ et al 2002 Nature Cell Biol 4:240.

ARG: An oncogene related to ABL in human chromosome 1q24-q25 and in mouse chromosome 1. It encodes a tyrosine kinase, different from that of the ABL product. ►oncogenes, ►ABL

Arg: Abbreviation for arginine.

Arginase: ►argininemia

Arginine (2-amino-5-guanidinovaleric acid): A positively-charged essential amino acid. Arginine methylation and demethylation play an important role in the regulation of gene expression. ►urea cycle, ►nucleosome, ►nuclear receptors; Lee Y-H et al 2005 Proc Natl Acad Sci USA 102:3611.

Argininemia (hyperargininemia): The accumulation of high levels of arginine in the blood and urine caused by autosomal recessive arginase deficiency (ARG1 and ARG2 genes). ARG1 (6q23) coded enzyme represents 98% of the arginase activity in the liver and its deficiencies the common argininemia. Arginine accumulates in the blood because it is not degraded. It is a relatively rare disease. Treatment with benzoate and restriction of arginine intake may ameliorate the condition. Shope virus infection may restore arginase activity in the cells. ►amino acid metabolism, ►citrullinemia, ►citrullinuria, ►urea cycle

Argininosuccinic Aciduria: A rare hereditary disorder (human chromosome 7cen-q11.2) involving mental retardation, seizures, hepatomegaly (enlargement of the liver that may become cancerous), intermittent ataxia, brittle and tufted hair, and accumulation of large quantities of argininosuccinic acid (an intermediate in the arginine-citrulline [urea] cycle) in the blood, urine, and the cerebrospinal (brain and spinal cord) fluid. Early and late onset types have been distinguished. The basic defect is argininosuccinase or argininosuccinate lyase deficiency. ►urea cycle

Arginyl tRNA Synthetase: The enzyme that charges the appropriate tRNA with arginine. The encoding gene was located to human chromosome 5. ►aminoacyl tRNA synthetase

Argon Dating: Potassium (^{40}K) decays to argon (^{40}Ar) with a half-life of about 1.25 million years. The gaseous Ar is trapped in the volcanic rocks after it is formed but expelled from the molten lava before the eruption because of the intense heat. Thus, the amount of ^{40}Ar indicates the time elapsed since the volcanic deposits were formed. If any relics (e.g., human bones) are found in the layers, their age can be inferred by potassium-argon dating of the rocks in case the time exceeds the limits of carbon dating. ►radio carbon dating

Argonaute (AGO): Exists in different forms. The enzyme argonaute-2 mediates the degradation of mRNA in response to interfering dsRNA (Liu J et al 2004 Science 305:1437). This protein may also function downstream of Dicer or RNA-dependent RNA polymerase in gene silencing in eukaryotes and probably in prokaryotes. AGO mediates through siRNA the dimethylation of histone H3 lysine 9 (H3K9me2) and RNA-dependent RNA polymerase complexes (Irvine DV et al 2006 Science 313:1134). ►RNAi, ►piRNA, ►PAZ, ►RISC, ►Dicer, ►miRNP, ►rasiRNA, ►RNA-directed DNA methylation; Williams RW, Rubin GM 2002 Proc Natl Acad Sci USA 99:6889; Martinez J et al 2002 Cell 110:563; Kidner CA, Martensen RA 2004 Nature [Lond] 428:81, crystal structure: Song J-J et al 2004 Science 305:1434; minireview: Tanaka Hall TM 2005 Structure 13:1403; mammalian miRNA: <http://www.ma.uni-heidelberg.de/apps/zmf/argonaute/interface/>.

Argos: A secreted *Drosophila* protein containing a single EGF motif. It is a repressor of eye and wing determination and it acts against *Spitz*. ►Spitz, ►DER, ►EGF; Klein DE et al 2004 Nature [Lond] 430:1040.

Argosomes: Epithelial membrane vesicles that are capable of moving cargo between cells. Greco V et al 2001 Cell 106:633.

Argyrophilic Grains: May accumulate in the brain in some dementias; they are stained by bound silver salts, reduced by light or reducing compounds and appear black in post-mortem study.

Arias Syndrome: Probably the same as Gilbert syndrome or Crigler-Najjar syndrome II.

Arithmetic Mean: $\bar{x} = \frac{\sum x}{N}$ is the sum of all measurements (x) divided by the number of measurements (N). ►mean

Arithmetic Progression: A series with elements increasing by the same quantity, e.g., 1, 3, 5, 7, 9. ►geometric progression

ARK β : β -adrenergic receptor, also called GRK2. ►adrenergic receptor, ►GRK1

Arlequin: A software for the analysis of population genetics data (<http://anthro.unige.ch/software/arlequin/>).

Arm Ratio: The relative length of the two arms of a eukaryotic nuclear chromosome. ►chromosome arm, ►chromosome morphology

Armadillo: *Euphractus sexcinctus* 2n = 58; *Dasypus novemcinctus* 2n = 64; *Cabassous centralis* 2n = 62; *ChaetophRACTUS villosus* 2n = 60.

Armadillo (arm, 1–1.2): Homozygosity of the recessive allele is lethal. The normal allele of *Drosophila* is involved in embryonic differentiation in connection with other genes. Its vertebrate homolog encodes β -catenin. It is positively regulated by *Wg* (wingless) and down-regulated by axin. ►morphogenesis in *Drosophila*, ►wnt, ►axin

Armitage-Doll Model: Interprets carcinogenesis as a multistage process developed by a series of subsequent mutations. ►Knudson's two-mutation theory, ►Moolgavkar-Venzon model

ARMS (amplification refractory mutation system): Along with PCR, it may detect the strand that contains a known mutation or identify polymorphism of a particular DNA stretch. Two sets of primers are used for amplification and one of the primers has a difference at the site of the suspected mutation. The different nucleotide is inserted at the 3' end of the primers and extension of the strands follows. However, the penultimate base frequently leads to a mismatch in both mutant and wild type primers and may be difficult to find a primer suitable to obtain a sequence-specific amplification. ►PCR, ►primer, ►primer ►extension, ►mutation ►detection; Chiu RW et al 2001 Clin Chem 47:667; Carrera P et al 2001 Methods Mol Biol 163:95.

Arms of Bacteriophage λ : When the stuffer segment is removed a left and a right segment (arms) of the genome remains and these are used for vector construction. ►stuffer DNA, ►lambda phage

arRNA: Ancient RNA. ►ancient organisms, ►ancient DNA

ARNO (ARF nucleotide binding site opener): A 399 amino acid human protein involved in the $\text{GDP} \rightleftharpoons \text{DGTP}$ exchange of ARF. This and similar proteins contain an amino-terminal coiled coil, a central secretory protein domain (Sec) and a C-terminal pleckstrin domain. It is a homolog of the yeast Gea1, and both are inhibited by brefeldin. ►ARF, ►GTP, ►pleckstrin, ►brefeldin, ►endocytosis

Arnold-Chiari Malformation: Multifactorial recessive brain anomaly. The brain stem is herniated into the foramen magnum (interconnecting the brain and

A

the vertebral column) resulting in hydrocephalus and anencephalus as well. ►anencephaly, ►hydrocephalus

ARNT (arylhydrocarbon-receptor nuclear translocator): A helix-loop-helix heterodimeric transcription factor with the AHR and other receptors mediating the metabolism of xenobiotics. ►aryl hydrocarbon receptor, ►xenobiotics, ►helix-loop-helix

Aromatase (ARO): A ~500 amino acid cytochrome 450 (CYP19) protein (estrogen synthetase) converting C19 androgen into C18 estrogen. It is encoded at human chromosome 15q21.1. It is present in the skin, muscle, fat, ovary, placental and nerve tissues. Its deficiency in females causes virility and pseudohermaphroditism and lowered fertility in male mice. An excess of it in human males may cause gynecomastia. ►estradiol, ►steroid hormones, ►gynecomastia, ►pseudohermaphroditism

Aromatic Molecule: A closed ring molecule with C in the ring, linked by alternating single and double bonds; they are frequently conjugated with other compounds.

ARP (autonomously replicating pieces): ►macronucleus

ARP2/3 Complex (actin-related protein complex): An actin assembly complex involved in the movement of cells and mitochondria during cell division and budding of yeast. It appears to be involved in regulating cell shape (Mathur J et al 2003 Development 130:3137). Arp4 is found in large multisubunits of the INO80 and SWR1 chromatin remodeling complexes, in the NuA4 histone acetyltransferase complex and in the assembly of the kinetochore (Ogiwara H et al 2007 Nucleic Acids Res 35:3109). ►actin; Robinson RC et al 2001 Science 294:1679; Cooper JA et al 2001 Cell 107:703.

ARPKD: ►renal-hepatic-pancreatic kidney disease, ►polycystic kidney disease

Array [V80] Hybridization: This is designed to identify single (or a small number) of nucleotide changes in genomic DNA. The procedure requires a large array of oligonucleotide probes, which are obtained by light-directed parallel chemical synthesis. Using in each oligonucleotide set four probes, which differ only in one of the four bases, A, T, G, C, whereas the flanking bases are kept identical. The complementary synthetic probes then query each sequence of the target:

The single-base different hybridization probes are distinguished on the basis of the signals provided by the differences in the fluorescence labels and hybridization intensities of the probes. The procedure also permits the identification of more than one base and deletions. A confocal device can thus scan an entire genome and its great merit lies in its rapidity

(see Fig. A121). ►light-directed parallel synthesis, ►DNA chips, ►microarray hybridization; Chee M et al 1996 Science 274:610.

Figure A121. Array hybridization

Arrayed Library: Cloned DNA sequences are arranged on two-dimensional microtiter plates where they can be readily identified by row and column specifications. ►DNA library, ►microarray

Arrayed Primer Extension (APEX): An array of oligonucleotide primers is immobilized by their 5'-end on a glass surface. The DNA is amplified by PCR, digested enzymatically and annealed to the immobilized primers. A template-dependent DNA polymerase extends the sequence using fluorescent-labeled dideoxynucleotides. Mutation is revealed by a change in the color code of the primer sites. The procedure is suited for analysis of DNA polymorphism. ►primer, ►PCR, ►dideoxynucleotide; Kurg A et al 2000 Genet Test 4:1.

Arrest, Transcriptional: Transcription is stopped because the supply of one or more types of nucleotides has run out or even due to protein factors. It can usually be restarted by the missing building block. T-rich sequences in the non-template DNA strand are frequently liable for the arrest. Genes like *LexA*, *lac* repressor, CAAT-box-binding and other binding proteins may block or impede transcription. In some instances the RNA polymerase may either bypass or remove the binding proteins in its way. The nucleosomal structure may not interfere with transcription although in some cases it may retard it. The degree of interference may depend on the dissociation of the protein. Strong positive or negative supercoiling of the DNA may impede RNA elongation. Some RNA polymerases may transcribe through the gaps of a few nucleotides but the transcript will have deletions. ►pause transcriptional, ►lexA, ►lac operon, ►nucleosome, ►supercoiled DNA, ►RNA polymerase

Arrestin: A 45-kDa phosphoprotein which regulates the phototransduction and β_2 adrenergic pathways (by non-visual arrestins) in animals. It is dephosphorylated when it interacts with the trimeric

G-protein-coupled signal receptor. It may serve as a deactivator of G protein-mediated signaling path by binding to the SH³ domain of the cellular Src molecules. Arrestin may also recruit clathrin to the receptor complex, resulting in the internalization of the complex into clathrin-coated pits. In such a situation it may stimulate cross-talk with the MAP kinase pathway. β -Arrestin 2 acts as a scaffold and transducers for seven-membrane spanning receptors and can regulate development through the *Hedgehog-Smoothed* pathway (Wilbanks AM et al 2004 Science 306:2264). Sinophilin antagonizes most of the arrestin functions (Wang Q et al 2004 Science 304:1940). ►phototransduction, ►signal transduction, ►desensitization, ►adrenergic receptor, ►PDZ, ►Src, ►cross-talk, ►clathrin, ►cargo receptors, ►hedgehog, ►seven-membrane protein, ►endocytosis, ►MAP, ►retinal dystrophy, ►dopamine, ►Oguchi disease, ►adaptin, ►AP180; Krupnick JG, Benovic JL 1998 Annu Rev Pharmacol Toxicol 38:289; Lefkowitz RJ, Shenoy SK 2005 Science 308:512.

Arrhenotoky: A mechanism of sex determination. The males are haploid and the females are diploid for the sex genes (as in bees and wasps). The males develop from unfertilized eggs (a form of parthenogenesis) and display one or the other allele(s) for what the diploid females (queens) are heterozygous for. The homozygous diploid males are either sterile or lethal or destroyed by the workers in the colony. This type of sex determination is seen in nearly 20% of animals (mites, white flies, scale insects, thrips, rotifera, etc.) ►chromosomal sex determination, ►sex determination, ►complementary sex determination, ►wasp; Cowan DP, Stahlhut JK 2004 Proc Natl Acad Sci USA 101:10374.

Arrhythmia, Cardiac: ►LQT

Arrowsmith: A computer tool for identifying the links between MedLine articles. http://arrowsmith.psych.uic.edu/arrowsmith_uic/index.html.

Arrhythmogenic Right Ventricular Cardiomyopathy (RVD): Eight different dominant and one recessive (17q21) forms of the disease, involving degeneration of the myocardium (heart muscles), followed by fibrous-fatty replacement have been described. ARVD1 (14q24.3), ARVD22 (1q42), ARVD3 (14q11-q12), ARVD4 (2q32), ARVD5 (3p23), ARVD6 (10p12-p14), ARVD7 (10q22) and ARVD8 (6p24) are the known dominant mutations. In mice, mutation of a laminin receptor gene (*Lamr1*) contained in an intron-free retroposon caused RVD. The transposon may move to different chromosomes. The gene product was bound to the heterochromatin protein HP1. HP1 is a regulator of heterochromatin sites and LAMR1 protein apparently caused the degeneration

of cardiomyocytes (Asano Y et al 2004 Nature Genet 36:123). cardiomyopathy, ►heart disease, ►long QT syndrome, ►laminin; Rampazzo A et al 2002 Am J Hum Genet 71:1200.

ARS (autonomously replicating sequences): These are nearly 100 bp long origins of replication of yeast chromosomal DNAs. The different ARS sequences share a consensus of 11 base pairs (5'-[A/T]TTTAT[A/G]TTT[A/G]-3'), and there are some additional elements around it that vary in the different chromosomes from where they were derived. ARS1 contains subdomains A, B1 that are recognized by ORC. Subdomain B2 unwinds DNA, and B3 is where ABF1 binding factor is attached. Artificial yeast plasmids must contain ARS sequences to be maintained and they may remain stable as long as selective pressure exists for their maintenance, i.e., they carry essential genes for the survival of the yeast cell (missing from or inactive in the yeast nucleus). ARS elements occur also in organellar and other DNAs. ►YAC, ►yeast vectors, ►DUE, ►cell cycle, ►ORC, ►MCM, ►Abf; Marilley M 2000 Mol Gen Genet 263:854.

Arsenic (As³⁺ or As⁵⁺): Refers to common contaminants produced by burning coal and glass manufacturing which are serious environmental poison (in impure drinking water) and human carcinogen (although not for rodents) (see Fig. A122). It may cause chromosomal deletions in rodents and humans by the generation of oxyradicals. Arsenic trioxide (As₂O₃) is an activator of the MAP kinases. Chronic arsenic poisoning may cause melanotic spots on the palm. Arsenic chaperone, ArsD, is encoded by the *arsRDABC* operon of *Escherichia coli* and it transfers trivalent metalloids to ArsA, the catalytic subunit of an As(III)/Sb(III) efflux pump. Interaction with ArsD increases the affinity of ArsA for arsenite, thus increasing its ATPase activity at lower concentrations of arsenite and enhancing the rate of arsenite efflux. Cells thus become resistant to environmental concentrations of arsenic and toxicity (Lin Y-F et al 2006 Proc Natl Acad Sci USA 103: 15617). Arsenic trioxide is an anticancer agent (Lu J et al 2007 Proc Natl Acad Sci USA 104:12288). ►MAP, ►soil remediation; Basu A et al 2001 Mutation Res 488:171; Oremland RS, Stolz JF 2003 Science 300:939; Croal LR et al 2004 Annu Rev Genet 38:175.

Figure A122. Arsenic spots

A

ART (assisted reproductive technology): This may benefit about 15% of infertile couples. Various techniques are available to assist in conception. Although most of these technologies appear safe, some concerns have been raised (Powell K 2003 Nature [Lond] 422:656). More recent evidence, however, indicates that the concerns are unwarranted and the offspring from intracytoplasmic sperm injection does not suffer any detectable harm (see Fig. A123) (Rosenwaks Z, Bendikson K 2007 Proc Natl Acad Sci USA 104:5709). ▶artificial insemination, ▶intrauterine insemination, ▶in vitro fertilization, ▶ROSI, ▶oocyte donation, ▶GIFT, ▶intrafallopian transfer of gamete and zygote, ▶surrogate mother, ▶sperm bank, ▶insemination by donor, ▶preimplantation, ▶genetics [▶PGD], ▶sex selection, ▶micromanipulation of the oocyte, ▶ICSI, ▶IUGTE, ▶counseling genetic; Baritt JA et al 2001 Human Reprod 16:513; Trounson A, Gardner D (eds) 2000 Handbook of In Vitro Fertilization. CRC Press, Boca Raton, Florida.

Figure A123. Qing dynasty enameled porcelain

Art in Science: Artworks and ancient relics provide much information about anthropology, evolution of species, diseases and technology. ▶Lascaux, ▶mammoth, ▶body mass index in humans, ▶inbreeding depression, ▶Toulouse Lautrec, ▶depression, ▶chimera, ▶gynecomastia, ▶Native Americans, ▶Van Gogh, ▶Poliovirus, ▶obesity, ▶gout, ▶musical ▶talent, ▶Mondrian

Artemis: A single-strand-specific 5'→3' exonuclease, which upon activation by a protein kinase (DNA-PK_{CS}) gains endonuclease function for 5' and 3' overhangs and hairpins. Its mutations render DNA hypersensitive to double-strand breaks and the loss of B and T lymphocytes results in severe combined immune deficiency. This exonuclease is required along with ATM and other proteins for the repair of radiation-induced double-strand breaks (Riballo E et al. 2004 Mol Cell 16:715). ARTEMIS is also required for plant cell and chloroplast division. ▶ATM, ▶endonuclease, ▶exonuclease, ▶lymphocyte, ▶severe combined immunodeficiency, V(D)J; Ma Y et al 2002 Cell 108:781; Fulgosi H et al 2002 Proc Natl Acad Sci USA 99:11501.

Artemis: DNA sequence viewer and annotation tool. ▶ACT; <http://www.sanger.ac.uk/Software/Artemis>.

Arterial Calcification of Infancy (occlusive infantile calcification, 6q dominant): Calcification of the internal lamina of the arteria due to defective ectonucleotide pyrophosphatase/phosphodiesterase 1. Normally the pyrophosphate generated by the enzyme prevents calcification. Rutsch F et al 2003 Nature Genet 34:379.

Arterial Tortuosity Syndrome (20q13.1): A disease of the arterial wall due to disruption of the elastic fibers which produces twists, elongation and aneurysm (sac formation). In one of the genes (SLC2A10), glucose transporter (GLUT10) deficiency upregulated TGF-β (Coucke PJ et al 2006 Nature Genet 38:452). ▶Loeys-Dietz syndrome, ▶Marfan syndrome

Arteriosclerosis: This refers to thickening and hardening of the walls of arterial veins, a common form of heart disease. ▶atherosclerosis

Arthritis: An inflammation and erosion of the major component (aggrecan) of cartilage in the joints is caused by several factors with incomplete penetrance and expressivity. It is a common occurrence in familial gout, a hyperuricemia (excessive uric acid production). Rheumatoid arthritis is generally described as an autoimmune disease. About one-third of the cases involve the HLA-DRB1 *04 alleles in the presence of this condition. The telomeres in CD4⁺ T lymphocytes are eroded during the first two decades of life followed by reduced homeostasis in T cell proliferation later (Schönland SO et al 2003 Proc Natl Acad Sci USA 100:13471). It appears to be autosomal dominant but the genetic control is not entirely clear. The erosion is mediated by aggrecanase (a metalloproteinase with thrombospondin, glycoprotein secreted by the endothelium). ADAMTS5 (a disintegrin and metalloprotease with thrombospondin-like repeats) destroys aggrecan, and its knockout is a promising therapeutic measure

for arthritis in mouse (Glasson SS et al. 2005 Nature [Lond] 434:644; Stanton H et al 2005 Nature [Lond] 434:648). IL-6, IL-8, GM-CSF promote inflammation whereas IL-10, IL-1ra, soluble TNF-R reduce inflammation in rheumatoid arthritis. Anti-TNF- α antibody treatment may offer some promise. In some forms the basic problem is that the lymphocytes target the cell's glucose-6-phosphate isomerase. Its prevalence is about 1% in the general population. ►rheumatic arthritis, ►arthropathy, ►arthropathy-camptodactyly, ►connective tissue disorders, ►cartilage, ►TNF, ►IFN, ►IL, ►NF- κ B, ►*Borrelia*, ►metalloproteinase, ►ADAM, ►osteoarthritis, ►IL-6, ►IL-8, ►IL-10, ►IL-1, ►IL-17, ►GM-CSF, ►TNF-R, ►ZAP-70, ►telomeres, ►T cell; Ota M et al 2001 Genomics 71:263; Feldmann M, Maini RN 2001 Annu Rev Immunol 19:163; Firestein GS 2003 Nature [Lond] 423:356.

Arthroconidiation: A process of fungal conidiation involving germination of conidia, forming hyphae with coupled septation and nuclear division. ►conidia, ►hypha, ►septate

Arthrogryposis: There is unclear (autosomal) genetic determination of this malformation of low recurrence which causes deformation of limbs, hip dislocation, scoliosis (crooked spine), frequently short stature, amyoplasia (poor muscle formation), etc. Distal arthrogryposis (DA1, 9p13.2-p13.1, 9p21-q21) is responsible for dominant club foot and encodes tropomyosin. The DA2B locus (11p15.5) encodes a mutant isoform of troponin (Sung SS et al 2003 Am J Hum Genet 72:681). A neurogenic type is in chromosome 5q35; it is a non-progressive multiple joint contracture disease that is not lethal. *Arthrogryposis-renal dysfunction-cholestasis syndrome* is caused by *VPS33B* mutations, in chromosome 15q26 is neurogenic, with renal tubular dysfunction and neonatal cholestasis that leads to death during the first year of life. X-linked forms have also been described. Severe forms are the *lethal congenital contractural syndrome* (LCCS) in 9q34, 12q13 and 19p13; it is likely that they involve mutation in PIP5K1C encoding phosphatidylinositol-4-phosphate 5-kinase, type I, gamma (PIPKI), an enzyme that phosphorylates phosphatidylinositol 4-phosphate to generate phosphatidylinositol-4,5-bisphosphate, PIP₂ (Narkis G et al 2007 Am J Hum Genet 81:530). *Lethal congenital contractural syndrome type 2* (LCCS2, 12q13) is an autosomal recessive neurogenic form of arthrogryposis that is associated with atrophy of the anterior horn of the spinal cord (Narkis G et al 2007 Am J Hum Genet 81:589). ►limb defects, ►connective tissue disorders, ►Freeman-Sheldon syndrome, ►clubfoot, ►tropomyosin, ►troponin, ►phosphoinositides

Arthroptalmopathy: ►Stickler syndrome

Arthropod: An invertebrate animal with a segmented body like insects, spiders, crustaceans, etc.

Arthropathy: Any disease that affects the joints.

Arthropathy-Camptodactyly (synovitis): This is based on autosomal recessive inheritance. It involves inflammation of the joints (synovial membranes) resembling arthritis. It may have an onset in early childhood. ►connective tissue disorders

Arthus Reaction: An inflammatory immunological reaction to antigen introduced into sensitized animals. The lesion causes activation of the complement and the large number of infiltrating neutrophils release lysosomal enzymes that lead to tissue destruction. ►antigen, ►antibody, ►immune response, ►complement, ►neutrophil, ►lysosomes

Artichoke (*Cynara scolymus*): Vegetable crop; $2n = 2x = 34$.

Artifact: Refers to something that is man-made or a result of human handling of the object, rather than due to entirely natural causes.

Artificial Chromosome: ►YAC, ►BAC, ►PAC, ►human artificial chromosome

Artificial Insemination: This method may be used to overcome the consequences of male infertility in humans or to obtain a larger number of offspring of male animals with economically desirable characters and high productivity. Generally, the sperm is obtained from sperm banks where the semen is preserved at very low temperatures. The cryopreservation may protect against sexually transmitted disease. ►sperm bank, ►ART, ►intrauterine insemination, ►surrogate mother, ►AID, ►AIH, ►ART, ►bioethics

Artificial Intelligence: A device (computer) with the ability to function similarly to human intelligence, i.e., capability of learning, reasoning and self-improvement. ►robot scientist

Artificial Seed (synthetic seed): This is formed usually from somatic embryos that are enclosed by a Na-alginate (polymer of mixed mannuronic and glucuronic acids) capsule in the presence of a calcium salt (CaNO₃ or CaCl₂). Within the capsule an "artificial endosperm" of nutrients may be included. Partially dehydrated embryos may also be used as artificial seed. Artificial seeds may be used for studying the physiology of such constructs and also for micropropagation of some plants. ►micropropagation

Artificial Selection: This process may alter the structure of the population in a way similar to natural selection. When the selection is relaxed or reversed due to

A

genetic homeostasis the selection may still be effective for various traits (e.g., bristle number in *Drosophila*, oil or protein content in plants, etc.) that are under polygenic control (see Fig. A124). ▶selection, ▶selection conditions, ▶selection index, ▶gain, ▶homeostasis

Figure A124. Artificial selection. Selection and reversed selection of oil content in maize. (After Dudley JW (1973) Rep. 28th Annu. Corn Sorghum Res. Conf. Am. Seed Trade Assoc. Washington, DC, p. 126)

Arts Syndrome: ▶ataxia

Arylesterase (ESA, paraoxonase): Encoded in human chromosome 7q22, this enzyme breaks down parathion and related insecticides. ▶cholinesterase, ▶pseudocholinesterase

Aryl Hydrocarbon Receptor (ARH): Mediates the carcinogenic and teratogenic, immunosuppressive, etc. responses to arylhydrocarbons present in many environmental toxins (dioxin, benzo(a)pyrene, cigarette smoke, polychlorinated and polybrominated biphenyls, etc.). ARH regulated genes include cytochromes P450, uridine diphosphate-glucuronosyl transferase, growth factors and proteins. In yeast 54/4507 genes examined modify the ARH signal transduction in five modules involving receptor folding, nuclear translocation, transcriptional activation, receptor level and the PAS complex. (Yao G et al 2004 PloS Biol 2:355). ▶ARNT, ▶PAS, ▶genetic networks, ▶networks, ▶items under separate entries

Arylsulfates: These are aromatic molecules with bound sulfate. Arylsulfatases deficiency is observed in the lipidosis group of diseases, collectively designated as metachromatic leukodystrophy. ▶lipidoses, ▶Krabbe's leukodystrophy, ▶metachromatic leukodystrophy

α-Satellite DNA This refers to centromeric repetitive DNA. ▶repetitious DNA, ▶satellite DNA

AS: ▶asparagine synthetase

AS ODN (antisense oligodeoxynucleotide): This may bind oncogene mRNA and may inhibit cancer growth and regulate the formation of megakaryocytes. It may be used in gene therapy. ▶antisense technologies, ▶cytofectin, ▶megakaryocytes, ▶gene therapy, ▶cancer gene therapy

ASAP: Cell adhesion molecule of the ARF family of proteins. ASAP1 is a regulator of protein sorting through membranes, it activates GTPase and regulates the cytoskeleton. ▶ARF, ▶protein sorting, ▶cytoskeleton, ▶polycystic kidney disease

ASAP: Aster associated protein binds microtubules at the COOH end. Over manifestation or under manifestation of ASAP results in aberrant spindle, delays in mitotic progression and causes cell death because of defects in cytokinesis (Saffin J-M et al 2005 Proc Natl Acad Sci USA 102:11302). ▶aster, ▶spindle, ▶cytokinesis

Asbestos: Mineral silicate fibers are carcinogenic supposedly by being phagocytized and then accumulate around the cell nucleus where they may interfere with chromosome segregation. The mechanical irritation may contribute to mesothelial (lung) cancer. The cells with asbestos release TNF-α and other cytokines. In vitro, asbestos is lethal to mesothelial cells. The treatment of human mesothelial cells with TNF-α considerably reduces toxicity by activating the NF-κB signaling pathway thereby constituting a potential therapy for asbestos damage (Yang H et al 2006 Proc Natl Acad Sci USA 103:10397). ▶TNS, ▶NF-κB; Tweedale G 2002 Nature Rev Cancer 2:311.

Ascaris megalocephala (horse threadworm): It shows very unusual chromosome behavior (see Fig. A125). It has only one pair of large chromosomes in the germline but during somatic cell divisions these large chromosomes are fragmented into numerous small chromosomes. On the basis of this organism Van Beneden discovered in (1883) reductional division in meiosis, a cornerstone of the cytological basis of Mendelian segregation.

Figure A125. *Ascaris megalocephala univalens*. (Boveri, T.)

A. megalcephala univalens has $2n = 2$, *A. megalcephala bivalens* $2n = 4$, and *A. lumbricoides* $2n = 43$ chromosomes. ▶chromosome breakage programmed

Ascertainment Test: This is generally required in larger mammals with few offspring to determine the segregation ratios on the basis of pooled data of several families. The problem involved in biased sampling (because those families where the parents are heterozygous for the recessive gene escape identification if no homozygotes are observed among the progeny) can be corrected for. The solution is mathematical. According to Mendelian expectation, 3/4 of single-child families has no affected children. Among the two-child families $(3/4)^2 = 9/16$ is the probability that neither will be of recessive phenotype. Of the remaining 7/16 of the families, 6/7 will have one recessive and one dominant and 1/7 should have 2 recessives. Thus, the average expectation is $(1) \times (6/7) + (2) \times (1/7) = 8/7 = 1.143$. In three-child families 27/64 will have no affected offspring, 9/37 will have 2, and 1/37 are expected to have 3 recessives. Therefore, the average expected is $(1) \times (27/37) + (2) \times (9/37) + (3) \times (1/37) = 1.294$. In the same manner the average expectation of recessives for various sizes of families can be determined (see Table A5):

Using this information the number of observed and expected data for affected and unaffected families of varying sizes can be analyzed with the chi square procedure and the goodness of fit can be evaluated:

$$\chi^2 = \frac{(25 - 26.9)^2}{26.9} + \frac{(24 - 22.1)^2}{22.1} = 0.298;$$

The degree of freedom = 1, and the probability of fit is >0.5 (for χ^2 only, values below 0.05 would have some

ground for doubting the fit). A simpler (and less reliable) procedure for determining the average number of recessives (\hat{q})

$$\hat{q} = \frac{R - N}{T - N}$$

where R is the number of recessive segregants observed, N is the number of families showing recessives, and T is the total number of children of these families.

The *ascertainment bias* (the correction for truncated/ incomplete selection of families on the basis of probands) can also be estimated by the Bernstein formula: Expected number of affected recessives $E_r = n_s(p/1 - q^s)$ where s = number of sibs per family, n_s = number of families with s number of sibs, p = segregation ratio, $q = 1 - p$. The results of the ascertainment may not be valid for populations which were not part of the samplings in complex cases. Using DNA sequence information the ascertainment bias may be eliminated because penetrance or expressivity does not affect the correct molecular information. ▶chi square, ▶sib, ▶proband, ▶penetrance, ▶expressivity, ▶segregation ratio; Burton PR et al 2000 Am J Hum Genet 67:1505; Lake SL et al 2000 Am J Hum Genet 67:1515; Haghighi F, Hodge SE 2002 Am J Hum Genet 70:142; Epstein MP et al 2002 Am J Hum Genet 70:886.

Aschheim-Zondek Test (AZT): Uses subcutaneous injection of the urine of human females into immature female mice to test for early pregnancy. Swelling, congestion and hemorrhages of the ovaries and precocious maturation of the follicles in the mice are positive indicators of pregnancy of the tested person. Today, a hemagglutination test or a chorionic gonadotropin test is used. Pregnancy immediately

Table A5. Ascertainment test

| Number of Children | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---------------------|-------|-------|-------|-------|-------|-------|-------|-------|
| Average Homozygotes | 1.000 | 1.143 | 1.297 | 1.463 | 1.639 | 1.825 | 2.020 | 2.223 |

| Number of Sibs/Family | Families | Number of Affected Sibs | | Number of Unaffected Sibs | |
|-----------------------|----------|-------------------------|---------------------------|---------------------------|----------|
| | | Observed | Expected | Expected | Observed |
| 1 | 7 | 7 | $7 \times 1 = 7.00$ | 0 | 0 |
| 2 | 10 | 8 | $10 \times 1.143 = 11.43$ | 12 | 8.57 |
| 3 | 4 | 6 | $4 \times 1.297 = 5.19$ | 6 | 6.81 |
| 5 | 2 | 4 | $2 \times 1.639 = 3.28$ | 6 | 6.72 |
| Total 25 | | | 26.90 | 24 | 22.10 |

A

raises dramatically the level of this hormone.
 ►hemagglutinin, ►gonadotropin

Asci: Is the plural of ascus. ►ascus

Ascidians: Invertebrate (chordate) sea animals with sexual and asexual reproduction. ►*Ciona intestinalis*; Davidson B, Christiaen L 2006 Cell 124:247, <http://www.ascidians.com/>; <http://crfb.univ-mrs.fr/aniseed/index.php>.

Ascites: In this condition the abdominal fluid (may contain also cells) is excreted in response to cell proliferation in the abdominal cavity because of a neoplasia. The fluid is serum, containing polyclonal antibodies. Cirrhosis or hypoalbuminemia, and experimental injections may also cause ascites.
 ►cirrhosis of the liver, ►albumin

Ascobolus: This fungal genus is advantageously exploited for tetrad analysis. ►tetrad analysis

Ascobolus immersus: An ascomycete where the dissection of the ascospores is very simple, the spores spring off when touched and can be captured on microscope slides. This fungus has been extensively used in studies of recombination and gene conversion; x = 12, 16, 18.

Ascomycetes: Refer to those sites in fungi where the perithecia and apothecia (fruiting bodies) develop.

Ascogenous Hyphae: These diploid or bikaryotic hyphae lead to the formation of fruiting bodies in fungi. ►fruiting body, ►hypha

Ascogonium: This refers to the gametangium (oogonium), the female sexual organ of fungi (also called protoperithecium).

Ascomycete: A large group of different fungi producing either asexual conidiospores and/or ascospores within asci as a consequence of meiosis. ►tetrad analysis

Ascorbic Acid (vitamin C): This anti-scurvy (antiscorbutic) substance is required for proper hydroxylation of collagen and its deficiency causes skin lesions and damages the blood vessels, i.e., symptoms of scurvy. It is also a reducing compound and upon oxidation it is converted into dehydroascorbic acid (see Fig. A126). Together with Fe(II) and O₂ it is a hydroxylating agent for aromatics. In the process H₂O₂ is formed. It has been claimed that high daily

Figure A126. Ascorbic acid

doses of ascorbic acid lower the risks of common cold and other ailments. Further, it has been found to be weakly mutagenic, probably because of its ability to generate free radicals. Most primates and guinea pigs cannot synthesize this vitamin because of numerous alterations in the gene (human chromosome 8p21) encoding L-gluconolactone oxidase and depend on dietary supplies (Nishikimi M et al 1994 J Biol Chem 269:13685). There is a need for an ascorbic acid transporter SLC23a1 (Sotiriou S et al 2002 Nature Med 8:514). The biosynthetic pathway in plants differs from that in animals, algae or fungi. Over expression of a NADPH-dependent D-galacturonate reductase may substantially increase ascorbate production in plants (Agius F et al 2003 Nature Biotechnol 21:177). Vitamin C degradation in plant material can take place enzymatically (via hydrolysis of 4-oxalyl-L-threonate) or during cooking (Green MA, Fry SC 2005 Nature [Lond] 433:83). The therapeutic applications of ascorbate against flu or cancer are controversial although high intravenous doses may have anticancer effects because of H₂O₂ effects (Chen Q et al 2005 Proc Natl Acad Sci USA 102:23604). In the presence of ascorbate low 0.2–2 μM doses of chromate caused 10–15 times more chromosomal breakage in primary human bronchial epithelial cells or lung fibroblasts (Reynolds M et al 2007 Nucleic Acids Res 35:465). ►vitamin C, ►Charcot-Marie-Tooth disease; Lee SH et al 2001 Science 292:2083; Smirnov N et al 2001 Annu Rev Plant Physiol Plant Mol Biol 52:437.

Ascospores: Haploid products of meiosis formed within an ascus (see Fig. A127). ►ascus, ►tetrad analysis

Figure A127. Ascospores

ASCT1: This is a zwitterionic amino acid transporter.
 ►transporters, ►zwitterion

Ascus: A sac-like structure in the *Ascomycete* fungi, containing the four products of meiosis (spores). In many fungi the number of ascospores may increase to eight due to a mitotic division following meiosis. The spores in the asci may be arranged in the same linear order as in the linear tetrad of meiosis (ordered tetrads such as *Neurospora*, *Ascobolus*, *Aspergillus*, etc.) or may be scrambled (unordered tetrad such as in yeast). Asci have been used very effectively to study the mechanics of recombination because the results of single meiotic events could be analyzed separately.
 ►tetrad analysis

Ascus-Dominant: A mutation or even a deletion affects (prevents) the expression of the dominant allele within an ascospore. It has been attributed to reduced dosage, defects in inter-nuclear communication and transvection. ▶ [transvection](#)

ASE1 (anaphase spindle elongation): This is a gene encoding MAP, required for elongation of the mitotic spindle and separation of the spindle poles. The anaphase-promoting complex (APC) degrades it. ▶ [MAP](#), ▶ [spindle](#), ▶ [cell cycle](#), ▶ [centriole](#)

Aseptic: This means that the culture is free from contaminating microorganisms. ▶ [axenic](#), ▶ [pasteurization](#), ▶ [autoclaving](#), ▶ [filter sterilization](#)

Asexual Reproduction: This does not involve fusion of gametes of opposite sex or mating type. Yet, genetic changes in asexual or mainly asexual crustacean *Daphnia* lines genotyped at 126 microsatellite loci and sequencing 16 nuclear protein-coding loci showed spontaneous loss of heterozygosity resulting from ameiotic recombination at many loci (Omilian AR et al 2006 Proc Natl Acad Sci USA 103:18638). ▶ [reproduction](#), ▶ [mitotic recombination](#), ▶ [parasexual mechanism](#)

ASF1 (anti-silencing function protein, CIA/CCG1 interacting factor 1): This is a chaperone for newly synthesized histones H4 and H4 and it participates in nucleosome assembly, DNA replication and repair. ▶ [chaperones](#), ▶ [nucleosomes](#), ▶ [chromatin](#), ▶ [RCAF](#), ▶ [NHEJ](#), ▶ [histone acetyltransferases](#); Mousson F et al 2005 Proc Natl Acad Sci USA 102:5975; English CM et al 2006 Cell 127:495, SR motif, structure: Natsume R et al 2007 Nature [Lond] 446:338.

AS-Fish (antisense fluorescent in situ hybridization): The probe labels the sense strand of the DNA and thus it may make possible to label differentially the transcribed and non-transcribed heterologous DNA, introduced by transformation in the cell. ▶ [FISH](#), ▶ [antisense strand](#)

Ash: The mineral residue of tissues left after igniting the organic material.

Ash Tree: Forest and ornamental trees (*Fraxinus excelsior*, 2n = 46; *F. americana*, 2n = 46, 92, 138).

Ashkenazi: Refers to Jews who lived during the Middle Ages in German lands although they migrated from there to Eastern Europe and other parts of the world. They preserved their ethnic identity and a special gene pool. Therefore, certain hereditary conditions such as Tay-Sachs disease, Gaucher disease, Niemann-Pick's disease, Bloom's syndrome, higher I.Q, etc. occur at increased frequencies in the population compared to some other ethnic groups. The haplotype spectrum based on the non-recombining

part of the Y chromosome and microsatellite haplotypes indicate some significant differences from the Sephardic Jews and similarities to some Eastern European Slavic and Turcic (Khazar) ethnic groups. Some likely Khazar introgression appeared among Hungarian Jews because among the invaders of the Carpathian basin the tribe of chieftain Taksony was of Turcic ethnicity and embraced Jewish religion during the seventh-eighth century. ▶ [Sephardic](#), ▶ [Jews and genetic diseases](#), ▶ [introgression](#); Behar DM et al 2003 Am J Hum Genet 73:768.

Asialoglycoprotein Receptor: Normally many soluble glycoproteins have sialic acid residues attached to their end. The sialic acid residues determine whether or not the glycoprotein is circulated in the bloodstream. If the sialic acid is lost the glycoprotein may bind to the plasma membrane of the liver cells (hepatocytes) and become asialoglycoprotein receptors. Glycoproteins attached to these receptors are generally degraded by the lysosomes of the liver. ▶ [sialic acid](#)

Asilomar Conference: In 1975, when recombinant DNA was beginning to be widely used, scientists convened at this place in California to prepare voluntary guidelines for protection against the potential hazards of the application of new techniques. ▶ [containment](#); Berg P et al 1975 Proc Natl Acad Sci USA 72:1981.

ASK1 (apoptosis signal regulating kinase): This member of the mitogen-activated MAP protein family is activated by TNF- α . It induces apoptosis but it may inhibit TNF- α -induced apoptosis. It stimulates JNK activation, and also interacts with the TRAF family especially with TRAF2- induced JNK activation. ▶ [apoptosis](#), ▶ [MAP](#), ▶ [TNF](#), ▶ [JNK](#), ▶ [TRAF](#)

ASLV (avian sarcoma-leukosis virus): ▶ [retroviruses](#)

ASMD (anterior segment mesenchymal dysgenesis): This is encoded by the dominant PTX3 gene (10q25) affecting the development of cataract and later midbrain, tongue, incisors, breastbone (sternum), vertebrae and limbs. ▶ [cataract](#), ▶ [Rieger syndrome](#), ▶ [eye diseases](#)

ASN.1 (Abstract Syntax Notation): Describes the format in sequence databases to which all other files correspond; asn.all describes the formats of both literature and genetic sequence messages. ▶ [Bioseq](#), ▶ [gi](#), ▶ [accession](#); <http://asn1.elibel.tm.fr/>.

Asn-Pro-X-Tyr: An amino acid sequence responsible for the internalization of low-density lipoproteins (LDL) of the membranes. LDL.

ASO: Refers to allele-specific oligonucleotide probe. Screening can be carried by semi-automated procedures. ▶ [allele-specific probe](#)

A

ASP Analysis: This analysis is used to estimate linkage in cases when a particular trait is under polygenic control. The co-segregation of multiple markers is followed in individuals who manifest the particular trait and determine which of the markers are most consistently present in these individuals. The analysis still requires the MAPMAKER/SIBS computer program, which evaluates multiple segregating families. ► [MAPMAKER](#), ► [QTL](#), ► [interval analysis](#)

Asparagine (α -aminosuccinamic acid): $\text{NH}_2\text{COCH}_2\text{CH}(\text{NH}_2)\text{COOH}$; its RNA codons are AAU, AAC.

Asparagine Synthetase (AS): Asparagine synthetase of bacteria uses ammonia as an amide donor, rather than glutamine as the mammalian enzyme. Cells expressing the bacterial AS will grow in asparagine-free medium if the glutamine analog, albizzin is present. In AS transfected mammalian cells the gene can be amplified in the presence of β -aspartyl hydroxamate, an analog of aspartate, and thus AS can be used as a dominant amplifiable marker in mammalian cell cultures. The mammalian genes are present in human chromosomes 7q21-q31, 8pter-q21, 21pter-q22. The AS genes do not have TATA and CAAT boxes in the promoter. They are homologous to the hamster *tsII* gene that is required for passing the cell cycle through the G1 stage. ► [amino acid metabolism](#), ► [cell cycle](#), ► [house keeping genes](#), ► [CAAT box](#), ► [TATA box](#), ► [AS in leukemia chemotherapy](#); Richards NGJ, Kilberg MS 2006 Annu Rev Biochem 75:629.

Asparaginyl tRNA Synthetase (ASNRS): This charges the appropriate tRNA with asparagine. In human cells it has been located in chromosome 18. ► [aminoacyl tRNA synthetase](#)

Asparagus officinalis (a dioecious monocot, $2n = 20$): Refers to sex determination by XX pistillate and XY staminate plants (see Fig. A128). By anther culture YY plants can be obtained that can be vegetatively propagated or by pollination they produce exclusively male progeny. The male plants are of special economic value because their yield/area of edible spears is substantially higher. Almost half of the human populations excrete methanethiol in their urine after consuming this vegetable. The excreter trait appears to be autosomal dominant. The ability to smell this particular odor may also be under dominant control. ► [YY asparagus](#), ► [olfactory genetics](#)

Figure A128. Asparagus

Aspartame (Nutra-Sweet): Refers to *N*-L- α -aspartyl-L-phenylalanine-1-methyl ester, an artificial low-calorie food and beverage sweetener; about 160 times as sweet as sucrose. It is not recommended for phenylketonurics because it contains phenylalanine. ► [saccharine](#), ► [fructose](#), ► [phenylketonuria](#)

Aspartate Aminotransferase (glutamate oxaloacetate transaminase, GOT1, GOT2): One of the functional forms of this enzyme GOT1, is encoded in human chromosome 10q24.1-q25.1 and it is expressed in the cytosol. A homolog GOT2 is encoded in human chromosome 16q12-q21 and it is expressed in the mitochondria. Pseudogenes of the latter have been located at 12p13.2-p13.1, 1p33-p32 and 1q25-q31. In the liver, the mitochondrial enzyme is largely present whereas the cytosolic enzyme is mainly located in the serum. ► [amino acid metabolism](#), ► [asparagine synthetase](#)

Aspartate Phosphatase: ► [two-component regulatory systems](#)

Aspartate Proteases: The opening up of DNA for the integration of retrotransposable elements. Their protein generally shares the motif D,D45E (aspartic acid, aspartic acid, 35 amino acids, glutamic acid). ► [transposase](#), ► [retrotransposons](#)

Aspartic Acid ($\text{HOOCCH}_2\text{CH}[\text{NH}_2]\text{COOH}$): This is a negatively charged amino acid. ► [amino acids](#), ► [aspartate aminotransferase](#), ► [ancient DNA](#)

Aspartic Acid Racemization: ► [ancient DNA](#)

Aspartoacylase Deficiency (aminoacylase-2 deficiency, Canavan disease, ACY2): This enzyme cleaves acylated amino L-acids into an acyl and amino acid group, whereas amino-acylase-1 (ACY-1) similarly cleaves all acylated L-amino acids, except L-aspartate. The autosomal recessive disorder has an early or late onset resulting in debilitating muscle, eye defects, mental retardation and spongy degeneration of the white matter of the brain. A defect in myelin synthesis is the major cause of the frequently fatal diseases (Madhavarao C et al 2005 Proc Natl Acad Sci USA 102:5221). There may be a 200-fold increase of *N*-acetylaspargic acid in the urine. Its incidence is increased among Jews of Ashkenazi descent and in Saudi Arabic populations. The chromosomal location is 17pter-p13. The catalytic site of aspartoacylase reveals close structural similarity to those of carboxypeptidases despite only 10–13% sequence identity between these proteins. Around 100 C-terminal residues of aspartoacylase form a globular domain with a two-strand β -sheet linker that wraps around the N-terminal domain. The long channel leading to the active site is formed by the interface of the N- and C-terminal domains. The

C-terminal domain is positioned in a way that prevents productive binding of polypeptides in the active site. The structures revealed that residues 158–164 may undergo a conformational change that results in the opening and partial closing of the channel entrance (Bitto E et al 2007 Proc Natl Acad Sci USA 104:456). ▶amino acid metabolism, ▶neuromuscular defects, ▶mental retardation, ▶eye diseases, ▶Jews and genetic diseases, ▶carboxypeptidase

Aspartylglucosaminuria (AGA): A chromosome 4 recessive defect of the enzyme aspartylglucosaminidase (4q32-q33) may eliminate an important S—S bridge of the protein resulting in neurological-mental and other defects. Its frequency is higher ($\sim 4 \times 10^{-5}$) in populations of Finnish descent. ▶amino acid metabolism, ▶disulphide bridge, ▶sialidosis; Saarela J et al 2001 Hum Mol Genet 10:983.

AS-PCR: Refers to allele-specific PCR. polymerase ▶chain reaction

ASPD (Artificially Selected Proteins/Peptides Database): ▶phage display

Asperger Syndrome (Xq22.3, Xq13-q21): This is a form of childhood autism with less severe expression than the adult forms encoded at several autosomal locations. Susceptibility genes have been located to 3q25-q27, 3q24-q21, 17p13, 1q21-q22 and to TBX1 (T-box protein) transcription factor at 22q11.2. ▶autism

Aspergillus: Numbering nearly ~185 species, including 20 human pathogens of ascomycetes, *Aspergillus nidulans* ($n=8$, $\sim 3 \times 10^7$ bp, 9,541 protein-coding genes) is a favorite organism for studies of recombination (see Fig. A129). One meiotic map unit is about 5–10 kbp. It has been extensively used for mitotic recombination. Asexual reproduction is by conidiospores (3–3.5 μm). This is a homothallic fungus and thus does not have different mating types. In the cleistothecium there are up to 10,000 binucleate ascospores in 8-cell linear, ordered asci. Transformation systems

Figure A129. *Aspergillus nidulans* conidiophore and conidia

are available. It yields about 5×10^3 transformants/ μg DNA. *A. flavus* is responsible for the production of aflatoxin, an extremely poisonous toxin that is found on infected plant residues, seeds, etc. *A. fumigatus* ($\sim 2.8 \times 10^7$ bp, 9,926 protein-coding genes) is a soil-born fungus, which causes ear, nose, lung and other infections in humans and animals. *A. oryzae* (3.7×10^7 bp, 12,074 protein-coding genes) is important for food technology (sake, soy sauce and miso [a fermented Japanese soy paste]). The size of protein-coding genes varies from 1,547 (*nidulans*) to 1,389 (*fumigatus*) and 1,1529 (*oryzae*). *A. nidulans* is more closely related to *A. fumigatus* than to *A. oryzae*. *A. nidulans* has a known sexual cycle whereas the other two species generally reproduce asexually. All three species display homology of 5000 non-coding regions. The homothallic *A. nidulans* has both the MAT locus and a HMG (high-mobility group) gene. The heterothallic *A. fumigatus* conserved through evolution only HMG but no MAT and the heterothallic *A. oryzae* has only the MAT locus but no HMG. The latter two species have, however, highly homologous sequence to the flanking sequences sex-determination loci of *A. nidulans*. The industrially important *A. nigr*a genome has also been sequenced (Pel HJ et al 2007 Nature Biotechnol 25:221). ▶aflatoxins, ▶mitotic recombination, ▶recombination, ▶cleistothecium, ▶conidia, ▶tetrad analysis, ▶mating type determination in yeast, ▶high-mobility group of proteins, ▶nuclear membrane, comparative genomic sequences of *Aspergilli*: Galagan JE et al 2005 Nature [Lond] 438:1105; Nierman WC et al 2005 Nature [Lond] 438:1151; <http://www.ncbi.nlm.nih.gov/genome/guide/aspergillus/>, scientific and medical information: <http://www.fgsc.net/aspergenome.htm>.

Aspermia: Refers to the lack of ejaculating ability of the male.

Asphyxiating Thoracic Dystrophy (Jeune syndrome, 15q13): This is a recessive chondrodysplasia causing constricted thorax and respiratory difficulties and possibly different malformations; it is frequently lethal in the case of infants. It bears similarity to Ellis-van Creveld syndrome. ▶Ellis-van Creveld ▶syndrome

Aspirin (salicylic acid acetate): An analgesic, anti-fever, anti-inflammatory and anti-coagulant drug (blood thinner) (see Fig. A130).

Figure A130. Aspirin

A

It inhibits cyclooxygenases, IKK and JNK. The aspirin metabolite salicylic acid inactivates staphylococcal virulence factors and thus acts directly on the bacteria rather than on the host organism (Kupferwasser LI et al 2003 J Clin Invest 112:2221). Aspirin reduces the risk of major cardiovascular disease in both men and women (Ridker PM et al 2005 New England J Med 352:1293). Nitroaspirin increases the function of tumor-antigen-specific T lymphocytes and aids the anti-tumor effect of cancer vaccines (De Santo C et al 2005 Proc Natl Acad Sci USA 102:4185). Some individuals may show hypersensitivity to aspirin and precautions are required in the case of some hearing deficits, gout, hyperthyroidism, some kidney and liver problems, anemia, glucose-6-phosphate deficiency and Hodgkin's disease. Contraindication is warranted for hemophilia, other bleeding diseases, pregnancy, nursing, chickenpox and Rye syndrome. ▶salicylic acid, ▶cyclooxygenases, ▶IKK, ▶JNK, ▶host-pathogen relations; Kurumbail RG et al 1996 Nature [Lond] 384:644.

Asplenia: One form (Ivemark syndrome) of asplenia is usually sporadic or autosomal recessive and it is associated with the absence or enlargement of the spleen or multiple accessory spleens and cardiac and other organ malformations. Another form of asplenia involves most conspicuously cystic livers, kidneys and pancreas. ▶spleen; Nikawa N et al 1983 Am J Med Genet 16:43.

ASPP (apoptosis stimulatory proteins of p53): These are specific activators of tumor suppressor p53. iASPP is an inhibitor of p53 and is thus an oncoprotein. ▶p53, ▶oncoprotein; Bergmaschi D et al 2003 Nature Genet 33:162.

Assay: Refers to a test for mutagenic effectiveness or efficiency or the velocity of a chemical reaction catalyzed by enzymes or the test of function of any biological process.

Assembly Initiation Complex: The minimal elements required for the completion of the assembly of the viral components. ▶bacteriophages

Assignment Test: ▶somatic cell hybrids

Assimilation: This is a process for converting nutrients into the cell constituents and also, for blending of an initially different ethnic (cultural) group into the general population. ▶genetic assimilation

Association: The joint occurrence of pathological symptoms, which do not have an expected common functional basis. Some of the associated genetic factors may indicate, however, disease risk. ▶syndrome, ▶PAF; Lohmueller KE et al 2003 Nature Genet 33:177.

Association Constant (K_a): Indicates the association between the components of a complex. The larger the K_a the stronger is the association.

Association Mapping: Identifies chromosomal regions containing disease-susceptibility or other genes on the basis of their association (linkage) with other marker(s) in a population rather than in a pedigree. The association may not necessarily indicate a linkage because selective forces may bias the observations in small populations. Moreover, recent migration or other admixture may lead to a bias. A transmission disequilibrium test may provide a remedy for the spurious association. With the availability of SNP and microsatellite markers genome-wide association between a number of genetic factors and complex disease traits can be attempted (Hirschhorn JN, Daly MJ 2005 Nature Rev Genet 6:95). ▶transmission disequilibrium test, ▶linkage disequilibrium, ▶haplotype block, ▶family-based association tests [▶FBAT], ▶QTL, ▶SNIPs, ▶triad ▶test; Sham PC 2000 Am J Hum Genet 66:1616; Wang WYS et al 2005 Nature Rev Genet 6:109, power and efficiency: de Bakker PIW et al 2005 Nature Genet 37:1217; Yu J et al 2006 Nature Genet 38:203; Laird NM, Lange C 2006 Nature Rev Genet, 7:385.

Association Phase: Refers to the coupling phase in a linkage, a term used in fungal genetics. ▶coupling phase, ▶repulsion, ▶crossing over, ▶linkage

Association Site: Periodically distributed, microscopically detectable multiple interstitial association points are also called nodules. The distance between the paired chromosomes is about 0.4 μm . ▶zygotene stage, ▶meiosis, ▶synaptonemal complex, ▶recombinational node

Association Test: This is basically a 2×2 contingency chi square test based on a panel:

where a, b, c, d represent the number of observations (+ +), (+ -), (- +) and (- -), respectively; n = the total number of observations. If b = c = 0, there is no association. The significance of the association is tested $\chi^2 = \frac{n(ad-bc-0.5)^2}{(a+c)(a+b)(b+d)(c+d)}$ chi square, and the probability of a greater chi square can be determined by a χ^2 table or χ^2 chart for 1 degree of freedom. The association test is most useful for studying a homogeneous population. A particular association may not be an indication of a genetic linkage, a physiological or cause-effect relationship but may provide useful information on the relation between two diseases or whether or not the reciprocal crosses are identical. A family-based association test for QTLs has similarity to the linkage disequilibrium approaches (Lange C et al 2002 Am J Hum Genet 71:1330). Single nucleotide polymorphism can be exploited for genome-wide search of SNP and disease

susceptibility association (Van Steen K et al 2005 Nature Genet 37:683). In the direct approach the candidate genes are sequenced and non-synonymous codon changes (SNPs) are most likely to be associated with disease (Cohen JC et al 2004 Science 305:869) although some non-synonymous substitution are neutral regarding function; the structural effect of SNPs may be more critical for disease and 26–32% of the non-synonymous natural SNPs affect function in a deleterious manner (Chaseman D, Adams RM 2001 J Mol Biol 307:683). The SIFT (sorting tolerant from intolerant) computer program can distinguish between neutral and deleterious amino acid changes in a protein sequence (Ng PC, Henikoff S 2003 Nucleic Acids Res 31:381, <http://blocks.fhcrc.org/sift.SIFT.html>). In the indirect approach, whole-genome associations are sought (Carlson CS et al 2004 Nature [Lond] 429:446). Such studies may rely on heritability estimates, which include the effect of several gene loci as well as the effects of the environment. The variations, however, can be partitioned to components by appropriate experimental design and statistics (see Table A6) (Mountain JL, Risch N 2004 Nature Genet 36:S48). ▶linkage disequilibrium, ▶association mapping, ▶chi square, ▶SNIPS, ▶heritability, ▶partitioning, ▶Odds ratio; Lange C, Laird NM 2002 Am J Hum Genet 71:575; Lange C et al 2003 Am J Hum Genet 73:801; Balding DJ 2006 Nature Rev Genet 7:781.

Table A6. Association test

| Association test | First Variable | | |
|------------------|----------------|---|---|
| | + | – | |
| Second variable | + | a | b |
| | – | c | d |

Assortative Mating: Mates are chosen on the basis of preference or avoidance (positive or negative assortative mating), rather than at random, e.g., tall people frequently chose tall spouses; educated, higher economic or social status individuals usually marry within their group. Traits unknown to the majority, like blood groups, usually do not come into consideration in mate selection. Assortative mating may contribute only slightly to the average coefficient of inbreeding (f) in human populations: $\bar{f} = \frac{r}{2n_e(1-r)+r}$ where r = correlation coefficient, n_e = an equivalent number of genes ($n_e = \frac{\sum_{ij} \sigma_i \sigma_j}{\sum_i \sigma_i^2}$). Assortative mating may have some effect on the expression of a quantitative trait and the heritability becomes $h^2 = \hat{h}^2 [1 - (1 - \hat{h}^2)A]$ where A is the product of the

average heritability and the phenotypic correlation, i.e., $r \hat{h}^2$. ▶controlled mating, ▶mating system, ▶inbreeding, ▶correlation; Rice TK, Borecki IB 2001 Adv Genet 42:35.

Astacin: This is a zinc-metalloprotease. ▶bone morphogenetic protein

Aster: Radiating structures around the two (round) centrosomes are visible in some animal cells (see Fig. A131). ▶centrosome, ▶centrioles, ▶ASAP; figure is redrawn after Cleveland LR 1938 Biol Bull 74:41.

Figure A131. Aster

Asthenozoospermia: Less than 25–50% of the spermatozoa show forward motility. It appears that reduced OXPHOS activity in the mitochondria affects them. Defects in dynein axonemal heavy chain (DNAH1, 3p21.3) may also be concerned. ▶OXPHOS, ▶dynein, ▶cytoplasmic male sterility; Ruiz-Pesini E et al 2000 Am J Hum Genet 67:682; Neesen J et al 2001 Hum Mol Genet 10:1117.

Asthma: This is a respiratory disease due to multiple causes affecting ~155 million people worldwide. Nasal polyps or elevated level of immunoglobulin A (IgA) or IgE may cause some autosomal recessive forms. Key players in the development of asthma are interleukin-13 (IL-13), IL-10 because they guide immature T cells into the development of T_H2 lymphocytes. IL-4 controls the development of B cells (that produce IgE) and IL-5, IL-3 and GM-CSF also play a role through eosinophils that are required for allergic inflammation. Transgenic mouse line genetically devoid of eosinophils lack the inflammatory response (mucus and airways hyper-responsiveness) of asthmatic animals (Lee JJ et al 2004 Science 305:1773). Mast cells and basophils affect the production of histamines, cytokines and chemokines control acute symptoms of asthma. The mast cells respond to IgE and the allergens. The interleukin gene cluster is located in human chromosome 5q31-q33. Genes in human chromosomes 1p32, 2q, 5q31, 6p21, 7p, 8p23, 11q21, 12q12, 13q, 14q24, 15q13 and perhaps other sites appear to be associated with the manifestation of asthma. In different populations different loci may play a major role. The α chain

A

of IL-4 receptor binds IL-13 to the T^H2. Susceptibility to asthma is controlled by a few genes and the heritability has been estimated as ~75%. Asthma—as well as some other anomalies of the immune system—also has a maternal effect. The risk of maternal transmission seems to be fourfold higher. This may be caused either by allelic exclusion, imprinting or by placental transfer or breastfeeding. Indeed, the IgE receptor (FCεRI-β, IL-5) has been mapped to a chromosome (11q13) that commonly affects imprinting. The metalloprotease ADAM33 (20p13) appears to be an important regulator of the disease (Van Eerdewegh P et al 2002 Nature [Lond] 418:426). Glucocorticoids are most commonly used in medication. Immunoglobulin free light chains (κ) mediate hypersensitivity response and the light chain antagonist 9-mer peptide F991 can abrogate the development of airways obstruction, hyperresponsiveness and pulmonary inflammation (Kraneveld AD et al 2005 Proc Natl Acad Sci USA 102: 1578). In asthma-sensitive mice, endogenous S-nitrosothiols (R-S-N=O) are depleted because of increased S-nitroso-glutathione reductase activity. Thus, the enzyme may be a logical target for therapeutic intervention (Que LG et al 2005 Science 308:1618). ▶immunoglobulins, ▶polyp, ▶protease ▶inhibitor, ▶allergy, ▶γδ T cell, ▶T cells, ▶IL-13, ▶IL-10, ▶IL-4, ▶IL-5, ▶IL-3, ▶imprinting, ▶allelic exclusion, ▶hypersensitive reaction [▶animals], ▶atopy, ▶platelet activating factor, ▶eczema ▶filaggrin, ADAM; Xu J et al 2001 Am J Hum Genet 68:1437; Niimi T et al 2002 Am J Hum Genet 70:718; Umetsu DT et al 2002 Nature Immunol 3:715; Laitinen T et al 2004 Science 304:300, nitrosothiol pharmacology: Hogg N 2002 Annu Rev Pharmacol Toxicol 42:585, genes; Ober C, Hoffjan S 2006 Genes Immunol 7:95, <http://cooke.gsfc.de/asthmagen/main.cfm>.

ASTRAL: This is a compendium of protein structures, protein structure, structural classification of proteins, SCOP; <http://astral.berkeley.edu/>.

Astrocytosis: Denotes an increase in astrocyte number because of neuronal loss.

ASV: The avian sarcoma virus of birds is an oncogenic RNA virus that can induce sarcoma in rodents.

▶sarcoma

Asymbiotic Nitrogen Fixation: This proceeds by a microorganism without dependence on cohabitation with other organisms such as by members of the soil bacterial species *Azotobacter* and *Clostridium*. ▶nitrogen fixation, ▶symbiosis

Asymmetric Carbon: This atom has four different covalent attachments. ▶covalent bond

Asymmetric Cell Division: This is a requisite for embryonal differentiation and these divisions specify the dorso-ventral and anterior-posterior polarities of the body pattern (see Fig. A133). Several protein factors specify the process. The orientation of the spindle in *Drosophila* involves the localization of the Numb and Prospero proteins in the basal cells and the polarity instructions may come from the product of the *inscrutable* (*insc*), *partner of inscrutable* (*pins*) and other loci. Yeast (*Ash1p*) and *Caenorhabditis* (*SKN-1*) also have controls similar to Numb and Prospero and *she* and *par* genes, respectively, are analogous to *inscrutable*. In *Drosophila* epithelium the adherens junctions inhibit asymmetric divisions. Centrosomally located mRNAs may be asymmetrically transmitted during the embryonic cleavage divisions (Lambert JD, Nagy LM 2002 Nature [Lond] 420:682). Cdc2 appears to link the asymmetric division machinery and the cell cycle. In the initial determination of the left-right axis in the embryo, the leftward flow of the extraembryonic fluid propelled by the primary monocilia plays a role in vertebrates from mouse, rabbit and medakafish and probably others too (Okada Y et al 2005 Cell 121:633). Embryonic stem cells have the potential of self-renewal (symmetric development) or differentiation into various types of cells (asymmetric divisions). ▶morphogenesis in *Drosophila*, ▶polarized differentiation, ▶spindle, ▶axis of asymmetry, ▶left-right asymmetry, ▶adherens junction, ▶polarCdc2; Grill SW et al 2001 Nature [Lond] 409:630; Knoblich JA 2001 Nature Rev Mol Cell Biol 2:11. Figure A133. Asymmetric cell division

Asymmetric Heteroduplex DNA: ► Meselson-Radding model of recombination

Asymmetric Hybrid: Some of the chromosomes of one or the other parent are lost. ► somatic hybrids

Asymmetric Inheritance: ► asymmetric cell division

Asymmetric Mutation: ► mutation asymmetry

Asymmetric Replication: At the replication fork DNA synthesis on the leading and lagging strands proceeds in an opposite direction relative to the base of the fork. ► replication, ► replication fork

Asynapsis: Refers to the failure of chromosome pairing. ► desynapsis, ► synapsis

Asymptomatic: This is a disease without any symptoms.

Asymptotic Distribution: This type of distribution is observed in a sample or population when the n becomes very large. *Asymptotic relative efficiency* indicates the ratio of sample sizes required to obtain the same accuracy. An *asymptote* is a curve steadily approaching but never intersecting a straight line.

At Hooks: These are DNA minor groove-binding peptides, common in chromatin-associated proteins. The AT hooks generally contain a conserved GRP (glycine-arginine-proline) core surrounded by basic amino acids. They assist other proteins in binding to DNA.

At Least One Hypothesis: Every NK cell in an individual expresses at least one inhibitory receptor molecule specific for one or another self-MHC class I molecule. Consequently, self-tolerance is increased since many NK cells would be capable of destroying any autologous cells that have down-regulated MHC class I molecules. ► killer cells, ► MHC, ► self-tolerance, Valiante NM et al 1997 Immunity 7:739.

Atabrine: This is a preparation of quinacrine, an antimalaria and antihelminthic (intestinal tapeworm) drug. The quinacrine mustard (ICR-100) is a radiomimetic mutagen. ► quinacrine, ► radiomimetic

ATase: ► UTase

Atavism: Refers to the recurrence of expression of traits of ancestors beyond great grandparents. It is based on either recessive, complementary recessive or recombination of genes or special environmental conditions. For some time in the twentieth century it was no longer used in genetic literature. Atavism may, however, have a real basis in the genetic material and may represent in an altered form of ancient genetic sequences that are expressed in an "atavistic"

manner if appropriately activated by a developmental program shift. Under such circumstances, from the rudimentary limb buds of the whales occasionally hind limb bones may develop. Hypertrichosis in humans, encoded in chromosome Xq24-q27.1, also represents such an atavistic reprogramming. These atavistic changes may not be basically very different from the expression of homeotic genes. (Atavus in Latin means great great grandfather). ► hypertrichosis, ► homeotic genes, ► non-Mendelian inheritance, ► paramutation; Verhulst J 1996 Acta Biotheor 44:59.

Ataxia Telangiectasia (AT): This is one of almost a dozen human ailments involving ataxias: poor coordination of the muscles because of dilations in the brain blood vessels, reduced immunity, elevated level of α -fetoprotein, DNA repair, etc. Its appearance in human diseases is attributed to instability and breakdown of chromosomes 14, 7, 2, 11 and 12 although the major locus (150 kb genomic DNA and 66 exons transcribed into 13 kb RNA) appears to be at chromosome 11q22-q23. Leukemias and other malignancies are very common among these patients. Cultured cells of the affected individuals are highly sensitive to both X-ray and UV damage. Further, standard radiation therapy for malignant tumors may prove fatal in such cases. The basic defect in AT is either in a DNA-dependent phosphatidylinositol protein kinase (M_r 350K) that controls progression of the cell cycle (p53) or in DNA repair and recombination (its homologs are MEC1, SAD3, ESR1). Alternatively, it has been found that an inositol 1,4,5-trisphosphate receptor (IP^3R1) deficient mouse mutants either die in utero or when born display severe ataxia and die shortly thereafter. The normal allele of AT stabilizes double-strand DNA breaks and promotes apoptosis and the deficiency of this function can explain the symptoms caused by its (ATM) mutation (Bredemeyer AL et al 2006 Nature [Lond] 442:466). It now appears that the mutant AT protein (ATM, 11q22.3) interacts with c-Abl oncogene resulting in radiation-sensitivity and in the arrest of the cell cycle at the G1 phase. An SH3 domain of c-ABL interacts with a DPAPNPPHFP amino acid sequence in ATM. As a consequence of radiation the tyrosine kinase activity of c-Abl is reduced in the ATM cells. Homozygosity of this recessive human gene has a frequency about 5×10^{-5} and the frequency of the carriers, prone to breast cancer and other malignancies, is about 1%. All mutations, which cause ataxia telangiectasia in homozygotes involve ~2.4 increased risk for breast cancer in the heterozygotes (Renwick A et al 2006 Nature Genet 38:873). The *spinocerebellar ataxia* (SCA5) of human chromosome 11 is caused by instability of the CAG trinucleotide repeats. SCAs include more

A

than 16 genetically distinct neurodegenerative anomalies. SCA6 involves defects in the α subunits of Ca^{2+} ion channel. SCA1 is in chromosome 6p23.5-p24.2 and has CAG instability resulting in polyglutamine protein misfolding. SCA2 maps to 12q23-q24.1, SCA3 in 14q24.3-qter, SCA4 in 16q. The autosomal dominant cerebellar ataxia type III (SCA11) maps to 15q14-21.3 region. SCA10 is in human chromosome 22. The *autosomal dominant cerebellar ataxia* (ADCA type II) with pigmentary muscular dystrophy is coded in human chromosome 3p12-p21.1, and ADCA-like recessive gene is at 9q14. A nonepisodic dominant form (19q13.4) is due to mutation in protein kinase $\text{C}\gamma$ (Chen D-H et al 2003 *Am J Hum Genet* 72:839). *Episodic ataxia* is associated with defects in potassium ion channel or in the α subunits of Ca^{2+} channel functions. Ataxia with oculomotor apraxia (AOA2, 9q34) is a recessive ataxia telangiectasia-like disease, characterized by difficulty in moving the eyes and elevated levels of α -fetoprotein. The basic defect is in DEAXQ-box helicase (senataxin) involved in RNA maturation (Moreira M-C et al 2004 *Nature Genet* 36:225). X-linked ataxia with deafness and vision loss (*Arts syndrome*, Xq22.1-q24) also involves mental retardation and is apparently caused by mutation in phosphoribosyl pyrophosphate synthetase 1 gene (PRPS1) and impaired purine biosynthesis (de Bouwer APM et al 2007 *Amer J Hum Genet* 81:507). ▶Friedreich ataxia, ▶Nijmegen breakage syndrome, ▶DNA repair, ▶DNA replication in eukaryotes, ▶excision repair, ▶carcinogenesis, and a number of genetic diseases, which may have ataxic symptoms such as neuromuscular diseases, ▶gangliosidosis, ▶ β -galactosidase, ▶Niemann-Pick disease, ▶metachromatic leukodystrophy, ▶neurofibromatosis, ▶olivopontocerebellar atrophies, ▶Refsum diseases, ▶Usher syndrome, ▶Hartnup disease, ▶light-sensitivity diseases, ▶myotonia, ▶cancer, ▶cell cycle, ▶DNA repair, ▶trinucleotide repeats, ▶AVED, ▶RAD3, ▶abl, ▶SH3, ▶phosphoinositides, ▶ion channels, ▶p53, ▶breast cancer, ▶Mre11, ▶Mantle cell lymphoma, ▶telangiectasia, ▶DEAD-box proteins, ▶fetoprotein- α ; Taroni F, DiDonato S 2004 *Nature Rev Neurosci* 5:641; Paulson HL et al 2005 *Neuron* 46:845, autophosphorylation of Atm protein-activation: Pellegrini M et al 2006 *Nature [Lond]* 443:222, Gros-Louis F et al 2007 *Nature Genet* 39:80.

Ataxin: The protein responsible for SCA1 ataxia associates with a cerebellar leucine-rich acidic protein and alters the nuclear matrix. The expression of the neurodegenerative disease depends on the phosphorylation of ataxin-1 containing expanded polyglutamine tract by Akt and then its association

with protein 14-3-3. Ataxin 3 is involved in deubiquitylation as well as in aggresome formation (Burnett BG, Pittman RN 2005 *Proc Natl Acad Sci USA* 102:4330). ▶ataxia, ▶spinocerebellar ataxia, ▶trinucleotide repeats, ▶Akt, ▶protein 14-3-3, ▶SCA, ▶aggresome, ▶ubiquitin; Emamian EE et al 2003 *Neuron*, 38:375; Chen HK et al 2003 *Cell* 2003 113:457.

Atelosteogenesis (5q32-q33.1): Refers to fetal defect in the formation/elongation of fetal skeletal bones due to a defect in the diastrophic dysplasia sulfate transporter. ▶diastrophic dysplasia

ATF2 (activating transcription factor): A family of proteins containing homologous basic/leucine-zipper (bZIP) binding domains; it is regulated by the JNK signal transduction pathway. Mutations in ATF2 interfere with the retinoblastoma and E1A oncogene's transcription suppressing activities. ATF6 is a membrane-bound transcription factor, which activates genes of the endoplasmic reticulum (ER). ATF4 is a suppressor of CREB-mediated long-term potentiation. When unfolded proteins accumulate in the ER ATF6 is released by Site-1 and Site-2 proteases. These two enzymes are required for the stress response of ER, lipid biosynthesis and for the processing of SREBPs in response to cholesterol deprivation (Ye J et al 2000 *Mol Cell* 6:1355). ATF3 is induced by lipopolysaccharide and it is a negative regulator of IL-6 and IL-12b by altering the chromatin structure. It also seems to regulate the Toll-like receptor 4 and thereby inflammatory responses (Gilchrist M et al 2006 *Nature [Lond]* 441:173). ▶retinoblastoma, ▶CREB, ▶long-term potentiation, ▶osteoblast, ▶bZIP, ▶JNK, ▶adenovirus [▶E1A], ▶SREBP, ▶Coffin-Lowry syndrome, ▶IL-▶6, ▶IL-▶12, ▶Toll; Fuchs SY et al 2000 *J Biol Chem* 275:12560; Bhoomik A et al 2002 *J Clin Invest* 110:643.

Athanogene: This generates an anti-apoptotic function. ▶BAG1, ▶apoptosis

Atherosclerosis: This condition is characterized by hardening and then degeneration of the walls of arteries because of the deposition of fatty acid nodules on the inner walls and obstruction of blood circulation (see Fig. A134).

Figure A134. Cross section of an artery with blood (red) at center. Normal artery (at left), foamy plaques accumulate within the smooth muscles of the arterial wall and reduce blood flow because of the constriction of the lumen (in the middle), ruptured plaque may eventually block the blood flow to the heart (right).

In the first phase lipid-filled foam cells (macrophages) appear. In the next phase, fibrous plaques are formed of lipids and necrotic cells, covered by smooth muscle cells and collagen. The final phase lesion involves platelet and fibrous clots (thrombus). This group of vascular diseases is one of the most common causes of heart diseases. The number of deaths annually due to coronary heart disease and stroke are 490,000 and 150,000 respectively in the USA. The underlying genetic mechanisms vary and non-genetic factors play a substantial role. In human atherosclerotic lesions CD40 and its ligand CD40L are expressed. Susceptibility is controlled by 10 to 13 genes in human chromosome 1q24.3-1q25.1 and by 11 gene at the *Ath* locus of mice (Wang X et al 2005 Nature Genet 37:365).

By blocking the latter signaling molecules, atherosclerosis and some autoimmune symptoms may be mitigated. Atherosclerosis develops at a high level of the enzyme ACAT (acylcoenzyme cholesterol acyltransferase). In the case of apolipoprotein E (APOE) deficiency in mouse atherosclerosis, caused by oxidation of arachidonic acid, symptoms can be reduced by oral administration of vitamin E. Monocyte chemoattractant protein (MCP-1), a chemokine, and low-density lipoprotein (LDL) deficiency, and substantially reduced lipid deposition in the arteries are some of the characteristics. MCP-1 apparently recruits monocytes to the arterial epithelium during the earliest stages of the disease. A number of different hereditary and environmental factors contribute to the development of atherosclerosis. The heritability of the genetic factors (high cholesterol, triglycerides, diabetes) may vary from 40 to 80%. High lipoprotein (A) level controlled by several genes has over 90% heritability. Bone marrow-derived vascular progenitor cells can alleviate the symptoms upon injection into mice. Apparently, due to aging the repair capacity of the bone

marrow decreases (Karra R et al 2005 Proc Natl Acad Sci USA 102:16789). The immunomicelles provide excellent, validated in vivo enhancement of atherosclerotic plaques. The enhancement seen is related to the macrophage content of the atherosclerotic vessel areas imaged by MRI. The immunomicelles may aid in the detection of high macrophage content associated with plaques vulnerable to rupture (Amirbekian V et al 2007 Proc Natl Acad Sci USA 104:961). The immunomicelles have an average mean hydrated size of 107.3 ± 0.21 nm and average concentration of gadolinium 2.23 mM. Gadolinium is a rare earth metal providing high resolution in magnetic resonance imaging. ▶cardiovascular diseases, ▶myocardial infarction, ▶heart disease, ▶sterol, ▶HDL, ▶LDL, ▶CETPL, ▶CD40, ▶arachidonic acid, ▶apolipoproteins, ▶vitamin E, ▶T-bet, ▶monocytes, ▶MCP, ▶APRF, ▶osteoarthritis, ▶MRI; Lusis AJ 2000 Nature [Lond] 407:233; Welch CL et al 2001 Proc Natl Acad Sci USA 98:7946; Glass CK, Witztum JL 2001 Cell 104:503; Lusis AJ et al 2004 Annu Rev Genomics Hum Genet 5:189.

α-Thiophosphate-dNTP: Refer to point mutagens when incorporated into gapped DNA by DNA polymerase I. The thiophosphates are not effectively removed by the 3' → 5' editing function of the DNA pol I enzyme. ▶pol

Atlas Human cDNA: This contains commercially available arrays of cDNAs (Clontech, Palo Alto, CA) on membranes in several quadrants, each specific for 96 genes of different specificity of expression. The membranes can be used for hybridization probes for the identification of genes with unknown function in different tissues or in healthy and diseased conditions. ▶microarray hybridization; Sehgal A et al 1998 J Surgical Oncol 67:234, protein atlas: <http://www.proteinatlas.org/>.

ATM (ataxia telangiectasia mutated, 370 kDa): It involves an altered phosphatidylinositol kinase. ATM kinase may activate p53 in response to radiation stress but if ATM is defective p53 does not respond to e.g., ionizing radiation and in the absence of apoptosis the chances of cancer may increase. ATM or loss of AT increases the chances of oxidative damage to the cell. It is homologous to *MEC1* and *rad53* of yeast and *mei-41* of *Drosophila*. ▶PIK, ataxia ▶telangiectasia, ▶ATR, ▶BID, ▶p53, ▶apoptosis, ▶Chk2, ▶breast cancer, ▶double-strand break, ▶X-ray ▶repair, ▶telangiectasia; Pincheira J et al 2001 Mutagenesis 16:419.

Atom Microscopy: This technique is being developed for imaging atomic structures. The equipment uses

A

mono-energetic sodium atoms ejected into a vacuum chamber and carried by noble gases such as argon. The beam is broken up into sub-components on a silicon nitride grid. The phase shift generated by the two beams is then measured.

Atomic Coordinate File: Lists molecular coordinates of macromolecules in three dimensions. ►[coordinate](#)

Atomic Force Microscope (AFM): An instrument that can image the surfaces of conductor and non-conductor molecules even in aqueous media. It can reveal molecular structure of surfaces, adhesion forces between ligands and receptors, and other biological processes in real time. It can also be adopted for DNA sequencing. ►[STM](#), ►[nanotechnology](#); Ljubchenko YL et al 1995 *Scanning Microsc* 9:705; Lyubchenko YL et al 2001 *Methods Mol Biol* 148:569; Müller DJ et al 2002 *Progr Biophys Mol Biol* 79:1.

Atomic Radiations: Killed 100,000 and injured 60,000 in Hiroshima (6 August, 1945) and Nagasaki (9 August, 1945) at the end of World War II, and caused substantial increase (about 4 fold or more at the epicenter) of cancer but showed no significant increase in human mutation. The incidence of cancer varied depending on a number of factors such as distance from the epicenter, age, sex (higher in females), by the type of cancers and some unexplained factors (such as geographic location of Hiroshima or Nagasaki).

The cause of the scarcity of mutations is not that these radiations were genetically ineffective rather the human breeding system, avoiding marriage between relatives, did not favor homozygosity of the recessive mutations resulting in lethality. Recent studies of the populations exposed to the radiation caused by the failure of the Chernobyl nuclear power plant (26 April 1986) indicate an increase not only in cancer but also of mutation (see Fig. [A135](#)).

Most likely, some of the mutations induced will be maintained in the exposed populations and may contribute to an increase of the genetic load. The total radiation from natural sources (cosmic radiation, disintegration of terrestrial isotopes [uranium, thorium, potassium], etc.), reaching the human gonads was estimated to be 100–125 millirads per year. The atomic bomb tests conducted during the years (1956) to (1965) contributed an average of about 76 millirads and expected to have exerted their effect mainly up to the year (2000) through the short half-life radioactive elements (Cesium¹³⁷, Strontium⁹⁰) and have substantially decayed by then. The long half-life Carbon¹⁴ will continue to pollute by an additional estimated 167 millirads even after year 2000.

The meltdown of the Chernobyl power plant in the Ukraine near the Byelorussian border, in the spring of 1986, exposed nearby populations up to 75 rem, whereas the whole of Byelorussia received about 3.3 rem.

In 1986, in that country, the total number of thyroid cancer in children was 2, and by (1992) it reached to about 60 cases. By (1999) more than 800 children who drank milk from cows exposed to the radiation developed thyroid cancer. The figures are still increasing. The thyroid cancer has been attributed to iodine¹³¹ released during the fallout. In the human minisatellite DNA the mutation rate doubled and in the feral populations of voles (*Microtus*) the base pair substitution frequency in the mitochondrial DNA was found to be in excess of 10^{-4} , over two orders of magnitude increase above the appropriate control groups. Nevertheless, the rodent populations appeared in good condition and their fertility was also good. This report of 1996, about the high mutation rate at Chernobyl, was retracted by the authors in (1997) (*Nature* 390:100). In barn swallows an increase of mutations at two microsatellite loci was observed (*Nature* 389:593). The Hanford Nuclear Reservation, in the state of Washington, exposed nearby populations in excess of 33 rads over a period of three years. The official estimates place 0.025 rads per year as safe for airborne pollution by nuclear weapon plants for the civilians living in the neighboring area and 5 rads for the workers in those plants for the entire body per year. According to some estimates based on irradiation of mice 20–40 rad is the doubling dose of mutation for ionizing radiation. It was estimated that the radioactive fallout from weapon testing may have increased the genetic risks by 2% over the natural background effects and by 8% for leukemia. The effects of atomic radiation on mutation rates in the minisatellite DNA remains controversial because of the difficulties of finding appropriate (concurrent) controls. The mutation rate in these very sensitive DNA sequences is much affected by environmental factors (pollution), age, etc.

When considering the harmful effects of radiation potentially released by atomic power plants, one must consider the harmful pollution generated by the coal-fired industry and the carcinogenic hydrocarbons released by the combustion in wood fireplaces, etc. Also, the shortage of energy may directly or indirectly cause substantial suffering and even death to the genetically more vulnerable part of the population, especially children.

Estimation of the risk is very complicated because of the many modifying factors (angle of the radiation, age, sex, length of exposure, genetic susceptibility to

cancer, life style [smoking, drug use, etc.]) involved. One simple formula for assessing the excess relative risk (ERR) is $1 + \beta z$, where β = ERR and z = radiation dose. Some variations of the following formula based on least squares regression models have also been developed for the estimation of excess risk: (Cases. $\text{PYR}_d = \alpha + \beta d + \epsilon$ where PYR is the dose-specific person years, α denotes the intercept of the regression term, β stands for the contribution of the doses of the radiation as an excess risk and ϵ is the error [formula after D.A. Pierce]. ▶cosmic radiation, ▶isotopes, ▶radiation hazard assessment, ▶doubling dose, ▶plutonium, ▶nuclear reactors, ▶mutation in human populations, ▶mutation detection, ▶rad, ▶rem, ▶control, ▶correlation, ▶public opinion; Dubrova YE et al 2002 Science 295:1037; Williams D 2002 Nature Rev Cancer 2:543; Dubrova YE et al 2002 Am J Hum Genet 71:801; Awa A 2003 Mutation Res 543:1.

Figure A135. The incidence of thyroid cancer in Belarus following the Chernobyl accident in 1986. (From *Sources and Effects of Ionizing Radiation*. United Nations Scientific Committee Report 2000. vol. II. New York.)

Atopy: A familial allergy, including asthma, hay fever and eczema. The blood serum carries an increased level of immunoglobulin E (IgE). An IgE responsiveness locus was assigned to 11q12-q13. Human chromosome 5q31-q33 harbors an asthma susceptibility region. Atopy is controlled also by epithelial barrier determined by the 370-kDa filaggrin protein, encoded at human chromosome 1q21; semidominant and dominant mutations or loss of this protein predisposes to dermatitis and/or asthma or to

both. In about 9% European populations, filaggrin variants occur (Palmer CNA et al 2006 Nature Genet 38:441). ▶allergy, ▶asthma, ▶immunoglobulins, ▶ichthyosis, ▶Netherton syndrome; Wheatley AP et al 2002 Hum Mol Genet 11:2143.

ATP: Adenosine-5'-triphosphate is a universal carrier of metabolic energy by transferring the terminal phosphate to various acceptors and resulting in ADP (adenosine diphosphate) that is recycled to ATP by either the chemical energy of oxidative phosphorylation or the solar energy of photosynthesis. Besides the thermodynamic role, ATP has also catalytic activity e.g., in nitrogen fixation. ATP provides also binding energy through non-covalent interactions with various molecules in order to lower activation energy. It provides energy for charging tRNA with amino acids, for DNA synthesis, for bioluminescence mediated by the firefly luciferase, it is indispensable in carbohydrate metabolism, it serves as a precursor of cyclic AMP that has major role in signal transduction and protein phosphorylation, etc. The major catabolic pathways (glycolysis, citric acid cycle, fatty acid and amino acid oxidation and oxidative phosphorylation) are coordinately regulated in the production of ATP. The relative abundance of ATP and ADP controls electron transfers in the cell. ATP is generated in the mitochondria and chloroplasts. ATP is the major link between anabolic and catabolic reactions mediated by enzymes. UTP (uridine triphosphate), GTP (guanosine triphosphate) and CTP (cytidine triphosphate) are also important in similar processes but have relatively minor role compared to ATP. ▶ATP synthase, ▶ATPase, ▶cAMP; Pfeiffer T et al 2001 Science 292:504.

ATP Synthase: A ~500 kDa multisubunit protein complex forming ATP from ADP and phosphate (oxidative phosphorylation) on plasma membranes (bacterial, mitochondrial, chloroplast); it is also a motor protein. ▶ATP, ▶ATPases; Boyer PD 1997 Annu Rev Biochem 66:717; Yoshida M et al 2001 Nature Rev Mol Cell Biol 2:669.

ATPase: Enzymes are required for active transport of chemicals and other functions in the cells. The *P-type* ATPases maintain low Na^+ , low Ca^{2+} and high K^+ levels inside the cells, generate low pH within cellular compartments and activate proteases and other hydrolytic enzymes of eukaryotes and generate transmembrane electric potentials. Na^+ , K^+ -ATPase has binding sites for cardiac glycosides such as ouabain, digoxin and digitoxin and mediates adrenocorticotrophic hormone (ACTH) induced hypertension

A

in mice and presumably in humans (Dostanic-Larson I et al 2005 Proc Natl Acad Sci USA 102:15845). The *V-type* (vacuolar) ATPases secure low pH inside lysosomes and vacuoles of eukaryotes. The *F type* ATPases (energy coupling factors, F_1 - F_0 -ATPase) are located in the plasma of prokaryotes. In the mitochondrial and thylakoid membranes of eukaryotes the *F type* ATPases are actually ATP synthase enzymes generating ATP from ADP and inorganic phosphate. The *DNA-dependent* ATPases are type I restriction endonucleases that depend on Mg^{2+} , ATP and SAM for cutting of DNA strands. After cleavage they function only as ATPases. ▶ATP, ▶SAM, ▶ACTH, ▶ouabain, ▶digoxigenin, ▶digitoxin; Palmgren MG 2001 Annu Rev Plant Physiol Plant Mol Biol 52:817; V-type Na^+ -ATPase structure: Murata T et al 2005 Science 308:654; F-type Na^+ -ATPase structure: Meier T et al 2005 Science 308:659.

A-Tract: Includes four or more AT base pairs in the DNA without a 5'-TA-3' step. Such elements cause curvature at the helix axis and influence nucleosome packaging and base pair opening due to the C⁵ methyl of thymine. Such structures modulate sequence-specific ligand binding and gene expression. (See Wärmländer S et al 2002 J Biol Chem 277:28491).

ATR (ATM - Rad3-related): Is a phosphatidylinositol kinase related to ATM and yeast gene product RAD3. It controls cell cycle checkpoints and double-strand breaks. Phosphorylation of its substrates inhibits DNA replication fork, mitosis and promotes repair, recombination or apoptosis. ▶ATM, ▶checkpoint, ▶PIK, ▶RAD3, ▶sex body; Cortez D et al 2001 Science 294:1713; Zou L, Elledge SJ 2003 Science 300:1542.

Atransferrinemia (3q21): A defect in the synthesis of the iron-regulatory protein transferrin, resulting in hypochromic anemia. ▶transferrin, ▶anemia

Atrazine (Lasso): ▶herbicides, ▶photogenes

Atresia: Closure of an organ (e.g., vagina, and it can be surgically corrected to permit procreation), parts of the digestive tract (pyloric atresia), closure of the bile duct (biliary atresia), etc. pyloric stenosis.

Atresia: Mediates the elimination—by apoptosis—of oocytes with mutant mitochondria. Although the primordial germ cells produce millions of oocytes in humans, only a small fraction of them reach the stage of ovulation. Thus, atresia serves as a genetic quality control. In the male germ cells (which do not transmit mitochondria) atresia was not observed. ▶apoptosis, ▶mtDNA; Krakauer DC, Mira A 1999 Nature [Lond] 400:125.

Atresia, Congenital Aural: A narrowing or closure of the auditory channel due to deletion of human chromosome 18q21–q23 region. Its prevalence is 1×10^{-4} per live birth. (See Veltman JA et al 2003 Am J Hum Genet 72:1578).

Atrial: Adjectivization of atrium. ▶atrium

Atrial Septal Defect: An autosomal recessive type developmental heart disease that displays increased recurrence when transmitted through the males although the prevalence is greater in the females. The dominant form encoding a transcription factor is in human chromosome 6. Dominant defects in the NXX2-5 gene (encoded at 5q35) affects cardiac septation and is responsible for congenital heart disease. Gene TBX5 (12q24) is responsible for ventricular septal defects. ▶heart diseases

AT-Rich DNA: Common in the repetitive sequences, and is generally not transcribed. Some of the petite colony mutants of yeast mitochondrial DNA contain mainly AT sequences. ▶mitochondrial genetics, ▶mtDNA

ATRIP: ATR-interacting protein. ▶ATR; Cortez D et al 2001 Science 294:1713; Zou L, Elledge SJ 2003 Science 300:1542.

AT-Risk-Motifs (ARM): Increase instability of the genome such as inverted repeats, palindromes, and insertion elements either by illegitimate or homologous recombination or rearrangements. ▶repeat inverted, ▶palindrome RecA-independent recombination, ▶Alu family, ▶instability genetic; Gordenin DA, Resnik MA 1998 Mutat Res 400:45.

Atrium: The entrance to an organ. ▶atrial

Atropa belladonna: A plant of the *Solanaceae* family (n = 50, 72) is a source of alkaloids. ▶henbane

Atrophine-1: Protein is encoded by the human gene DRPLA and affects other trinucleotide repeat genes. ▶dentatorubral-pallidoluyian atrophy, ▶Huntington's chorea

Atrophy: Under-nutrition or lack of nutrition; wasting away of cells and tissues. ▶Kugelberg-Welander syndrome, ▶Kennedy disease, ▶dystrophy, ▶muscular dystrophy, ▶neuromuscular diseases, ▶spinal muscular atrophy

Atropine: A highly toxic alkaloid. ▶henbane

ATRX: A helicase protein encoded at human chromosome Xq13 (>220 kb). It is similar to the RAD54 and the SWI/SNF proteins. It is implicated in psychomotor functions, DNA methylation, regulation of transcription, DNA repair and chromosome segregation. Mutations have been found in cases of

Figure A136. att sites

thalassemia/mental retardation and in the Juberg-Marsidi syndrome. See separate entries for the terms mentioned.

att SITES: At the position where site-specific integration and excision takes place, lysogenic bacteria and temperate phage have consensus sequences (see Fig. A136). The att sites are about 150 nucleotides long in l and 25 bp in the bacterium. 15 bp sequences are identical in both.

The underscored sequences (see figure) are then reciprocally recombined and POB' and BOP' sequences are generated from the left (attL) and right (attR) sequences. The integration requires the phage-coded INT and the bacterial coded HF proteins. The excision requires an additional protein XIS to be coded by the bacterial gene *xis*. This is probably because it is not exactly the reverse type of process since the original attP and attB elements were not identical except the 15 bps. ▶lambda phage, ▶integrase; Williams KP 2002 Nucleic Acids Res 30:866.

Attached X Chromosomes: Two X chromosomes fused at the centromere (see Fig. A137). They have been exploited for cytogenetics. Among others, they were first used to carry out half-tetrad analysis in *Drosophila*. Females with attached-X produce eggs but half of them have only autosomes and no X-chromosome. If the attached X-chromosomes carry different alleles of a locus, double dose of the same allele in the eggs can be achieved only if there is a recombination between that gene and the centromere. This is because the first meiotic division is reductional and the second is equational. ▶half-tetrad analysis, ▶compound X chromosomes; Anderson EG, 1925 Genetics 10:403.

Figure A137. Attached X-chromosomes (→) in the oögonium of an XXY *Drosophila*. (After a drawing by Curt Stern in the 1920s)

Attachment Point (ap): A mappable site in the chromosome of the chloroplast of *Chlamydomonas reinhardtii* green alga, representing a hypothetical centromere-like element. It is called *ap* because it attaches to the chloroplast membrane and assists the disjunction of the ring DNA during division. In genetic recombination this is taken as the 0 coordinate of marker segregation. ▶chloroplast genetics, ▶mapping of chloroplast genes

Attachment Site: ▶att site

Attention Deficit-Hyperactivity (ADHD): A condition observed in 2 to 5% of elementary school children that causes learning disabilities and emotional problems. Boys have about 5-fold higher chance to be affected than girls. It frequently goes into remission as age progresses but some personality disorders (hyperactivity, antisocial behavior, alcoholism, hysteria) may persist even in adulthood. About 25 to 30% of the parents of affected children had some of the symptoms in childhood. The genetic basis is unclear. The dopamine receptor 4 encoded in human chromosome 11p15.5 may be responsible for the behavioral anomalies but not necessarily for the attention deficit. The heritability is 0.75–0.91. Chromosomal locations 17p11, 15q, 7p and 9q have been implicated (Bakker SC et al 2003 Am J Hum Genet 72:1251). Childhood asthma is strongly associated with ORMDL3, a member of a gene family that encodes transmembrane proteins anchored in the endoplasmic reticulum in human chromosome 17q21 (Moffatt MF et al 2007 Nature [Lond] 448:470). ▶affective disorders, ▶dyslexia, ▶autism, ▶behavior genetics; Fisher SE et al 2002 Am J Hum Genet 70:1183; Wilens TE et al 2002 Annu Rev Med 53:113.

Attenuate: Tapered appearance.

Attenuation: A regulatory process in bacteria. ▶attenuator region, ▶host-pathogen relations, ▶tryptophan operon, ▶antitermination

Attenuation, Viral: A reduction in virulence achieved by subculturing in a new cell population. In this process, numerous adaptive mutations occur after a period of

A

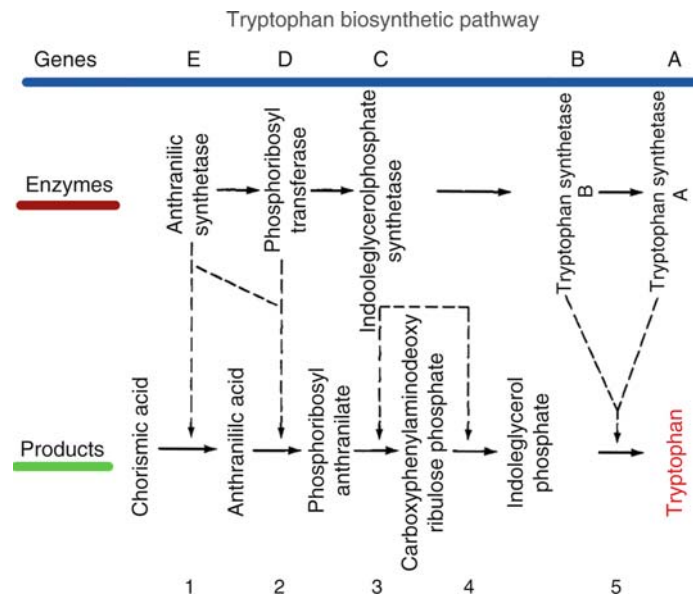

Figure A138. The biosynthesis of tryptophan from chorismic acid in *E. coli* bacteria requires five steps, mediated by five enzymes. The sequence of the encoding genes in the bacterial genetic map corresponds to the sequence of the metabolic steps. This was the first case of recognition of such a [co-ordinate](#) regulation in bacteria. Primarily, a repressor controls the five genes, and attenuation provides an additional fine-tuning. Some of the enzymes are composed from more than a single functional unit. Indoleglycerolphosphate synthetase catalyzes two synthetic steps as shown in figure

time that permit them to grow well in the original cells but with diminished virulence. These mutations generally occur in the 5'-non-translated region and modify the translation of the viral RNA although attenuating mutations may occur all over the viral RNA genome. attenuator region.

Attenuation, Vaccines: The virus is immunogenic but not pathogenic in the vaccine.

Attenuator Region: Region where RNA polymerase may stop transcription when all the cognate tRNAs are charged. Then the mRNA assumes a special secondary structure and this leads to a temporary cessation of transcription, leading to a reduction of transcription by a factor of 8–10. It is one of the regulatory mechanisms of bacterial amino acid operons. A type of attenuation also regulates the pyrimidine operon of *E. coli*. The operon is induced by low concentration uridine triphosphate. (see Fig. A138; tryptophan biosynthetic pathway).

When the UTP level increases, slippage occurs at the promoter incorporating long stretches of uridylic acid and the RNA polymerase cannot escape the promoter. The cytosine deaminase/cytosine transport locus behaves similarly. The histidine operon does not even use the more common type of operator repressor/inducer system.

Sucrose, β -glucoside, β -glucan utilization enzymes in bacteria use RNA-binding proteins that inactivate transcription termination and thus promote transcription. The elongation of some lipid biosynthesis RNAs may be also negatively controlled. Attenuation appears to be a widely used mechanism of regulation in bacteria (see Fig. A139) (Merino E, Yanofsky C 2005 Trends Genet 21:260).

(See diagrams of the [tryptophan operon](#), [TRAP](#), [tryptophan](#), [tryptophan repressor](#), [antitermination](#), [slippage](#); Yanofsky C 2000 J Bacteriol 182:1).

Attractin: A human serum glycoprotein-regulating cell mediated immunity and is homologous to the *mg* locus of mouse. It is a low affinity receptor for agouti protein. [obesity](#), [agouti](#); He L et al 2001 Nature Genet 27:40.

Attrition: The cost of failure in the development of an effective drug. The cost of developing a highly successful therapeutic agent generally exceeds \$800 million and the chance of failure is over 90% either because of insufficient efficacy or unacceptable side effects. [translation](#)

Auberger Blood Group: [Lutheran blood group](#)

Figure A139. A genetic and molecular map of the tryptophan operon in *Escherichia coli* bacterium. Attenuation may dictate an early termination of transcription. The site of attenuation (*a*) is within the tryptophan leader sequence (*trpL*) and the site of the transcription pause (*tp*) precedes it. Transcription is primarily under the control of the promoter - operator region and the process begins at the left end of the *trpL* site. The RNA polymerase pauses at the *tp* site before proceeding further. In case most of the tryptophanyl tRNAs (tRNA^{Trp}) are charged with tryptophan and therefore there is no need for additional molecules of this amino acid, transcription is momentarily terminated at the attenuator (*a*) site. If however the tRNA^{Trp} is largely uncharged because of shortage of tryptophan and active protein synthesis, the transcriptase RNA polymerase passes through the *a* site without interference. This passage is made possible by alterations in the secondary structure of the RNA transcript of the operon. The initial segment of the leader sequence encodes a short tryptophan-rich peptide. In case there is a scarcity in tryptophan, translation on the ribosome is stalled at the tryptophan codons in the leader sequence. During the pause (*tp*), the mRNA transcript assumes a hairpin-like structure by base pairing between segments marked by (2) and (3) and thus the passage through the *attenuator* (*a*) site is facilitated. In case, however, most of the cognate tRNAs are charged, the transcript shows base pairing between segments (3) and (4), resulting in stoppage of transcription until the over-supply is exhausted by protein synthesis. The tryptophan operon also relies on suppressive transcriptional controls. See base sequences of the attenuator at the entry “tryptophan operon”. (Modified after Yanofsky C 1981 Nature (Lond.) 289:751)

AUC (area under the curve): See Fig. A140.

Figure A140. AUC

Auer Bodies: Clusters of granules or bundles of rods in the nuclei of acute promyelocytic leukemia cells.
▶ leukemias

AUG Codon: In mRNA, AUG is the only one codon that specifies methionine yet there are two different tRNAs for methionine. In a majority of cases in prokaryotes one of the methionine-tRNAs is formylated at the amino group by N¹⁰-formyltetrahydrofolate, and this formylmethionine tRNA initiates translation whereas the other methionine-tRNA carries methionine to all other sites in the polypeptide. In eukaryotes the *initiator methionyl-tRNA* is not formylated, the primary structure and conformation of the tRNA specify its initiator attribute. Thus, the overwhelming majority of nascent proteins that start at the NH₂ end with a methionine. In the mature

A

protein this methionine may be absent because of processing. ►[genetic code](#)

Auger Emission: ^{125}I (iodine) or $^{195\text{m}}\text{Pt}$ (platinum) isotopes may emit electrons or Auger positrons (^{64}Cu) when excited by external radiation. When incorporated, these isotopes may deliver high doses within the radius of a cell and can be used to damage tumor cells.

Augmenting Genes: Facilitate viral reproduction although not absolutely essential for it.

AU-Rich Elements (ARE): ARE in the 3'-untranslated region may target the mRNAs of proto-oncogenes, cytokines and lymphokines for rapid degradation. However, these AU-rich mRNAs are stabilized by heat shock, UV, hypoxia, stimulation and oncogenic transformation. ELAV family of proteins, such as HuRs, may bind AREs. ►[ELAV](#), ►[HuR](#); Stoecklin G et al 2001 RNA 7:1578.

Auricles: Small projections at the upper part of leaf sheath in cereals (see Fig. [A141](#)). They are of importance for taxonomic characterization.

Figure A141. Auricles

Aurones: Plant flavonoids conveying yellow color to flowers. They are synthesized from chalcones by aureusidine synthase (39-kDa copper glycoprotein) and a member of polyphenol oxidases.

Auroras: Are threonine/serine protein kinase(s), regulating the mitotic spindle, chromosome segregation, cytokinesis, etc. Humans have three Aurora kinases, A, B and C. Its activator is the Ajuba protein of the LIM family. Inhibitors have relevance to cancer therapy. Loss of the mitotic checkpoint protein Chfr can ubiquitinate and regulate Aurora. It promotes chromosomal instability (Yu X et al 2005 Nature Genet 37:401). Aurora A and B are associated with and over-expressed in several types of cancer. The inhibitors target serine 10 in histone H3 and may cause tetraploidy. ►[LIM domain](#), ►[passenger proteins](#), ►[co-orientation](#), ►[infertility](#), ►[condensin](#); Taguchi S et al 2002 FEBS Lett 519:59; Keen N, Taylor S 2004 Nature Rev Cancer 4:927.

Austin Disease: ►[mucosulfatidosis](#)

Australopithecus: An extinct, fossil (5–1 million year old) of the bipedal Hominidae of the Old World. Its brain size is intermediate—between modern humans

and apes. Exact relation to existing species is unclear. (“Austral” means Southern). ►[hominidae](#)

Autapomorphy: A condition when a particular trait(s) occurs only in a particular evolutionary line and not in other related species.

Autapsis (adj. autaptic): Are synapses that cells form with themselves. ►[synaps](#)

Autism: A human behavioral anomaly involving reticent, self-centered, subjective thoughts and actions, learning and communication difficulties. Its prevalence is 0.02 to 0.05% in the general population, and the recurrence risk in families may be 6–8%. More recent estimates of the prevalence are about 0.06%. The concordance between monozygotic twins appeared 36 to 96% while between dizygotic ones none to 24% was observed. Its incidence is about 4-fold higher in males than females. Because of its behavioral nature, animal models cannot be used efficiently and directly. It is generally associated with mental retardation and other psychological disorders. Although the incidence within affected families is 50 times higher than that in the general population, no single gene could be identified as a causative agent although some role of serotonin transporter has been suspected. Actually even in humans, the diagnosis is somewhat difficult because of the complexity of the traits and differences among the alleles. Several features of the condition overlap some symptoms of other diseases. Autism may be associated with genes in several chromosomes but 7q31 or 1p or 1q23-q24, or 3q25-q27 or 17q11 appear to be the most likely locations of the major factors involved. However, other search have revealed several other putative linkage relations (Liu J et al 2001 Am J Hum Genet 69:327; Bartlett CW et al 2005 Am J Hum Genet 76:688). An aminophospholipid-transporting ATPase situated in the imprinted region 15q11-q13 near the ubiquitin ligase E3A and the Angelman syndrome genes is associated with a small percent of the autisms (Herzing LBK et al 2001 Am J Hum Genet 68:1501; Folstein SE, Rosen-Sheidley B 2001 Nature Rev Genet 2:943). Additional loci have also been identified (Yonan AL et al 2003 Am J Hum Genet 73:886). Using Affymetrix 10K SNP microarrays and 1,168 families with at least two affected individuals implicate chromosome 11p12–p13 and neurexins, respectively, among other candidate loci (The Autism Genome Project 2007 Nature Genet 39:319). De novo copy number variations (CNVs) in the genome were significantly associated with autism ($P = 0.0005$). Such CNVs were identified in 12 out of 118 (10%) patients with sporadic autism, in 2 out of 77 (3%) of patients with an affected first-degree relative, and in 2 out of 196 (1%) of controls. Most de

novo CNVs were smaller than microscopic resolution (Sebat J et al 2007 Science 316:445).

The infantile autism becomes apparent during the first year of life. Apparently it is under polygenic control. In the dominant autism with onset after an initial normalcy (Rett syndrome, RTT, prevalence 1×10^{-4}), the symptoms are shared but progressive dementia, uncoordination and deterioration of all mental functions follow. This view about autism is gradually changing as current studies reveal the other end of the condition that involves preoccupation with details and qualities of a genius. The latter type appears to be coded at Xq28 as McPqG2. The Rett syndrome affects primarily females. Earlier the short arm of the X had also been implicated. The Xp22.3 region encodes the NLGN4 neuroligin and Xq13 encodes NLGN3 neuroligins, their mutations are associated with autism (Jamain S et al 2003 Nature Genet 34:27). Neuroligins are essential factors for the formation of synapses. ▶affective disorders, ▶Asperger syndrome, ▶attention deficit-hyperactivity, ▶disorder, ▶mental retardation, ▶neurexin, ▶McPqG2; Fombonne E 1999 Psychol Med 29:769; Folstein SE, Mankoski RE 2000 Am J Hum Genet 67:278; Geschwind DH et al 2001 Am J Hum Genet 69:463; Shao Y et al 2002 Am J Hum Genet 70:1058; Yu C-E et al 2002 Am J Hum Genet 71:100; Veenstra-VanderWeele J et al 2004 Annu Rev Genomics Hum Genet 5:379.

Autoallopolyploid: A polyploid in which the genome(s) is/are duplicated from one or more species, e.g., AAAABBBB or AAAABB. ▶allopolyploid, ▶sesquidiploid

Autoantibody: An antibody formed against the body's own antigens, such as in autoimmune disease. During early B lymphocyte development 55–75% of all antibodies formed may display self-reactivity but most of them are destroyed as the B cells mature (Wardemann H et al 2003 Science 301:1374). ▶autoimmune disease, ▶B lymphocyte

Autoantigen (self-antigen): A normal cellular protein yet it may be attacked by the cellular immune system. This is similar to what happens in autoimmune disease. ▶immune system, ▶immune reaction

Autocatalytic Function: Of DNA is the process of replication; also, any reaction that is promoted by its own product. Although self-replication is the most common property of nucleotide chains, peptides and other molecules may be involved in autocatalysis and cross-catalysis (i.e., the formation of other molecules). ▶replication, ▶heterocatalysis; Paul N, Joyce GF 2002 Proc Natl Acad Sci USA 99: 12733.

Autochthonous: Located at its original site or a graft of an individual at another position within the same body.

Autoclaving: Heating under pressure (1 atmosphere above sea level) by steam, usually at 121 °C, for a minimum of 15 min to kill non-spore-forming bacteria and other cells. ▶sterilization, ▶filter sterilization

Autocorrelation, Spatial: Compares data (e.g., DNA sequences and haplogroup frequencies) within arbitrary areas in order to study diversity distribution. Measures of overall genetic similarity are evaluated in each distance class and the degree of genetic similarity at the different genetic distances determined. A variable can be autocorrelated either (+) or (–) if its value at a given point in space is associated with its measures at other locations. (Simoni L et al 2000 Amer J Hum Genet 66:262).

Autocrine: Signal production within a cell in response to external stimuli.

Autocrine Stimulation: Cells infected by proto-oncogene carrying virus secrete a growth factor that further stimulates the cell's proliferation. ▶proto-oncogenes, ▶paracrine stimulation

Autoecious: A parasite that completes its life cycle on the same host.

Autogamy: A process of self-fertilization common in hermaphroditic and monoecious plants; autogamy in the unicellular animals, *Paramecia*, is preceded by meiosis and one the four haploid products survive. This cell then divides into two cells by mitosis. These two identical cells may then fuse and a genetically homozygous diploid zygote is formed. ▶alogamy

Autogenesis: ▶Lamarckism

Autogenous Control: The own product of genes regulates the coding gene either in a positive or a negative way. In genetic networks the autogenous control appears superior to the non-autogenous system. The autogenous control better prevents false triggering due to transient fluctuations of input (Camas FM et al 2006 Proc Natl Acad Sci USA 103:12718). ▶negative control, ▶positive control, ▶genetic network

Autogenous Evolution: Structures and organelles evolved through differentiation of the cells own system. ▶exogenous evolution

Autogenous Suppression: The *Salmonella* RF2 translation termination protein occasionally fails to recognize or misreads the UGA stop codon resulting in readthrough by suppressing termination. ▶translation termination, ▶readthrough, ▶recoding, ▶stop codon

A

Autograft: The tissue transplantation is within one individual. ►homograft

Autoimmune Disease: The immune system fails to recognize the cell's own antigens and attacks them. In many instances altered glycosylation is responsible for the pathogenesis. Normally the lymphocytes with defects in self-antigen recognition are eliminated by apoptosis. It has been shown that receptor tyrosine kinases (Tyro 3, Axl, Mer) plays an essential regulatory role in the development of the immune response. Normally these receptors control the function of antigen presenting cells by supplying growth-promoting and pro-survival molecules. They also seem to have negative control. Mutation of these receptors may disable the binding of gamma interferon and the inability to clear the dying cells results in overactivity of the macrophages that then attack the body's own cells (Lu Q, Lemke G 2001 Science 293:306). The regulatory CD4⁺ CD25⁺ T cells can suppress the autoreactive T cells by engaging the B7 protein molecules on the surface of the target T cells (Paust S et al 2004 Proc Natl Acad Sci USA 101:10398). Mutation in ICOS, an essential co-stimulatory receptor of follicular T cells results in overproduction of IL-21 and fails to repress autoantibody formation. A RING-type ubiquitin ligase can repress these T cells and autoimmunity (Vinueza CG et al 2005 Nature [Lond] 435:452).

Lupus erythematosus cells (a variety of skin and possibly visceral inflammations) make antibodies against their own DNA and RNA. In insulin-dependent diabetes the insulin producer β cells of the pancreas are attacked by the body's immune system, coded for by the major histocompatibility genes. The Rasmussen's encephalitis, a rare form of epilepsy, and the paraneoplastic neurodegenerative syndrome (PNS), both are caused by autoantibodies against the glutamate receptors of the nervous system. PNS is a rare sign of cancer and often the patient is unaware of the cancer. The symptoms are generally memory loss, sensory deficiency, motor dysfunction or blindness. The most common cause is breast or ovarian or small-cell lung cancer. The tumor cells express proteins that are normally only expressed in neurons. The CD8⁺ T cells are then activated and the immune lymphocytes somehow cross the blood-brain barrier and evoke neuronal degeneration (Albert ML, Darnell RB 2004 Nature Rev Cancer 4:36). Herpes Simplex virus Type 1 expresses a coat protein which recognizes autoreactive T cells targeting mouse corneal antigens and may cause stromal keratitis (inflammation of the fibrous coat of the eye). Autoimmune diseases include a series of different anomalies (p = prevalence, r = risk of siblings relative to risks in the general population): psoriasis (p: 2.8, r: 6),

rheumatoid arthritis (p:1, r: 8), goiter (p: 0.5, r: 15), insulin-dependent diabetes (p: 0.4, r: 1.6), ankylosing spondylitis (p: 0.13, r: 54), multiple sclerosis (p: 0.1, r: 20), lupus erythematosus (p: 0.1, r: 20), Crohn disease (p: 0.06, r: 20), narcolepsy (p: 0.06, r: 12), celiac disease (p: 0.05, r: 60), cirrhosis of the liver (p: 0.008, r: 100). Autoimmune diseases have been attributed to increased V(J)D recombination in a class of B (B-1) lymphocytes as a result of increased RAG activity. Several autoimmune diseases (multiple sclerosis, rheumatoid arthritis) are more prevalent in females. The cause is apparently the difference in response to hormones of the T_H1 and T_H2 lymphocytes. Low estrogen level T_H1 cells secrete IL-2, INF- γ and lymphotoxins due to which, multiple sclerosis and rheumatoid arthritis are aggravated. At high estrogen (increased progesterone, testosterone) levels, T_H2 cells promote IL-4, IL-5, IL-6, IL-10. As a consequence, during pregnancy the symptoms of multiple sclerosis and rheumatoid arthritis are mitigated but lupus erythematosus may be aggravated. Immune therapies are being sought for the cure of these diseases (Steinman L 2004 Science 305:212). Autoimmune diseases seem to be clustered in certain families because they share common environment, genes and the interaction of the two. Protein tyrosine-phosphatase (PTPN22, 1p13) is lymphoid-specific and intracellular. Fc gamma RIII receptor may mediate early neutrophil recruitment in immune complex-mediated inflammation and reduced copy number of the gene increases the susceptibility to systemic lupus erythematosus, microscopic polyangiitis and Wegener's granulomatosis (6p21.3). However, the organ-specific Graves' disease or Addison's disease did not show this association (Fanciulli M et al 2007 Nature Genet 39:721). Single nucleotide polymorphism in this gene confers four autoimmune phenotypes: Type 1 diabetes (T1D), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), Hashimoto thyroiditis (HT). The Multiple Autoimmune Disease Genetics Consortium survey detected nine "core" diseases, which included at least two autoimmune phenotypes: rheumatoid arthritis, systemic lupus erythematosus, type 1 diabetes, multiple sclerosis, autoimmune thyroid diseases (Hashimoto thyroiditis), Graves disease, juvenile rheumatoid arthritis, inflammatory bowel disease (Crohn disease), psoriasis and primary Sjögren syndrome (Criswell LA et al 2005 Am J Hum Genet 76:561). (See named diseases under separate entries, ►immunotherapy, ►statins, ►PPAR, ►CTLA4, ►AIRE, ►IPEX, ►HLA, ►NF- κ B, ►complement, ►B7 protein, ►T cell, ►Sjögren syndrome, ►goiter, ►Hashimoto disease, ►Goodpasture syndrome, ►APECED, ►bullous pemphigoid autoimmune disease, ►hemolytic anemia, ►Borrelia, ►V(J)D, ►RAG, ►B cell, ►T helper cell, ►signal transduction, ►interferon,

Autoimmune Lymphoproliferative Disease: ALPS.

Autoimmune Polyendocrinopathy: APECED.

Autoinduction: A type of cell-to-cell interaction in bacteria and other organisms. The cells release small extracellular signaling molecules, which are taken up again by the cells. It adjusts gene expression in the cells responding to a level appropriate for the local density of the signaling cells. The autoinducer signals may be acylated homoserine lactones, Tra proteins, amino acids, short peptides and pheromones. ►auto-regulation, ►pheromones, ►quorum sensing, ►tra, ►Tata, ►homoserine ►lactone; Tata JR 2000 Insect Biochem Mol Biol 30:645.

Autoinhibition: Inactive conformation of a receptor in quiescent cells. It is controlled by a variety of mechanisms such autophosphorylation, ligand binding, etc. Schlessinger J 2003 Science 300:750.

Autointerference: The process when defective virions may interfere with the replication of intact ones.

Autologous: Its origin is within the cell or individual; a self-made molecule.

Autologous Transplantation: Used in cancer therapy by implanting e.g., genetically modified bone marrow cells of the same individual. Thereby, the undesirable immune rejection may be avoided. ►immune system, ►gene therapy, ►cancer gene therapy

Autolysis: Is the decomposition of cells and cell content by the action of the natural enzymes of the cells. It takes place generally in injured cells.

Automaton: Is a machine that can react automatically to preset conditions. The biological system can also be considered an automaton, which maintains continuous operations in response to potentially variable conditions. An applied possibility is to devise a DNA computer, which has three main functional parts. The first measures the absence or excess of a particular nucleic acid (RNA) in the cell that indicates e.g., a particular disease. The second part identifies the mRNA and the third part then releases an antisense

RNA, which can suppress e.g., small-cell lung carcinoma or prostate cancer. Such device can work under selected laboratory conditions but its clinical applicability is still awaited. ►DNA computer, ►small cell lung carcinoma, ►prostate cancer; Benenson Y et al 2004 Nature [Lond] 429:423.

Automixis: ►Self fertilization

Automutagen: A metabolite of the organism may become mutagenic, e.g., tryptophan.

Autonomous Controlling Element: A plant transposable element carries the transposase function and controls its own movement, e.g., Ac versus Ds in maize, the latter is a defective form of Ac, incapable of moving by its own power unless the autonomous (intact) Ac is present in the cell. ►transposable elements, ►Ac - Ds, ►Spm

Autonomous Developmental Specification: Maternal information or prelocalized morphogenetic information regulates the initiation of transcription of morphogenetic genes. ►morphogen

Autonomous Parvovirus: Uses the host system for productive replication. Only strain B19 is pathogenic in humans. They display antineoplastic properties in Ehrlich ascites tumors. ►parvoviruses, ►ascites

Autonomously Replicating Pieces: ►macronucleus

Autonomously Replicating Sequences: ►ARS

Autonomy: Cells transplanted into tissues of different genotype, or forming parts of genetically different sectors, still maintain the expression encoded by their genotype, and are not, or barely, affected by the genetically different tissue environment.

Autophagy: Destruction of cytoplasmic particles within a cell by delivering dispensable structures or molecules (in autophagosome vehicles), to lysosomes or to vacuoles (see Fig. A142). Autophagosomes are large (500–100 nm) double-membrane vesicles. Autophagy, a pathway of cell elimination, is different from apoptosis. This process gets rid of and re-utilizes the molecules during adverse conditions (e.g., cell starvation). The same machinery may degrade infective microorganisms. Before autophagy, isolation membranes sequester certain molecules. In resting cells, TOR inhibits autophagy; starvation and rapamycin dephosphorylate, and inactivate TOR, and can lead to the formation of *autophagosomes*. Autophagosomes can fuse with lysosomes and non-degraded proteins and viruses can be transported to the cell surface. Degradation within the lysosomes is also called *microautophagy*. In *macro-autophagy*, the subcellular membranes are altered and part of the cytoplasm is sequestered into double-membrane-surrounded

A

Figure A142. Autophagy

autophagic vacuoles (autophagosomes). Caspase 8 mediates autophagy through ATG7 (an ATP-dependent activator) and beclin 1 (Yu L et al 2004 Science 304:1500). Autophagy may have both advantageous (defensive) and deleterious features for health and disease (Shintani T, Klionsky DJ 2004 Science 306:990). Loss of autophagy in the central nervous system leads to neurodegeneration mice (Komatsu M et al 2006 Nature [Lond] 411:880; Hara T et al 2006 Nature [Lond] 441:885). When the proteasomes cannot handle the load, the non-degraded proteins may aggregate as *aggresomes*. Eventually the aggresomes can also be degraded (Wileman T 2006 Science 312:875). ▶lysosomes, ▶aggresome, ▶ubiquitin, ▶apoptosis, ▶beclin, ▶pexophagy, ▶dauer larva, ▶trinucleotide repeat, ▶TORs, ▶rapamycin, ▶endoplasmic reticulum-associated degradation; Klionsky DJ, Emr SD 2000 Science 290:1717; Subramani S 2001 Developmental Cell 1:6; Ohsumi Y 2001 Nat. Rev Mol Cell Biol 2:211; Khalfan W, Klionsky DJ 2002 Curr. Opin Cell Biol 14:468; yeast microautophagy; Duyboulou F et al 2005 Mol Cell 19:15, mini review: Yoshimori T 2007 Cell 128:833.

Autophene: Genetically determined trait, which is expressed independently of the position in case of transplantation. ▶allophenic

Autophosphorylation: Upon binding a ligand to a receptor it results in rapid phosphorylation of the receptor by its own subunits, e.g., by members of a dimeric molecule generally at tyrosine sites. ▶receptor tyrosine kinase

Autoploid (autopolyploid): Autoploid is the presence of more than two complete sets of identical genomes per cell. Autopolyploids may be [auto] tetraploid ($2n = 4x$), hexaploid ($2n = 6x$), octaploid ($2n = 8x$), etc. Autotetraploids in meiosis may pair as

quadrivalents, however, at a particular point only two chromosomes synapse (see Fig. A143). In autopolyploids, pairing may be also as two bivalents, one trivalent and univalent, and may form four univalents. When all chromosomes pair as bivalents, it is called selective pairing, and segregation of genes resemble that of diploids with duplicate genes. Autotetraploids

Figure A143. Association of homologs in autotetraploids

may carry a different allele in each of the four chromosomes; therefore, they can produce a larger variety of gametes than diploids. The maximal number of gametic combinations can be determined by the formula (see Table A7 and A8):

$\begin{bmatrix} n \\ x \end{bmatrix}$ where n = the total number of alleles, and x = the number of alleles in a gamete, thus in autotetraploids it becomes $\begin{bmatrix} 4 \\ 2 \end{bmatrix}$ for octaploids it is $\begin{bmatrix} 8 \\ 4 \end{bmatrix}$

and these can be rewritten as $\frac{4 \times 3}{2 \times 1} = 6$ for autotetraploids and $\frac{8 \times 7 \times 6 \times 5}{4 \times 3 \times 2 \times 1} = 70$ for autooctaploids, and this means that the number of allelic combinations possible with 4 different alleles are 6 types ($[4 \times 3] / [2 \times 1] = 6$) of gametes and in an octaploid with 8 different alleles ($[8 \times 7 \times 6 \times 5] / [4 \times 3 \times 2 \times 1] = 70$), the total number of gametic types is 70.

In case all the four alleles are dominant, AAAA, the individual is a quadruplex, AAAa = triplex, AAaa = duplex, Aaaa = simplex and aaaa = nulliplex. The segregation ratios in F_2 depend on whether there is

crossing over between the gene and the centromere, the type of pairing (as indicated above) and the type of disjunction at anaphase II (alpha parameter). The phenotypic proportions in F_2 are determined by the gametic output of the parents or selfed individuals. The gametic output and F_2 segregation of autopolyploids is very difficult to generalize because the genes are rarely linked absolutely to the centromere and the frequency of recombination may vary from 0 to 50%. There are additional variables that may be estimated by the alpha parameter. Segregation ratios at higher level of polyploidy can be predicted only theoretically, the actual results may be quite different, however. ▶synteny, ▶bivalent, ▶trivalent, ▶univalent, ▶synteny, ▶alpha parameter, ▶maximum ▶equational ▶segregation; Haldane JBS 1930 J Genet 22:359; Rédei GP 1982 Genetics, Macmillan, New York; see chromosome association diagram.

Autopodium: The skeletal portion of the hand and foot.

Autoprocessing: Occurs when a sequence of a protein (e.g., the C-terminal) is involved in its processing.

Table A7. Gametic output of autotetraploids

| Parent | Absolute Linkage* | | | Independence from Centromere [†] | | |
|--------|-------------------|----|-----------|---|----|------------|
| | AA | Aa | aa | AA | AA | aa |
| AAAA | 1 | 1 | 0 | 13 | 10 | 1 (4.2%) |
| AAaa | 1 | 4 | 1 (16.6%) | 2 | 5 | 2 (22.2%) |
| Aaaa | 0 | 1 | 1 (50.0%) | 1 | 10 | 13 (54.2%) |

Table A8. Phenotypic segregation ratios in autotetraploids in case the dominance is complete in F_2

| Mating | Absolute Linkage* | | Independence from Centromere [†] | |
|-------------|-------------------|-----------|---|-----------|
| | Dominant | Recessive | Dominant | Recessive |
| AAAA selfed | 1 | 0 | 575 | 1 |
| AAaa Selfed | 35 | 1 | 19.3 | 1 |
| Aaaa selfed | 3 | 1 | 2.4 | 1 |
| AAAA×AAaa | 1 | 0 | 107 | 1 |
| AAAA×Aaaa | 1 | 0 | 43.3 | 1 |
| AAAA×aaaa | 1 | 0 | 23 | 1 |
| AAaa×Aaaa | 11 | 1 | 7.3 | 1 |
| AAaa×aaaa | 5 | 1 | 3.5 | 1 |
| Aaaa×aaaa | 1 | 1 | 1 | 1.2 |

*No recombination between gene and centromere (chromosome segregation).

[†]The distance between gene and centromere is 50 map units or more, and therefore recombination occurs freely as if they (gene and centromere) would not be syntenic (chromatid segregation or maximum equational segregation).

A

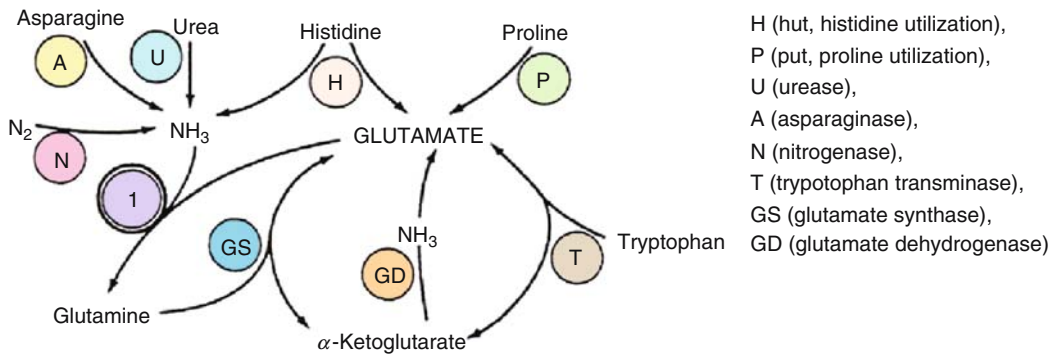

Figure A144. Metabolic steps involved in the regulation and autoregulation of Glutamine synthetase ①

Autorad: Lab slang for autoradiogram. ► [autoradiography](#)

Autoradiography: Labeling technique by which a radioactive substance reveals its own position in a cell or on a chromatogram when brought into contact with photographic film. For cytological analyses, most commonly H^3 -labeled thymidine is used because it gives the clearest resolution of chromosomal regions without serious DNA breakage, whereas in molecular genetics the much higher energy P^{32} -labeled compounds are employed usually. ► [non-radioactive labels](#), ► [immunoprobes](#); Taylor JH et al 1957 Proc Natl Acad Sci USA 43:122.

Autoreactive: When the lymphocytes recognize the individual's own molecules and develop an immune reaction to them. ► [autoimmune disease](#)

Autoreduplication: self-duplication.

Autoregulation: Occurs when a compound (or system) controls the rate of its own synthesis (see Fig. A144). For, e.g., the bacterium *Klebsiella aerogenes* uses glutamine dehydrogenase to make glutamate from α -keto-glutarate and ammonia, if the concentration of the latter exceeds 1 nM. If the concentration of ammonia is low, glutamate dehydrogenase cannot function to an appreciable extent. In this case, the ammonia + glutamate are converted into glutamine by glutamine synthetase. The active form of glutamine synthetase is non-adenylylated. In the presence of high concentration of ammonia, the enzyme is adenylylated and thus, the activity is reduced by this mechanism of autoregulation. In its non-adenylylated states it represses glutamate dehydrogenase instead. ► [regulation of gene activity](#), ► [nitrogen fixation](#), ► [genetic network](#); Magasanik B et al 1974 Curr Top Cell Reg 8:119; Chandler DS et al 2001 Nucleic Acids Res 29:3012; Isaacs FJ et al 2003 Proc Natl Acad Sci USA 100:7714.

Autosegregation: May take place in an apomictic or vegetatively multiplied organism due to chromosomal loss or somatic mutation. ► [apomixis](#), ► [mutation](#)

Autosexing: Identification of sex by genetic markers rather than by the genitalia. Silkworm breeders and poultry producers have exploited this procedure. Homozygosity for the *B* (barring) genes suppresses the appearance of colored spots on the head of the newly hatched chicks, controlled by this sex-linked gene (remember that in birds the males are homogametic). The *B* gene is dominant yet it shows clear dosage effect. In the females that are heterogametic, the spot is evident. Thus, the hens can be separated early from the roosters when the recognition of gender by anatomy is very difficult. Since most of the roosters will be used for meat production and the hens for egg production, they can be fed and managed accordingly. In the silkworm, the male cocoons (chrysalis) produce 25 to 30% more silk than the females and therefore, autosexing may have economic advantage. An electronic device may sort the silkworm eggs according to color (sex). (see Fig. A145; ► [chromosomal sex determination](#), ► [sexing](#))

Figure A145. Left: Autosexing in the silkworm. The dominant gene in the Y chromosome permits the distinction between the eggs which will hatch to become a male (pale color) and female (dark). Right: The homozygous male (b/b) chicks are light colored while the hemizygous b/o females develop colored spots on the head. (In the Lepidoptera and birds the males are WW and the females are WZ)

Autosomal Dominant Mutation: Readily detected and identified in many instances because the novel type appears suddenly without precedence in the pedigree. Achondroplasia in humans is frequently cited as such an example. The homozygotes generally suffer perinatal death. Therefore, most of the achondroplastic dwarfs are heterozygotes and new mutants. These dwarfs are of normal and frequently of superior intelligence. One must not forget that over 70 gene loci are responsible for various types of dwarfing in humans. Autosomal dominant mutation rates (per gamete/generation) in human populations for ten diseases vary from 4 to 100×10^{-6} . ▶ [mutation rate](#), ▶ [achondroplasia](#)

Autosomal Recessive Lethal Assay: A tester stock used for the detection of recessive second chromosomal lethals in *Drosophila*. It is of the following genetic constitution: *Cy L/Pm* where *Cy* (*Curly*) *L* (*Lobe*) and *Pm* (*Plum*) are heterozygous viable but homozygous lethal dominant genes. The *Cy* chromosome generally carries three inversions to prevent the recovery of crossovers. The heterozygotes of either sex are crossed with a mate that carried no mutation in either of the two second-chromosomes before the test. Single F_1 male(s) are then backcrossed with the *Cy L/Pm* female tester. From their offspring *Cy L* individual sibs are mated. From this mating, an F_2 is obtained. If all the survivors are *Cy L*, this indicates that a new lethal mutation occurred in the grandfathers' or grandmothers' 2nd chromosome and therefore *non-Curly* and *non-Lobe* homozygous individuals could not live. The diagram does not show the genotypes in the F_2 (see Fig. A146). ▶ [sex-linked recessive lethal assays](#)

Figure A146. Autosomal recessive lethal assay

Autosome: Autosome is a chromosome that is not a sex chromosome. ▶ [chromosomal sex determination](#)

Autosynthesis: May take place between homoeologous chromosomes in the absence of homoeologous pairing-suppressor genes. ▶ [homoeologous](#), ▶ [chromosome 5B](#)

Autotoxic Enterogenous Cyanosis: An obsolete name for human familial NADH-methemoglobin deficiency. ▶ [methemoglobin](#)

Autotroph: Can synthesize cellular C- and N- containing molecules from carbon dioxide and ammonia.

Autozygous: A genotype, which is not just homozygous but the alleles at the locus are *identical by descent*. ▶ [allozygous](#), ▶ [inbreeding coefficient](#), ▶ [coancestry](#), ▶ [homozygosity](#)

Autozygosity Mapping: ▶ [homozygosity mapping](#), ▶ [inbreeding coefficient](#); Kruglyak L et al 1995 Am J Hum Genet 56:519.

Auxanography: A method for mutant selection. A minimal medium is over-layered with auxotrophic spore or cell suspension and subsequently to different segments of the plate small quantities of various substances that the cells may need for growth are added. Where growth occurs, the cells utilize the compounds added and their nutritional requirement is identified.

Auxilin: 100-kDa brain-specific chaperone with C-terminal homology to DnaJ. Auxilin-bound clathrin mediates also uncoating of clathrin-coated vesicles (Fotin A et al 2004 Nature [Lond] 432:649). ▶ [DnaJ](#), ▶ [clathrin](#)

Auxins: phytohormones (morphogens) produced by the plant metabolism such as indole-3-acetic acid or of synthetic origin such as α -naphthalene acetic acid or 2,4-dichloro-phenoxyacetic acid (see Fig. A147). They play important role in cell elongation, signal transduction and required supplements for proliferation and regeneration in tissue culture. The transport of auxins in the plant tissues is regulated by chemosmosis aided by various transporter proteins. Auxin is synthesized in the leaves of the plants and it is transported to the stem apex where it plays an important role in the generation of flowers. Auxins also regulate root development. The *pin* family of proteins controls the transport of auxin either to the shoot and/or to the root and is essential for the development/growth of these organs (Kaplinsky NJ et al 2004 Science 306:822). The (▶ [PLETHORA](#) *PLT*) genes are required for *PIN* transcription and for stabilizing auxin at the root tip (Blilou I et al 2005 Nature [Lond] 433:39). The auxin-binding protein (ABP1)—with its crystal structure known—is essential for normal function of auxin (Napier RM et al 2002 Plant Mol Biol 49:373). The auxin-response factor (ARF) and AUX/IAA proteins are involved in regulation of auxin-dependent genes. The latter binds ARF and ARF binds directly to DNA (Hagen G, Guilfoyle T 2002 Plant Mol Biol 49:373; Liscum E, Reed JW 2002 Plant Mol Biol 49:387). These proteins are considered repressor of gene expression.

A

Figure A147. Pin-like mutants of *Arabidopsis* do not develop normal flowers at the tip of the stem. (Rédei, unpublished)

H⁺-pyrophosphatase (AVP1) controls auxin distribution and auxin-mediated shoot and root development (Li J et al 2005 Science 310:121). Auxin aides the interaction between the large number of AUX/IAA family of proteins and the ubiquitin ligase SCF, and the TIR1 and three other F-box proteins appear to be auxin receptors and transport inhibitors, which degrades AUX/IAA (Dharmasiri N et al 2005 Nature [Lond] 435:441; Kepinski S, Leyser O 2005 *ibid.* 446). The leucine-rich repeat domain of TIR1 of *Arabidopsis* contains an inositol hexakisphosphate co-factor and recognizes auxin and the AUX/IAA polypeptide substrate through a single surface pocket. Anchored to the base of the TIR1 pocket, auxin binds to a partially promiscuous site, which can also accommodate various auxin analogues (such as naphthalene acetic acid and 2,4-D). Docked on top of auxin, the AUX/IAA substrate peptide occupies the rest of the TIR1 pocket and completely encloses the hormone-binding site (Tan X et al 2007 Nature [Lond] 446:640). Inositol hexakisphosphate (IP6) and inositol heptakisphosphate (IP7) kinase activities generally regulate cell growth and morphology (Mulugu S et al 2007 Science 316:106).

Auxin modulates the response to gibberellin and the latter opposes the nuclear DELLA proteins, which are growth repressors (Fu X, and Harberd NP 2003 Nature [Lond] 421:740). Genes (*iaaH*, *iaaM*) in the Ti plasmid of *Agrobacterium* have instructions for their production and regulation, and these genes play a role in crown gall formation (in cooperation with cytokinins). An auxin response element first identified in the octopine synthase (*ocs*) gene of *Agrobacterium tumefaciens* (AuxRe [named *as-1* in cauliflower mosaic virus]) is an enhancer and it is present in many

genes. The *ocs/as-1* consensus consists of a more or less well-conserved 20- bp direct repeat with a 4 base spacer: TGACGTAAGCGCTGACGTAA. These elements respond to various auxins, salicylic acid, methyljasmonate and many other diverse compounds. The binding transcription factors have basic leucine zipper (bZip) motifs. Indole-3-acetic acid is biosynthesized mainly from tryptophan (aminotransferase) through indole-3-pyruvate (decarboxylase). ▶plant hormones, ▶crown gall, ▶Ti plasmid, ▶embryogenesis somatic, ▶ARF1, ▶SCF, ▶chemosmosis, ▶bZip, ▶SAUR, ▶sirtuin, ▶phosphoinositides; Guilfoyle TJ, Hagen G 1999 In: Reynolds PHS (ed) Inducible gene expression in plants. CABI, New York, p 219; Sabatini S et al 1999 Cell 1999:463; Zhao Y et al 2001 Science 291:306; Gray WM et al 2001 Nature [Lond] 414:271; Leyser O 2002 Annu Rev Plant Biol 53:377.

Axiom: Is a self-evident statement, which does not require proof; a basic tenet, e.g., nucleic acids represent genetic material.

Auxonography: ▶auxotrophy

Auxotroph: A mutant that requires nutritive(s) not needed by the wild type (prototroph) (see Fig. A148). Auxotrophic mutations have been extensively used for the study of biochemical pathways and for the identification enzymes catalyzing particular metabolic steps. In genetic analysis, auxotrophs facilitate selective techniques in backmutation, recombination, transformation, etc. A pyridoxine deficiency, causing seizure in humans, has been identified.

Figure A148. Left: Thiazole auxotrophs of *Arabidopsis* on basal medium; Right: on thiamine medium. (From GP Rédei, unpublished)

True auxotrophic animal mutations are exceptional and are also rare in higher plants. In *Arabidopsis*, over 200 mutations were obtained in the thiamine pathway without any obligate auxotrophy for other metabolites. The scarcity of auxotrophic mutations may be

due to redundancy of the genomes, alternative metabolic pathways and to compensatory effects in large genetic networks. ▶pyridoxine, ▶autotroph, ▶redundancy, ▶genetic network; Rédei GP 1982 Genetics, Macmillan, New York.

AuxRE (auxin response element): ▶ARF1, ▶auxin

Avastin (Bevacizumab): Avastin is a monoclonal antibody drug targeting vascular endothelial growth factor (VEGF) to reduce the blood supply (angiogenesis) for cancer cells. ▶angiogenesis, ▶VEGF, ▶monoclonal antibody, ▶biomarkers

AVED (ataxia with vitamin E deficiency): Caused by mutation in the large subunit of microsomal triglyceride transfer protein (encoded in human chromosome 8q13). Although the intestinal absorption of α -tocopherol is normal, the hepatic secretion into the blood is defective. The condition is very similar to Friedreich ataxia. ▶Friedreich ataxia

Avena: A genus of grasses (oats) with basic chromosome numbers $x = 7$ and form an allopolyploid series, $2n, 4n, 6n$.

Average: Arithmetic mean, i.e. the sum of all measurements (x) divided by the number of measurements (N): $\bar{x} = \frac{\sum x}{N}$. ▶mean, ▶median, ▶mode

Average Inbreeding Coefficient: α .

Avian: Pertaining to the taxonomic class of *Aves*. (sing. *Avis*, bird[s]). ▶chicken; <http://www.grcp.ucdavis.edu/publications/doc20/full.pdf>.

Avian Erythroblastosis (erbB): Viral oncogene (prevents maturation of the red blood cells in fowl) has its cellular homolog as a proto-oncogene in several eukaryotes. It is a protein kinase, phosphorylating primarily tyrosine residues. The normal allele specifies a plasma membrane receptor of epidermal growth factor (EGF). ▶erythroblastosis ▶fetalis

Avian Influenza Virus: ▶influenza

Avian MC29 Myelocytomatosis: A viral oncogene (*myc*, causes carcinoma, sarcoma and myelocytoma [a kind of leukemia]). It is present as a cellular proto-oncogene in vertebrates and its homologs are also present in plant cells. ▶oncogene, ▶proto-oncogene, ▶carcinoma, ▶sarcoma, ▶leukemias

Avian Myeloblastosis: ▶MYB oncogene

Avian Sarcoma Virus: ▶ASV

Avidian: A computer generated “artificial life form” useful for simulating genetics and evolutionary processes in a virtual environment of cybernetics. ▶genetics digital, ▶cybernetics

Avidin: A ca. 68,000 M_r protein of four subunits, each having strong affinity to biotin. It binds strongly to any molecule complexed with biotin such as nucleic acids, and biotin containing enzymes. It is widely used for non-isotopic labeling of nucleic acids. Originally, it was found and isolated from raw egg white. Eating raw eggs may cause biotin deficiency (cooking inactivates it). It is isolated also from *Streptomyces avidinii* under the name streptavidin. ▶biotinylation, ▶genomic subtraction

Avidity: ▶antibody

Avirulence: The lack of competence for causing pathological effects by an infectious agent.

Avogadro Number: The number of molecules ($= 6.02 \times 10^{23}$) in a gram molecular weight, a constant for all molecules.

Avoidance Learning: This is a classical test of animal behavior. In a two-compartment box one is electrically wired to provide test animals, an electric shock after a light turns on. After a learning period, some of the animals immediately move to the safe compartment when they see the light signals and learn that the shock comes from one compartment. The learning ability of inbred mice strains is genetically different. In some, about half of the individuals “learn,” in others only 10% associates the light signal with the shock. In *Drosophila* olfactory sensory neurons mediate the avoidance of CO_2 emitted by stressed flies (Suh GSB et al 2004 Nature [Lond] 431:854). ▶behavior genetics

Avuncular: Ancestral relatedness such as existing between nephews/nieces and uncles/aunts.

Awn (arista): Awn is a part of the glume present in some monocot plants (wheat). It supposedly has a role in photosynthesis, water regulation of the kernel and in seed dispersal. ▶glume; Elbaum R et al 2007 Science 316:884.

Axenic: The pure culture of organisms or cells without any contamination by other (micro) organisms. ▶aseptic culture, ▶tissue culture

Axenfeld-Rieger Anomaly (FKHL7/FOXC1, 6p25): Anterior eye segment defect and glaucoma caused by mutation in the human homolog of the *Drosophila* forkhead gene, FOXC1 (see Fig. A149). Additional loci at 4q25 (PITX2, a bicoid-related protein), 13q14, and 16q22-q24 (FOXC2 forkhead-like). ▶forkhead, ▶bicoid, ▶glaucoma; Priston M et al 2001 Hum Mol Genet 10:1631; Lines MA et al 2002 Hum Mol Genet 11:1177.

A

Figure A149. In the Axenfeld-Rieger syndrome with-in a reduced size iris, a light-colored ring (the sphincter muscle) is conspicuous around the pupil

Axial Elements: The lateral elements of the tripartite synaptonemal complex. ►[synaptonemal complex](#)

Axillary: Formed in the axil, the upper surface of the area between the leaf petiole and stem.

Axin: A protein-controlling body axis formation. Mutant axin may interfere with the normal developmental pathway and cause cancer, especially when the mismatch repair is defective. It is homologous to conductin. ►[conductin](#), ►[Wnt](#), ►[DNA](#) ►[repair](#)

Axis of Asymmetry: Axis through which objects or molecules form mirror images. In the body of the majority of organisms three axes are recognized: anterior–posterior (front–hind), dorsal–ventral (back–abdominal) and left–right. Recently, genes controlling asymmetry of the body have been identified. It had been known for a long time that changing the placement of internal organs has multiple deleterious consequences ►[situs inversus viscerum](#). It has been shown now in the *lefty* mouse mutant that the expression of the transforming growth factor (TGF β) family plays the role of a morphogen in controlling asymmetry by expressing only in the left half of the gastrula. This asymmetry is transient and sets on before lateral asymmetry becomes visible. Similar genetically-controlled mechanisms have also been discovered in chickens and other organisms. ►[morphogen](#), ►[TGF](#), ►[activin](#), ►[Kartagener syndrome](#), ►[asymmetric cell division](#), ►[situs inversus visceri](#); Lall S, Patel NH 2001 *Annu Rev Genet* 35:407.

Axl: A receptor tyrosine kinase, which is human myeloid leukemia transforming protein. ►[leukemias](#)

Axon: A long nerve fiber that, generally in a bundle surrounded by a myelin sheath, communicates impulses between the central and the peripheral nervous system. Organelles and molecules can be transported along the nerve axons outward from the cell or back to the cell. ►[neurogenesis](#), ►[netrin](#), ►[Slit](#), ►[Robo](#), ►[comm](#), ►[neuropilin](#), ►[axotomy](#); Kamal A et al 2000 *Neuron* 28:449; axonal transport; Stokin GB, Goldstein LSB 2006 *Annu Rev Biochem* 75:607.

Axon Guidance: Axons grow and move through the embryonal body toward their targets and allow for

synaptic connections of the neurons. Many proteins guide their advance. Some axons follow the same path, and bundle together by a process called fasciculation. Brain wiring and axon guidance can be monitored with the aid of the *PLAP* (placental alkaline phosphatase) vector equipped with an IRES site 5' to the *PLAP* gene. The vector includes another part carrying β -galactosidase and neomycin phosphotransferase (*G418*^r). This portion of it is expressed by virtue of its fusion to neural body cell-specific promoter. Transformants can be selected on neomycin media. The β -gal gene marks the cell body by blue color on X-gal medium; the *PLAP* gene is expressed exclusively in the dendritic part of the neurons. Thus, the wiring pattern of the brain can be monitored without laborious chemical purification. The Netrin, Slit, Semaphorin and Ephrine families of proteins—besides being involved with axons—contribute to the development of many other organs too by regulating transcription and translation of morphogenetic genes (Hinck L 2004 *Developmental Cell* 7:783). ►[axon](#), ►[Parkinson disease](#), ►[neuron](#), ►[IRES](#), ►[G418](#), ► [\$\beta\$ -galactosidase](#), ►[X-gal](#), ►[sema-phorin](#), ►[netrin](#); Leighton PA et al 2001 *Nature [Lond]* 410:175; Lin MZ, Greenberg ME 2000 *Cell* 101:239; Stein E, Tessier-Lavigne M 2001 *Science* 291:1928; Patel BN, Van Vactor DL 2002 *Curr. Opin Cell Biol* 14:221; Dixon BJ 2002 *Science* 298:1959; Zhu F-Q et al 2004 *Neuron* 42:897.

Axoneme: Cylindrical structures of microtubule doublets and about 250 attached polypeptides that are the major part of cilia, flagella and sperm. Two rows of the motor protein dynein are situated along the microtubules. ►[microtubule](#), ►[dynein](#), ►[cilia](#); Nicastro D et al 2006 *Science* 313:944.

Axoplasm: The cytoplasm of axons. ►[axon](#), ►[cilia](#)

Axotomy: Lesion of axons; may affect expression of genes. ►[regulation of gene activity](#)

5-Azacytidine: A pyrimidine analog (and suspected carcinogen) that interferes with methylation of DNA bases and may even restore the function of genes silenced by methylation (see Fig. A150). 5-azacytidine covalently binds cytosine methyltransferase enzymes and dramatically reduces methylation of cytosine in the DNA (Santi DV et al 1984 *Proc Natl Acad Sci [USA]* 81:6993). It may affect differentiation and development because hypomethylated genes are preferentially transcribed. It is noteworthy that some small eukaryotic genomes (yeast, *Drosophila*) do not contain methylcytosine yet their genomes are regulated during development. ►[methylation of DNA](#), ►[housekeeping genes](#), ►[fragile X](#), ►[trichostatin](#)

Figure A150. Azacytidine

Azaguanine: A toxic analog of guanine, it is readily incorporated into RNA or DNA (see Fig. A151).

►HAT medium

Figure A151. Azaguanine

8-Azaguanine Resistance: A commonly used marker in mammalian cell cultures; the resistance is based on a deficiency of the enzyme azaguanine-hypoxanthine phosphotransferase and therefore, this toxic purine cannot be processed by the metabolism. ►HAT medium

Azaserine (O-diazoacetyl-L-serine): An alkylating, antitumor, antifungal and mutagenic agent. The oral LD50 for rodents is 150–170 mg/kg. ►LD50

Azathiopurine (azathioprine): An anticancer, immunosuppressive drug (see Fig. A152). It is also a receptor of ultraviolet light A and increases the cells sensitivity to oxidative damage brought about by UV. Therefore, people who underwent azathioprine therapy may have increased risk for skin cancer (O'Donovan P et al 2005 Science 309:1871).

►thiopurine-S-methyltransferase [TPMT]

Figure A152. Azathiopurine

6-Azauracil: An antineoplastic pyrimidine analog; its nucleotide is inhibitory to orotidylic-acid decarboxylase and may repress the synthesis of orotidylic acid

pyrophosphorylase, key enzymes in the de novo pathway of nucleotide synthesis. ►TIIFS

Azide: A compound with a NH_3 ; sodium azide, a respiratory inhibitor, is a strong mutagen for certain organisms at low pH but not for others. Nitrogenase enzymes may reduce azides to N_2 and NH_4 .

►nitrogenase

Azidothymidine: ►AZT

Azoospermia: Human gene AZF (azoospermia factor) appears to be the expression of the DAZ (deleted in azoospermia) site and it has been assigned to human chromosome Yq11. At the AZF site three long palindromic sequences encoding 11 transcription units have been identified (Kuroda-Kawaguchi T et al 2001 Nature Genet 29:279). At Yq11.2, in the vicinity of AZF, is the DFFR (*Drosophila* fat-facet related), another spermatogenesis control gene. The frequency of the DAZ causes sterility is about 1.25×10^{-4} in men. There is no sperm in the ejaculate although the testes may produce sperm. This gene is substantially (42%) homologous to the *Drosophila* gene *boule* (*bol*) controlling meiotic G2 - M transition. Mouse gene *Dazla* is 33% homologous to DAZ. Both the mouse and the *Drosophila* genes are, however, autosomal yet they also involve male sterility. It has been shown recently that the human AZF gene was originally in the short arm of human chromosome 3 (where highly homologous sequences still exist), and it was transposed to the Y chromosome, amplified and pruned. The human Y chromosome encodes an RNA recognition motif, which is active particularly in the testes and the deletion of this motif may cause azoospermia. Histological analysis revealed that *Brek*^{-/-} germ cells (deficient in a brain-enriched kinase) differentiated normally until the round-spermatid stage, but failed to undergo the normal change in morphology to become elongated spermatids. Testicular somatic cells appeared normal in these mice. Expression of *Brek* in testis was restricted to the germ cells, suggesting that the maturation of germ cells in *Brek*^{-/-} mice are affected in a cell-autonomous manner. *Brek* seems to be essential for a late stage of spermatogenesis and may help to identify new targets for reproductive contraceptives and treatments against infertility (Kewa S et al 2006 Proc Natl Acad Sci USA 103:19344). ►holandric genes, ►twine, ►pelota, ►boule ►[bol], ►RBM, ►agonadism, ►oligospermia, ►CBADV, ►infertility; Hackstein JHP et al 2000 Trends Genet 16:565; Xu EY et al 2001 Proc Natl Acad Sci [USA] 98:7414.

Azorhizobium: ►nitrogen fixation

A

Azotobacter: ►nitrogen fixation

AZT (azidothymidine, also called zidovudine): A thymidine analog with an azido (N_3) substitution of the 3'-OH group (see Fig. A153); it may slow down the reverse transcriptase activity of HIV virus by

Figure A153. AZT

preferentially selecting this analog that has only minor effect on DNA polymerase of the mammalian cells. Unfortunately, some bone marrow damage is associated with the drug and this limits its usefulness in protecting against the full-scale development of AIDS. Mutations in the HIV reverse transcriptase may result in resistance against the drug by removing the AZTMP that blocks transcription. Eventually it may also debilitate the cells by the inhibition of DNA polymerase γ . It should be remembered that the Aschheim-Zondek test for pregnancy is also abbreviated as AZT. ►acquired immunodeficiency, ►AIDS, ►HIV, ►mtDNA; Lim SE, Copeland WC 2001 J Biol Chem 276:23616.

Azurocidin: ►antimicrobial peptides**Historical vignettes**

The Cambridge (Massachusetts) City Council were not the first to disapprove of recombinant DNA. Joshua Sylvester (1563–1618) answers the “New objection of Atheists, concerning the capacite of the Ark”:

“O profane mockers! if I but exclude
Out of this Vessel a vast multitude
Of since-born mongrels, that derive their birth
From monstrous medly of *Venerian* mirth:
Fantastick Mules, and spotted Leopards,
Of incest-heat ingendred afterwards:
So many sorts of Dogs, of Cocks, and Doves,
Since, dayly sprung from strange & mingled loves,
Wherein from time to time in various sort,
Dedalian Nature seems her to disport:
If plainer, yet I prove you space by space,
And foot by foot, that all this ample place,
By subtile judgement made and *Symmetrie*,
Might lodge so many creatures handsomely,
Sith every brace was *Geometricall*:
Nought resteth (*Momes*) for your reply at all;
If, who dispute with God, may be content
To take for current, Reason's argument.”

– *The Complete Works of Joshua Sylvester*,
Vol. I, ed. Rev. Alexander B Grosart, printed
for private circulation, 1880, p. 136

Ayala FJ 2007 Proc Natl Acad Sci [USA] 104 (Suppl. 1):8567

“On 1 July 1858, three papers were read by the [Linnean Society] society's undersecretary, George Busk, in the order of their date of composition: Darwin's abbreviated abstract of his 230-page essay from 1844; an ‘abstract of abstract’ that Darwin had written to the American botanist Asa Gray on 5 September 1857; and Wallace's essay, ‘On the Tendency of Varieties to Depart Indefinitely from Original Type; Instability of Varieties Supposed to Prove the Permanent Distinctness of Species’ (1858; ref 10).

The papers generated little response and virtually no discussion, their significance apparently lost to those in attendance. Nor was it noticed by the president of the Linnean Society, Thomas Bell, who, in his annual address the following May, blandly stated that the past year had not been enlivened by ‘any of those striking discoveries which at once revolutionize’ a branch of science.”

B.C.E. (before the common era): An archaeological concept for the designation of age of event(s) or artifacts based on different criteria such as carbon dating, old scriptures, etc.

B Cell: B lymphocyte, B lymphocyte receptor.

B Chromosome: This is the accessory (supernumerary) chromosome. They are generally heterochromatic and carry no major genes yet they may be present in several copies in many plants. B chromosomes have no homology to the regular chromosomal set (A chromosomes) and are prone to non-disjunction because their centromeres appear to be defective. If A-B translocations are constructed, the placement of genes to chromosomes, arms or even shorter regions may be facilitated. The principle of the use of A-B chromosome translocations is presented in the

diagram here. The A chromosome or a translocated segment carries the dominant *A* allele and the B chromosome has no counterpart to it, therefore a null phenotype (*a*) appears in its absence. In the diagram the male has the translocation and the female is homozygous recessive for the *a* allele. In case there is no B chromosomal non-disjunction—when the chromosomal constitution is as diagramed—both the endosperm and the embryo express the dominant gene. In the case of non-disjunction the phenotypic effects depend on the constitution of the sperm, which fertilizes the diploid polar nucleus of the endosperm or the embryo, respectively (see Fig. B1).

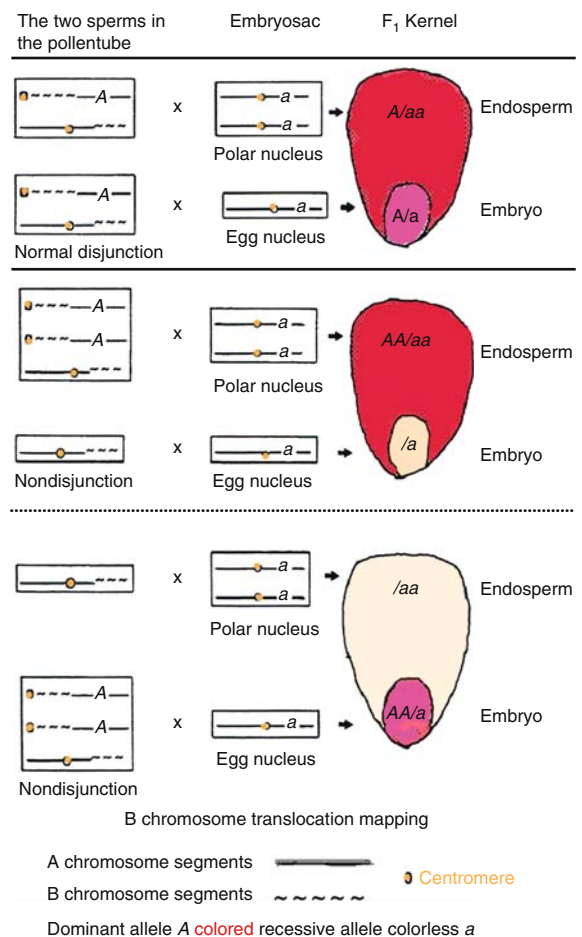

Figure B1. B chromosome translocation mapping

This type of difference reveals the approximate physical and genetic position of the locus. Had the dominant allele been outside the translocated segment, the recessive allele would not have been unmasked. The example given here describes the most favorable case when the consequence of the translocation can be identified without tissue-specificity.

B

B chromosomes have been reported in ~1300 species of plants and in ~500 species of invertebrate and vertebrate species of animals. The transmission of the B chromosomes varies in different species and it may be preferential in the female member (e.g., in grasshoppers) or in some wasps by the male. A total of 19 B chromosome sequences of maize have been isolated by microdissection and cloned and characterized according to their information content (Cheng Y-M, Lin B-Y 2003 *Genetics* 164:290). ▶**mapping genetic**, ▶**trisomic analysis**, ▶**translocation genetic**, ▶**centromere**, ▶**centromere silencing**; Beckett JB 1982 *J Hered* 73:29; Page BT et al 2001 *Genetics* 159:291; Camacho JPM et al 2000 *Philos Trans R Soc Lond B* 355:163.

B DNA: ▶**DNA type**, ▶**Z DNA**

B Lymphocyte (B cell): This is responsible for humoral antibody synthesis and secretion. Pro-apoptotic proteins, BAX and BAK, limit the number of B cells. The deletion of *Bax* and *Bak* genes leads to autoimmune disease in mice (Takeuchi O et al 2005 *Proc Natl Acad Sci USA* 102:11272). There are two types of B cells, B1 and B2. T cells activate the common B2 cells. Its differentiation from hematopoietic cells (plasma cells) depends on transcription factors (XBP-1) of the bone marrow, cytokines and antigens, T_H cells and a series of non-receptor and receptor tyrosine kinases and phosphatases, proteins mediating the pathway shown in italics (see Fig. B2) in the diagram outlining the developmental pathway of B lymphocytes. The B1 cells also employ an RNA editing system for the diversification and amplification of their antigen receptors in contrast to T cells, which rely on the V(D)J recombination system, and

appear independent of T cell activation. ▶**T cells**, ▶**apoptosis**, ▶**EBF**, ▶**CpG motifs**, ▶**CD40**, ▶**TAPA-1**, ▶**blood**, ▶**immune reactions**, ▶**germinal center**, ▶**Blimp-1**, ▶**BTK**, ▶**surrogate chains**, ▶**Pax**, ▶**immunoglobulins**, ▶**BASH**, ▶**V(D)J**, ▶**RNA editing**, ▶**XBP**; Fagarasan S, Honjo T 2000 *Science* 290:89; ▶**blood**, ▶**bone marrow**, ▶**thymus**, ▶**immune system**; Hardy RR, Hayakawa K 2001 *Annu Rev Immunol* 19:595; Reimold AM et al 2001 *Nature [Lond]* 412:300; Berland R, Wortis HH 2002 *Annu Rev Immunol* 20:253.

B Lymphocyte Receptor (B cell receptor, BCR): This is constructed from the membrane-bound immunoglobulin molecules IgM and IgD as receptors and after the attachment of the antigen they can also use IgG, IgA and IgE (see Fig. B3). The intracellularly linked IgA and IgB heterodimer that is the signaling portion of the receptor and the complex transmits the immunoglobulins recognized by the BCR. All the immunoglobulins are attached to the receptors associated with the IgA and IgB heterodimer through their heavy-chain terminal amino acids. This tail consists of 3 amino acids in IgM and IgD but it has 28 amino acids in IgG and IgE. In both, part of the A-B heterodimer includes an ITAM (immunoreceptor tyrosine-based activation motif). The latter is instrumental in activating the Sky and Lyn protein tyrosine kinases that mediate the switching to the IgG, IgA and IgE molecules when the appropriate antigen is presented. These tails are required for the endosomal targeting of the immunoglobulins. The B cell linker protein (BLNK) is also required for the normal development of B lymphocytes. ▶**B lymphocyte**, ▶**BASH**, ▶**immune system**, ▶**ITAM**, ▶**ITIM**, ▶**BAP**, ▶**endocytosis**, ▶**agammaglobulinemia**; Meffre E et al 2001 *J Clin Invest* 108:879; Vilches C, Parham P 2002 *Annu Rev Immunol* 20:217.

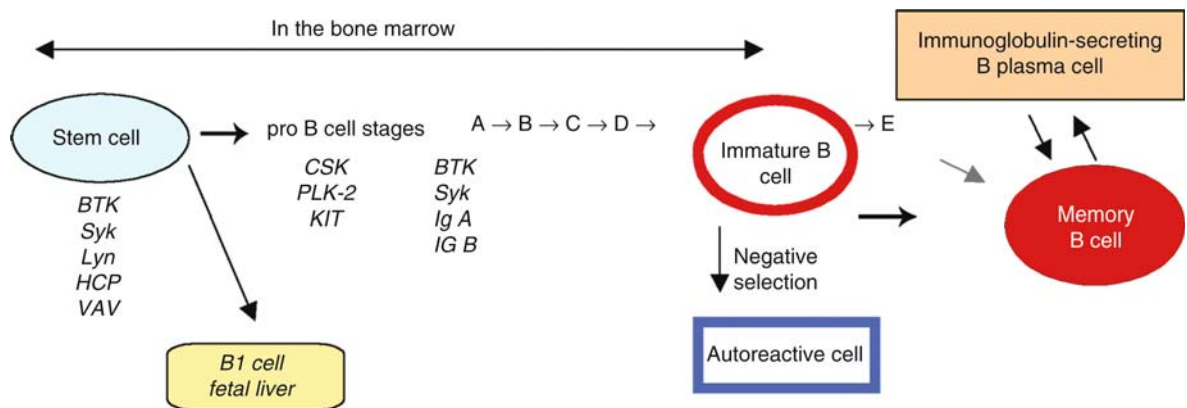

Figure B2. B lymphocyte-bone marrow. During the pro-B cell stages in the bone marrow first the IgH and then the IgL immunoglobulin chains are rearranged through signaling by the pre-BCR (B cell receptor). After expression of the BCR, some cells leave the bone marrow and mature into IgM and IgD cells that move between the peripheral lymphoid organs

Babelomics: This is the web server for the interpretation of microarray data as well as gene annotation and interaction networks: <http://www.fatigoplus.org>.

Baboon (*Papio*): ▶Cercopithecidae, ▶xenotransplantation

BAC (bacterial artificial chromosome): Refers to bacterial cloning vector (derived from F plasmid) that can accommodate up to 350 kb (most commonly 120–150 kb) DNA sequences and has a considerably lower error rate than the still larger capacity yeast artificial chromosome (YAC). BACs usually exist in a single copy per cell. *Random BACs* are selected at random from a genomic library and are then shotgun-sequenced. Most BAC vectors lack selectable markers suitable for mammalian cell selection but can be retrofitted by employing the Cre/loxP site-specific recombination system. ▶vectors, ▶PAC, ▶YAC, ▶BIBAC, ▶shotgun sequencing, ▶genome projects, ▶F plasmid, ▶Cre/loxP, ▶selectable marker, ▶TAC; Wang Z et al 2001 Genome Res 11:137, http://www.nih.gov/science/models/bacsequencing/end_sequencing_project.html.

BACE (beta site APP-cleaving enzyme): The amyloid precursor protein (APP) cleavage enzyme—a β -secretase [a membrane-bound aspartyl protease]—is involved in the production of brain plaques in Alzheimer's disease. The transmembrane BACE splits APP into soluble β -sAPP and a membrane-attached carboxy-terminal fragment, CTF- β . The latter is expected to be the substrate for γ -secretase. Bace1 also controls the myelination of peripheral nerves (Willem M et al 2006 Science 314:664). BACE1 deficient mice do not generate A β peptide, responsible for Alzheimer plaques and appear to be normal. BACE is encoded at human chromosome 11q23.3. Its homolog BACE2 is in chromosome 21, near the region critical in Down's syndrome trisomy. Research on drug development for the treatment of Alzheimer's disease has a likely target in BACE. ▶Alzheimer's disease, ▶secretase, ▶Down's syndrome, ▶presenilin, ▶GSK; Roberds SL et al 2001 Hum Mol Genet 10:1317, substrate binding; Gorfe AA, Catfish A 2005 Structure 13:1487.

BACH (BRCA1-associated carboxy-terminal helicase): This is a DEAH family protein. Phosphorylated BACH helicase interacts with the C-terminal domain of BRCA1 (BRCT) and in the case of DNA damage it controls the G2→M transition in the cell cycle as a checkpoint. BRCT mediates the tumor-suppressor function of BRCA1. BACH1 seems to be identical to Fanconi anemia FANCI, and is essential for homologous recombination (Litman R et al 2005 Cancer Cell 8:255). ▶breast cancer, ▶DEAH box proteins, ▶cell cycle, ▶checkpoint; Yu X et al 2003 Science 302:639.

B

Bach, Johann Sebastian: One of the greatest geniuses of classical music, Bach's (1685–1750) family included over 50 more or less renowned organists, cantors and musicians (see Fig. B5). Of the four surviving children from his first marriage to his second cousin Maria Barbara Bach, three were musicians (inbreeding coefficient 1/64 [three offspring died in infancy]). Five of the 13 children from his second marriage to unrelated singer Anna Magdalena Wilcken (assortative mating) survived and of these three were musically talented. This family tree reveals that musical ability may be controlled by relatively few genes, and the cultural environment may also play a major role. Recent studies have demonstrated that musical talent is correlated with stronger development of the left planum temporale, increased leftward asymmetry of the cortex. ▶[dysmelodia](#), ▶[musical talent](#), ▶[Mozart](#), ▶[Beethoven](#); Wolff C 2000 Johann Sebastian Bach: The learned musician, Norton, New York.

Figure B5. Bach and Bach morning prayer. Morning prayers in the family of Sebastian Bach, painted in 1870 by American artist Toby Edward Rosenthal in Europe. Members of the large family are either playing music or singing. From Music with Ease (<http://www.music-with-ease.com>); courtesy of Paul Wagner.

Bacillus: This is a rod-shape bacterium. (▶[Bacillus subtilis](#), ▶[Bacillus thuringiensis](#))

Figure B6. Bacillus

Bacillus Calmette-Guerin (BCG): This attenuated form of *Mycobacterium bovis* bacillus is used to vaccinate against the human *Mycobacterium tuberculosis* and may serve as a suitable vector for the *B. burgdorferi* and the HIV virus. BCG differs from the virulent *M.t.* by the deletion of ~91 open reading frames and several (~38) additions. BCG has also been introduced into liver cancer cells, skin tumors and other cancer cells with some beneficial effects on slowing down metastasis and/or delayed recurrence. Protection against tuberculosis has the highest correlation with the rapid accumulation of specific CD8⁺ T cells in the infected tissues of challenged mice. Specific IFN-production by CD4⁺ T cells reflected the load of *M. tuberculosis* rather than the strength of protection (Mittrücker H-W et al 2007 Proc Natl Acad Sci USA 104:12434. ▶[Borrelia](#), ▶[acquired immuno-deficiency](#), ▶[mycobacteria](#), ▶[metastasis](#), ▶[T cell](#), ▶[interferon](#); Sasseti CM et al. 2001 Proc Natl Acad Sci USA 98:12712; Hsu T et al 2003 Proc Natl Acad Sci USA 100:12420.

Bacillus cereus: This opportunistic pathogen causes diarrhea and emetic syndromes. Its 4,559,996 bp sequenced genome is closely related to that of *Bacillus anthracis* and *Bacillus thuringiensis*. (▶[anthrax](#), ▶[Bacillus thuringiensis](#); Ivanova N et al 2003 Nature [Lond] 423:87)

Bacillus subtilis: A gram-positive, rod-shaped soil bacterium that lives on decayed organic material and is therefore harmless. Under conditions of starvation, most of the cell content, particularly the DNA moves to one end of the cell. This area, constituting about 10% of the cell, is walled off and becomes a spore. Before spore formation a checkpoint protein (DisA) scans the chromosome for DNA damage and halts spore formation until the damage is repaired (Bejerano-Sagie M et al 2006 Cell 125:679). The spore is extremely resistant to various environmental effects that can destroy vegetative cells. Under favorable conditions the spore regenerates the bacterium. Before the cells form spores, half of the bacterial population exports a killer protein,

SdpcC. The killer protein destroys the non-producer cells, which are then cannibalized by the producer cells. The exporter cells produce an immunity protein SdpI that protects these cells from the killer protein. SdpC stimulates SdpI production. SdpI synthesis is under the control of a two-gene operon which is controlled by the SdpR repressor (Ellermeier CD et al 2006 Cell 124:549). The size of its cells is similar to those of *E. coli*, and its genome of 4,214,810 bp (4,100 ORF) was completely sequenced by 1997 (Nature 390:248). Among the 4,100 genes only 271 appeared indispensable for growth of the bacterium when the genes were inactivated singly (Kobayashi K et al 2003 Proc Natl Acad Sci USA 100:4678). The DNA has a different base composition from that in *E. coli*, A + T/G + C ratio is 1.38 in the former and 0.91 in the latter indicating that *B. subtilis* has more A + T than *E. coli*. The genome includes many repeats in only half of the chromosome, at both sides of the replicational origin. For transcription it uses 18 different σ factors although its major RNA polymerase is similar to that of *E. coli* ($\alpha\alpha\beta\beta'\sigma$). The 43 kDa (σ_{43}) recognizes some of the consensus sequences of *E. coli* promoters. Its best known phage is SPO1 that is transcribed either by a phage RNA polymerase or by the host. It contains 4100 protein-coding genes with an average length of 890 bp. 78% of them start with ATG. 75% of the genes are transcribed in the direction of the replication. 53% of the genes occur only once (singlets) whereas the putative ATP binding transporter family paralogues appear to be 77 (14% of the genome). The DNA is not methylated. ►*E. coli*, ►forespore, ►endospore, ►sporulation, ►paralogous, ►fratricide; Hecker M, Engelmann S 2000 Int J Med Microbiol 290:123, <http://genolist.pasteur.fr/>.

Bacillus thuringiensis: This gram-positive bacterium produces the BT toxin. The toxin (delta endotoxin) is within the crystalline inclusion bodies produced during sporulation. In an alkaline environment (such as in the midgut of insects) the crystals dissolve and release proteins of M_r 65000 to 160000 that are cleaved by the proteolytic enzymes of the insects into highly toxic peptides. These toxins are most effective against *Lepidopteran* larvae (caterpillars) but some nematodes are susceptible to one or another form of the toxin (Wei J-Z et al 2003 Proc Natl Acad Sci USA 100:2760; Cappello M et al 2006 Proc Natl Acad Sci USA 103:15154). The most economical solution is to transform plants (tobacco, cotton, maize etc.) with the *Bt2* gene, which codes for the 1,115 amino acid residue pro-toxin protein. Actually, a smaller polypeptide, Mr 60K, and even smaller fragments are still fully active. The transgenic plants kill the invading

caterpillars within a couple of days and remain practically immune to any damage. The activity of the transgene has been further enhanced by the use of high efficiency promoters in the T-DNA constructs. In some instances, however, transgenic cotton was overpowered by bollworms. There are differences in the spectra of the bacterial toxins produced by different strains of the *bacillus* and this provides an opportunity to extend the range of toxicity to other insect species. For the production of corn rootworm resistant transgenic plants, the toxin gene of *B. thuringiensis tenebrionis* has been used. Mutation in insect aminopeptidase receptors, in a cadherin superfamily gene and β -1,3-galactosyltransferase may impart resistance to the BT toxin. Glycolipids are the receptor to the BT toxin and the absence of the special glycolipid (vertebrates) or mutation in the receptor imparts resistance (Griffitts JS et al 2005 Science 307:922). *B. thuringiensis*-induced mortality depends on the presence of enteric bacteria in the gut of the target organisms (Broderick NA et al 2006 Proc Natl Acad Sci USA 103:15196).

The resistance of pests to BT is surprisingly rare under field conditions, only the diamondback moth (*Plutella xylostella* [L]) seems to be an exception (Fox JL 2003 Nature Biotechnol 21:958). The transfer of the BT toxin gene into commercial varieties may have some deleterious effects on the Monarch butterfly and other lepidopteran larvae, however under field conditions these adverse effects may not be very serious. Resistance genes to the BT toxin are located in different chromosomes of plants and experimental evidence shows that insects cannot simultaneously overcome the two-gene hurdle unless single and two-gene resistance crops are grown at the same time. In such a situation the insect can develop immunity against one than the other gene and eventually the plant resistance may be lost. However, when only two-gene resistant plants are grown the evolution of the insects may not be possible (Zhao J-Z et al 2005 Proc Natl Acad Sci USA 102:8426). The culture of the BT toxin transgenic cotton did not affect biodiversity as much as the use of broad-spectrum insecticides and secured higher yield in two years of large scale agricultural production (Cattaneo MG et al 2006 Proc Natl Acad Sci USA 103:7571). ►transformation of plants, ►promoter, ►*Photorhabdus luminescens*; pest eradication by genetic means, ►hookworm, ►Cry9C, ►cadherins, ►insect resistance in plant, ►GMO, ►*Bacillus cereus*, ►anthrax; Gahan LJ et al 2001 Science 293:857; Griffitts JS et al 2001 Science 293:860; series of articles in Proc Natl Acad Sci USA 98:11908–11937 [2001]; membrane receptor: Pérez C et al 2005 Proc Natl Acad Sci USA 102:18303.

B

Back Cross: The F1 is crossed (mated) by either of its two parents (►test cross). Each back crossing reduces by 50% the genetic contribution of the non-recurrent parent; thus after (r) back crosses it will be $(0.5)^r$. The percentage of individuals homozygous for the (n) loci of the recurrent parent in (r) number of back crosses = $[(2^r - 1)/2^r]^n$. The chance of eliminating a gene linked to a selected allele is determined by the intensity of linkage (p) and the number of back crosses (r) according to the formula $1 - (1 - p)^{r+1}$.

Back Mutation: This mutation (recessive) reverts to the wild type allele. ►reversion

Back Reaction: Refers to a property of RNA polymerase to move backward and cleave the synthesized RNA if a nucleotide needed for the forward (synthetic) reaction is not available. ►dead end complex

Backbone: An example is the sugar-phosphate chain of nucleic acids or the N–C chain of amino acids in a protein. To the backbone, side chains may be attached such as nucleotides or some other molecular groups in amino acids, except in glycine, which has no side chain. ►Watson and Crick model

Background, Genetic: Refers to the (residual) genetic constitution without considering particular loci or genes under special study. Knowledge of the genetic background may be of substantial importance because different sets of modifier genes may influence the expression of particular genes. ►modifier genes

Background Radiation: This is the natural radiation from cosmic or terrestrial sources. ►cosmic radiation, ►terrestrial radiation

Background Selection: The recurrence of deleterious mutations reduces the effective size of the population. The selection is directed against the chromosomal background carrying the particular allele(s). The balance between hitchhiking and background selection determines the extent of genetic variation in a population. ►hitchhiking, ►effective population size; Charlesworth D et al 1995 Genetics 141:1619.

Backtracking, Transcription: In this process the RNA polymerase (the elongation complex) slides backward on the DNA template by one or more nucleotides. In this case the RNAP may lose the 3'-end of the transcript and the complex may be temporarily inactivated thereby interrupting transcript elongation. Reactivation may require (prokaryote) GreA, GreB and TFIIS (eukaryote) and other protein factors (Mfd). Reinitiation may be facilitated by the use of multiple RNAP molecules. (►Gre, ►Mfd, ►TFIIS, ►reinitiation, ►Epshtein V; Nudler E 2003 Science 300:801).

Bactenein: antimicrobial peptides.

Bacteremia: Refers to bacterial infection of the blood.

Bacteria: This broad taxonomic group of microscopically visible (prokaryotic) organisms has DNA as the genetic material (nucleoid) that is not enclosed by a distinct membrane within the cell and may have various numbers of extrachromosomal elements, plasmids that constitute from about 2 to 20% of the DNA per cell. The size of the bacteria varies considerably from 0.2 to 750 µm. Bacteria are capable of protein synthesis and of independent metabolism even if they are parasitic or saprophytic. Their cell wall is mucopolysaccharide and protein. Their cells contain ribosomes (70S) but no mitochondria, plastids, endoplasmic reticulum or other compartments. They divide by fission in an exponential manner as long as nutrients and air are not in limited supply. The division rate of bacteria during exponential growth can be expressed as $N = 2^g \times N_0$ where N is the number of cells after g generation of growth and N_0 is the initial cell number. After the exponential phase, unless their increasing need is met, the growth either declines or may become stationary. The generation time of *E. coli* under standard conditions may be 20–25 minutes.

Bacteria can be classified into three main groups: *Archeobacteriales*, *Eubacteriales* and *Actinomycetales*. *Eubacteriales* includes *Pseudomonadaceae* (*Pseudomonas aeruginosa*), *Azotobacteriaceae* (*Azotobacter vinelandii*), *Rhizobiaceae* (*Rhizobia*, *Agrobacteria*), *Micrococcaceae* (*Micrococcus pyogenes*), *Parvobacteriaceae* (*Haemophilus influenzae*), *Lactobacteriaceae* (*Diplococcus pneumoniae*, *Streptococcus faecalis*), *Enterobacteriaceae*, (*Aerobacter aerogenes*, *Escherichia coli*, *Salmonella typhimurium*), *Bacillaceae* (*Bacillus subtilis*, *B. thuringiensis*). *Actinomycetales* includes *Mycobacteriaceae* (*Mycobacterium phlei*, *Mycobacterium tuberculosis*) and *Streptomycetaceae* (*Streptomyces coelicolor*, *S. griseus*). There are many other types of classification systems. It is common to identify bacteria as gram-positive (indicating that they retain the deep red color of the gram stain [crystal-violet and iodine] after treatment with ethanol) or gram-negative that fail to retain it (and may appear colorless or just slightly pinkish). These properties depend on the composition and structure of the cell wall. Gram-positive bacteria are surrounded by peptidoglycan outside of the plasma membrane, and gram-negative cells have an outer membrane enveloping the peptidoglycan wall. The peptidoglycans are polymers of sugars and peptides and are cross-linked by pentaglycines that determine the shape of the cell wall and the bacterium. There are at least 10^{30} bacteria on the planet and at least as many bacteriophages. Probably less than 1% of the bacteria can be cultured in the laboratory and that makes their study

difficult (Amann RI et al 1995 Microbiol Rev 59:143). Closely related bacteria can be distinguished—even if the difference between two 16S RNAs is in only one nucleotide—by the use of quenched autoligation probes. ►conjugation, ►bacterial recombination frequency, ►bacterial transformation, ►recombination molecular mechanisms in prokaryotes, ►bacteria counting, ►quenched autoligation probe; bacterial names and standing nomenclature: <http://www.bacterio.net>, chromosome maps of several bacteria: <http://wishart.biology.ualberta.ca/BacMap/>.

Bacteria Counting: This is done either by counting the number of colonies formed or by determining cell density in a volume, using a photometer. In the first procedure an inoculum of a great dilution of a culture is seeded on a nutrient agar plate and incubated for a period of time (e.g., 2 days). Each colony thus formed represents the progeny of a single cell and the number of colonies indicates the number of *live* bacteria in the volume of the inoculum. Optical density obtained through the second procedure indicates the cell density that becomes meaningful only if information is available on the correlation between light absorption and cell number, determined earlier by the plating technique. If the plate was seeded by 2 mL of the culture diluted 10^7 times and 100 colonies are observed then the number of live cells is $(100/2) \times 10^7 = 5 \times 10^8$ cells/mL. ►bacteria, ►lawn bacterial

Bacterial Artificial Chromosome: ►BAC

Bacterial Recombination Frequency: In the case of conjugation transfer of genes recombination frequency is determined by the time in minutes since the beginning of mating. This procedure is useful for genes that are more than 2 to 3 minutes apart. It takes about 90–100 minutes at 37 °C to transfer from a Hfr donor bacterium to an F[−] recipient cell the entire genome (more than 4 million nucleotides). The efficiency of transfer depends on the nature of the Hfr strain used. Approximately $5-6 \times 10^4$ nucleotides are transferred per minute. Bacterial recombination does not permit the recovery of the reciprocal products of recombination and all detected cross-over products are double cross-overs. If bacterial genes are closer than 2 to 3 minutes, then recombination mapping is used. For bacterial recombination, selectable (auxotrophic) markers are generally used so that the phenotypes can be easily recognized. The recipient strain carries genes, e.g., a and b^+ , and the donor strain carries the alleles a^+ and b defining the interval where recombination is studied. In order to measure the number of successful matings, the donor strain also carries the prototrophic gene (c^+) and the recipient is marked by the auxotrophy allele (c) of the same locus. The c gene does not have to be

very close to the interval studied:

$$\frac{a \quad b^+}{a^+ \quad b} \quad \frac{c^+}{c}$$

The *frequency of recombination* (p) is then calculated:

$$p = \frac{\text{number of cells } a^+ b^+ \text{ constitution}}{\text{number of } c^+ \text{ cells}}$$

The $a^+ b^+$ recombinants are the result of an exchange between a^+ and b^+ and also beyond the c^+ site as shown by the arrows: $a^+ \uparrow b^+ c^+ \downarrow$.

To determine *gene order by recombination* one must use at least three loci in a reciprocal manner (see Tables B1 and B2):

Would the gene order be $a b c$:

Table B1. Gene order determination by recombination in bacteria

| | | |
|-----------|-----------------------------------|---|
| Donor | $a \downarrow b^+ c^+ \downarrow$ | To obtain triple prototrophs double exchange is sufficient in both of the reciprocal crosses |
| Recipient | $a^+ b c$ | |
| Donor | $\downarrow a^+ \downarrow b c$ | |
| Recipient | $a b^+ c^+$ | |

Would the gene sequence be $b a c$:

| | | |
|-----------|--|---|
| Donor | $\downarrow b^+ \downarrow a c^+ \downarrow$ | In order to obtain triple prototroph recipients, the number of exchanges must be at least quadruple as shown by the arrows |
| Recipient | $b a^+ c$ | |
| Donor | $b \downarrow a^+ \downarrow c$ | In the reciprocal cross only double recombination is required to produce $b^+ a^+ c^+$ prototrophs |
| Recipient | $b^+ a c^+$ | |

Thus, depending whether the gene order is abc or bac one can tell from the frequency of prototrophs in the reciprocal crosses. The higher numbers of exchanges are less frequent.

Recombination frequency in bacteria within very short intervals, such as between alleles within a gene can also be determined by transduction. If the constitution of the donor DNA is $a^+ b^+$ and the recipient is $a b$, the *frequency of transduction* (recombination) is:

$$\frac{[a^+ b] + [ab^+]}{[a^+ b] + [ab^+] + [a^+ b^+]}$$

Gene order in bacteria can be determined by a three-point transformation test as illustrated by a hypothetical experiment described here when the donor DNA is

B

$a^+ b^+ d^+$ and the recipient is $a^- b^- d^-$, and the reciprocal products of recombination are not recovered:

Table B2. Gene order determination by transformation in bacteria

| Genes | Genotypes of Transformants | | | | | | |
|-----------------|----------------------------|------|-----|-----|------|-----|------|
| <i>a</i> | + | - | - | - | + | + | + |
| <i>b</i> | + | + | - | + | - | - | + |
| <i>d</i> | + | + | + | - | - | + | - |
| Number of cells | 12000 | 3400 | 700 | 400 | 2500 | 100 | 1200 |

Recombination for a particular interval is calculated by the number of recombinants in the interval(s) divided by the total number of cells transformed in that interval. There are 7 classes of cells. Recombination is calculated in three steps: in the *ab*, *bc* and *ad* intervals.

In the *ab* interval we have here

$$\frac{[3400 + 400 + 2500 + 100]}{[1200 + 3400 + 400 + 2500 + 100 + 1200]} \approx 0.33$$

in the *bd* interval

$$\frac{[700 + 400 + 100 + 1200]}{[12000 + 3400 + 700 + 400 + 100 + 1200]} \approx 0.14$$

in the *ad* region

$$\frac{[3400 + 700 + 400 + 2500 + 100 + 1200]}{[12000 + 3400 + 700 + 400 + 2500 + 100 + 1200]} \approx 0.41$$

Although the frequency of recombination in three-point transformation test is never exactly additive, it is clear that the *a-d* distance is the longest and thus the conclusion that the gene order is *abd* appears to be reasonable. Recombination may affect the population structure and it permits evolutionary conclusion. ►physical mapping, ►crossing over, ►mapping genetic, ►conjugation, ►transduction, ►bacterial transformation, ►generalized transduction; Lederberg J 1987 Annu Rev Genet 21:23; Feil EJ, Spratt BG 2001 Annu Rev Microbiol 55:561.

Bacterial Transformation: Refers to genetic alteration brought about by the uptake and integration of exogenous DNA in the cell that is capable of expression. The exogenous DNA is generally supplied at a concentration of 5 to 10 µg/mL to transformation competent cells. Competence is a physiological state when the cells are ready to accept and integrate the

exogenous DNA. Competence is maximal in the middle of the logarithmic growth phase. The donor DNA may synapse with the recipient bacterial chromosome and naked DNA generally replaces a segment of the bacterial genetic material rather than adding to it. The entire length of the donor DNA may not be integrated into the host and the superfluous material is degraded. The integrated DNA may form a permanent part of the bacterium's chromosomal genetic material. During integration only one or both strands of the donor DNA may be integrated. Transformation may be regarded as one of the mechanisms of recombination and can be used for determining the gene order in the bacterial chromosome. The frequency of transformation in prokaryotes is generally less than 1% and it is usually within the range of 10^{-3} to 10^{-5} . Transformation of bacterial protoplasts (spheroplasts) may occur at a higher frequency. Transformation may also denote the transfer and expression of plasmid DNA in the cell. These plasmids may remain as autonomous elements within the bacteria. Transformation with the aid of plasmids is much more efficient. Moreover, competence can greatly be enhanced by some divalent cations and by other means. ►transformation genetic, ►competence of bacteria, ►bacterial recombination frequency; vectors, Hotchkiss RD, Gabor M 1970 Annu Rev Genet 4:193; Oishi M, Cosloy SD 1972 Biochem Biophys Res Commun 49:1568.

Bacteriocin: Denotes natural bacterial products that may kill sensitive bacteria. ►colicins, ►pyocin, ►pesticin; Riley MA 1998 Annu Rev Genet 32:255; bacteriocin identifying tool: http://bioinformatics.biol.rug.nl/web/software/bagel/bagel_start.php.

Bacteriocyte: Refers to special cells of eukaryotes harboring bacterial symbionts. (Spaulding AW, Dohle CD 1998 Mol Biol Evol 15:1506; Nakabachi A et al 2005 Proc Natl Acad Sci USA 102:5477).

Bacteriome: This is a cytoplasmic polyploid organ of insects harboring one or more species of bacteria. The exact function of the bacteriome is unknown; it probably synthesizes useful nutrients for the host. (Von Dohlen CD et al 2001 Nature [Lond] 412:433; Normark BB 2004 PloS Biol 2:0298).

Bacteriophages: These are viruses infecting bacteria (see Table B3). (►phage, ►phage life cycle, ►phage morphogenesis, ►filamentous phages, ►lambda phage, ►T4, ►T7, ►φX174, ►MS2, ►Mu bacteriophage, ►icosahedral, ►virulence, ►temperate phage, ►development, ►phage therapy; Knipe DM, Howley PM (eds) 2001 Fundamental Virology Lippincott Williams & Wilkins, Philadelphia, PA); Brüssow H, Hendrix RW 2002 Cell 108:13; Campbell A 2003 Nature Rev Genet 4:471, <http://www.phage.org>.

Table B3 Major types of bacteriophages

| Phage | Type | Host | Da × 10 ⁶ | Morphology |
|-----------------|--------------------|--------------------------|----------------------|------------------|
| MS2, f2, R17 | RNA, ss, virulent | <i>E. coli</i> | 1 | icosahedral |
| φ6 | RNA, ds, virulent | <i>Pseudomonas</i> | 3.3, 4.6, 7.5 | icosahedral |
| φX174, G4, St-1 | DNA, ss, virulent | <i>E. coli</i> | 1.8 | icosahedral-tail |
| M13, fd, f1 | DNA, ss, virulent | <i>E. coli</i> | 2.1 | filamentous |
| P22 | DNA, ds, temperate | <i>Salmonella</i> | 26 | icosahedral-tail |
| SPO1 | DNA, ds, virulent | <i>Bacillus subtilis</i> | 91 | icosahedral-tail |
| T7 | DNA, ds, virulent | <i>E. coli</i> | 26 | octahedral-tail |
| lambda | DNA, ds, temperate | <i>E. coli</i> | 31 | icosahedral-tail |
| P1, P7 | DNA, ds, temperate | <i>E. coli</i> | 59 | head-tail |
| T5 | DNA, ds, virulent | <i>E. coli</i> | 75 | octahedral-tail |
| T2, T4, T6 | DNA, ds, virulent | <i>E. coli</i> | 108 | oblong head-tail |

ss = single-stranded, ds = double-stranded

The major types and characteristics of bacteriophages are presented here:

Bacterioplankton: This includes prokaryotes and plays a major role in biogeochemical processes in seawater. *Silicibacter pomeroyi* represents 10–20% of bacterioplankton; it has a chromosome of 4109611 bp and a megaplasmid of 491611 bp in its sequenced genome (Moran MA et al 2004 Nature [Lond] 432:910).

Bacteriorhodopsin: This is a light receptor protein in the plasma membrane of some bacteria; it pumps protons upon illumination. ▶[rhodopsin](#)

Bacteriostasis: This prevents the reproduction of bacteria without destroying them. In the long run, however, this may lead to their destruction. Many antibiotics have such an effect. ▶[antibiotics](#)

Bacteroid: These are specialized, modified forms of bacteria such as the ones found in the root nodules where they act in the fashion of intracellular “organelles” in nitrogen fixation. ▶[nitrogen fixation](#); Li Y et al 2002 Microbiology 148:1959.

Bacteroides fragilis: This is an obligate anaerobic, opportunistic pathogen of the human colon. Its circular chromosome is 5,205,140 base pairs with an estimated 4,274 genes; it harbors a plasmid too. Its genome, like that of *B. thetaiotaomicron*, has many inversions and rearrangements, which affect gene expression. Several species of bacteroides are part of the indigenous intestinal flora and may be represented by 10¹¹ to 10¹² cells/g feces. They constitute 15–20% of gingival flora and 8–16% of dental plaques. It is somewhat of a paradox that the host does not marshal

the immune defense against them. These organisms apparently decorate their surface polysaccharides with L-fucose and mimicking host polysaccharides thus acquiring an evasive tool in their competitive environment (Coyne MJ et al 2005 Science 307:1778). The pathogenic bacteria apparently do not have this self-defense against the host. (▶[fucose](#); Cardeno-Tárraga AM et al 2005 Science 307:1463).

Bacteroides thetaiotaomicron: This is a gram-negative anaerobic bacterium with a 6.26 Mb sequenced genome. It is a predominant member of the human and mouse small intestinal and colon microbiome. It plays an important role in the metabolism of dietary polysaccharides, which are not digestible by human enzymes. (▶[microbiome](#); Kuwahara T et al 2004 Proc Natl Acad Sci USA 101:14919).

Bactigs: Contigs of BACs. (▶[contig](#), ▶[BAC](#))

Bacto Yeast Extract: This water-soluble fraction of autolyzed yeast contains vitamin B complex.

Bacto-Tryptone: A peptone, rich in indole (tryptophan), is used for bacterial cultures and the classification of bacteria on the basis of activity.

Baculoviruses: These are large (130 kbp) double-strand DNA viruses used for the construction of insect transformation vectors. Baculoviruses do not efficiently transform mammalian or plant cells. The baculovirus vectors accommodate large amounts of DNA and the foreign DNA replacing the polyhedrin gene is expressed under a powerful polyhedrin promoter. The majority of the proteins within the insect remain soluble. The extracellularly present virus particles appearing *late* in the infection are called

B

non-occluded virus. The occluded virus particles occur in the cell nuclei and appear *very late* in the infection phase. The polyhedra viral protein coating is responsible for the occlusion. (►polyhedrosis, ►AcNPV, ►transformation, ►viral vectors; insect viruses, Grabherr R et al 2001 Trends Biotechnol 19[6]:231; Herniou EA et al 2003 Annu Rev Entomol 48:211).

Baculum: This is a bony structural element above the urethra in the penis of many species (e.g., rodents, carnivores, primates) but not in humans.

Bad: Refers to an apoptosis-promoting protein when phosphorylated by MAPK/RSK or Akt or a c-AMP-dependent protein kinase. When it is dephosphorylated (by calcineurin) it may interfere with the apoptosis suppression of Bcl proteins and that may lead to carcinogenesis. Also, when RSK phosphorylates CREB, cell survival is facilitated. The combined inhibition of EGFR (epidermal growth factor receptor) and PI3K (phosphatidylinositol kinase)—regulated by BAD—synergistically favors apoptosis (She Q-B et al 2005 Cancer Cell 8:287). ►apoptosis, ►survivin, ►CaM-KK, ►Bcl, ►MAPK, ►RSK, ►CREB, ►Akt; Konishi Y et al 2002 Mol Cell 9:1005; Ranger AM et al 2003 Proc Natl Acad Sci USA 100:19324.

Badger (*Taxidea taxus*): $2n = 32$.

Badnaviruses: These are double-stranded DNA viruses of plants (►pararetrovirus).

Baf Complex: This is similar to SWI/SNF proteins and it regulates chromatin remodeling. The Baf60c subunit (60-kDa, encoded by mouse gene *Smardc3*) is essential specifically for the expression of the differentiation of the heart and somites of the early embryo (Lickert H et al 2004 Nature [Lond] 432:107). ►SWI/SNF; chromatin remodeling, Liu R et al 2001 Cell 106:309.

BAFF (B cell activating factor): TNF receptor ligand, which among other proteins regulates B cell proliferation and differentiation. Autoreactive B cell survival is regulated by BAFF-dependent protein kinase, PKC δ , which phosphorylates serine 14 in histone H2B (Mecklenbräuer I et al 2004 Nature [Lond] 431:456). ►Blys, ►TNFR, ►APRIL, ►NF- κ B, Thompson JS et al 2001 Science 293:2108; Schiemann B et al 2001 Science 293:2111.

BAG1: (Bcl2-associated athanogene, 9p12): This is part of an anti-apoptotic complex and affects cell division, cell migration and differentiation. The BAG family proteins recruit molecular chaperones and thus play a role in regulating protein conformation. ►BCL, ►athanogene; Takayama S, Reed JC 2001 Nature Cell Biol 3:E237.

BAIT: ►Two-hybrid system

BAK: A member of the Bcl protein family comprising BH1, BH2 and BH3 domains that after a conformational change induced by other members of the

Bcl family of proteins containing only BH3 domain, promotes apoptosis by opening the permeability transition pore complex channel in the mitochondrial membrane. The mitochondrial outer-membrane protein VDAC2 inhibits BAK and apoptosis. ►Bcl, ►BID, ►Bim, ►apoptosis, ►porin; Wei MC et al 2000 Genes Dev 14:2060; Korsmeyer SJ et al 2000 Cell Death Differ 7:1166; Cheng EH et al 2001 Mol Cell 8:705; Cheng E H-Y et al 2003 Science 301:513.

Bal 31: The exonuclease removes simultaneously nucleotides from the 3' as well the 5' ends and thus it can be used for mapping functional sites in a DNA (see Table B4): The fragments can then be separated by electrophoresis and assayed after transformation. ►deletions unidirectional, ►exonuclease electrophoresis; Wei C-F et al 1983 J Biol Chem 258:13506.

Table B4. Bal 31 exonuclease

| | | |
|--------------------|-----------|--------------|
| 0 Time | a b c d e | Original DNA |
| After 1 time unit | b c d | Digest |
| After 2 time units | c | Digest |

Balance of Alleles: This population model assumes that at the majority of loci several different alleles are present and these are maintained in a dynamic equilibrium by the continuous but variable selective forces. ►balanced polymorphism, ►Hardy-Weinberg theorem, ►fitness, ►selection

Balanced Lethals: These are genetic stocks heterozygous for two or more non-allelic linked recessive lethal genes. Since both homozygotes die, only heterozygotes survive that are phenotypically wild type or in some cases exhibit mutant phenotype and continue to produce both types of lethals. Such stocks can be maintained indefinitely as long as recombination between the linked loci can be prevented.

Figure B7. Beaded (From Bridges CB, Morgan TH 1923 Carnegie Inst Wash 327:152)

For balancing, generally spanning inversions are used that eliminate the cross-over gametes because of the duplications and deficiencies generated by recombination within the inverted region. The first balanced lethal of *Drosophila* contained the gene *Bd 1* (*Beaded*, incised wing in heterozygotes, lethal in

homozygotes, at map location 3–91.9 [slightly different in some other alleles]) and *l(3)a*, a spontaneous lethal mutation (map position 3–81.6) within the inversion *In(3R)C* (see Fig. B7). In the multiple translocations of plants of different *Oenothera* species, there are gametic and zygotic recessive lethal genes that are prevented from becoming homozygous and thus help to maintain these lethal genes by balanced heterozygosity. Besides the biological advantage of balanced lethals, they may be useful for various types of research. The *Bd* alleles have been extensively studied at the molecular level and the developmental functions may be revealed by the availability of heterozygotes for the mutations. ▶lethal factors, ▶lethal equivalent, ▶translocation ring; Muller HJ 1918 Genetics 3:422.

Balanced Polymorphism: When the fitness (reproductive success) of heterozygotes exceeds both homozygotes at a locus, a stable genetic equilibrium may be established and the heterozygotes may reproduce the homozygotes in equal frequencies. This type of heterozygote advantage may lead to balanced polymorphism, i.e., the population may maintain several genotypes in stable proportions even if some of the homozygotes have low adaptive value. ▶selection coefficient, ▶fitness, ▶balanced lethals, ▶autosomal recessive lethal assay, ▶balance of alleles, ▶Hardy-Weinberg theorem, ▶fitness, ▶selection, ▶Muller's ratchet; Rucknagel DL, Neel JV 1961 Progr Med Genet 1:158.

Balanced Translocation: Refers to a reciprocal translocation where each of the interchanged chromosomes has a centromere. Unbalanced translocations have an acentric piece due to the interchange. ▶translocation chromosomal

Balancer Chromosomes: These are structurally modified (by inversions, translocation) so the recombinants (because of duplications or deficiencies in the meiotic products) are not recovered in the progeny, and facilitate the maintenance of certain chromosomal constitutions without recombination. Balanced systems permit the maintenance of recessive lethal factors in a heterozygous condition. Balancer chromosomes have been developed in the past with the use of clastogenic agents. By inserting the *LoxP* gene in opposite orientations and bringing about recombination with the aid of the *Cre* recombinase, inversions can also be generated in e.g., mouse cells at particular intervals. ▶*CIB* method, ▶*Base*, ▶inversion, ▶translocation chromosomal, ▶Renner complex, ▶balanced lethals, ▶autosomal recessive lethal assay, ▶*Oenothera*, *Cre/Lox*, ▶targeting genes; Muller HJ 1918 Genetics 3:422; Yu Y, Bradley A 2001 Nature Rev Genet 2:780.

Balancing Selection: This includes heterozygote advantage (overdominance), or alleles differently selected by

sex, season and niche in the habitat or in a frequency-dependent manner. ▶selection, ▶sexual selection, ▶overdominance, frequency dependent selection; Verelli BC et al 2002 Am J Hum Genet 71:1112.

BALB/c Mice: An albino inbred laboratory strain used frequently in immunoglobulin (antibody) and cancer research (see Fig. B8). It is highly susceptible to *Salmonella*. ▶mouse

Figure B8. Albino Mouse (Courtesy of Dr. Paul Szauter, <http://www.informatics.jax.org/mgihome/other/citation.shtml>)

Balbiani Body: This is a large distinctive organelle aggregate found in developing oocytes of many species; it contains a mitochondrial “cloud” and Golgi bodies.

Balbiani Ring: Refers to a puff (bloated segment) of the polytenic chromosome indicating special activity (intense RNA transcription) at the site, it loosens up the multiple elements of the chromosome (see Fig. B9). ▶polytenic chromosomes, ▶puff, ▶BR RNP

Figure B9. Balbiani ring

Baldness: This sex-influenced trait in humans is more common among males than females (particularly with later onset) and it probably depends to some extent on the level of androgen receptor.

Apparently a polyglycine-encoding GGN repeat in exon 1 of the gene in X chromosome causes

B

baldness (see Fig. B10). This also explains the fact that inheritance is primarily through the maternal line (Hillmer AM et al 2005 Am J Hum Genet 77:140). In this condition a developmentally manifested pattern is seen starting from the front hairline toward the top of the head. It has a strong hereditary component but it may be caused by certain diseases (alopecia), exposure to higher doses of ionizing radiation and to certain carcinostatic drugs. Early baldness may be determined by an autosomal dominant gene (10q24) encoding steroid 17 α -hydroxylase with better penetrance in males than in females. Loss of hair on the human scalp may be controlled by a deletion in chromosome 3q27, the site of (LIPH) phospholipase (Kazantseva A et al 2006 Science 314:982). ▶alopecia, ▶hair, ▶androgen, ▶penetrance, ▶monilethrix

Figure B10. X-chromosomal baldness

Baldwin Effect: The physiological homeostasis permits the survival of a species until mutation may genetically fix the adaptive trait in an originally inhospitable environment. ▶homeostasis, ▶canalization, ▶genetic assimilation; West-Eberhard MJ 2003 Developmental Plasticity and Evolution, Oxford University Press, New York.

Ball-And-Stick Model (ball-and-spoke model): ▶stick-and-ball model

Ball-In-Urn: This is used to characterize the distribution of repeats in the genome; urns correspond to all DNA words of a given size and balls refer to the observed words in a given DNA sequence. Rare words may be the binding sites of transcription factors. Also, they may be discriminated against because of structural incompatibilities. Frequent words may be repetitive, structural and regulatory sequences as well as transposable elements. (Karlin S 2005 Proc Natl Acad Sci USA 102:13355).

BamH1: Refers to restriction enzyme with recognition sequence G↓GATCC.

BAMBE (Bayesian Analysis in Molecular Biology and Evolution): This is a free software for the analysis of phylogeny based on nucleotide sequences. ▶Bayes

theorem, ▶phylogeny; <http://www.mathcs.duq.edu/larget/bambe.html>.

β-Amyloid: This exists as extracellular deposits of the brain plaques in Alzheimer's disease (see Table B5). It is split off the amyloid precursor protein (APP) by secretase. In the neuronal tissue APP₆₉₅ is prevalent. If Ile, Phe or Gly replaces Val642, the substitutions lead to fragmentation of nucleosomal DNA in the neurons and presumably contribute to neurotoxicity. ▶Alzheimer's disease, ▶scrapie, ▶amyloidosis, ▶amino acid symbols in protein sequences, ▶secretase, ▶prion

Table B5. Amyloid fibers in Alzheimer disease

The major amyloid fibers (Aβ1-42) in Alzheimer disease are truncated at the C terminus:

Aβ1-40: DAEFRHDSGYEVHHQLVFFAEDVGSNK-GAIIGLMVGGVV

Aβ1-42: DAEFRHDSGYEVHHQLVFFAEDVGSNK-GAIIGLMVGGVVIV

Aggregation of the fibers may lead to plaque formation seen in amyloidosis. The aggregation may be initiated by "seeding" like a crystallization process.

Banana (*Musa acuminata*, x = 11): This is a fruit plant. The diploid fruits are full of seeds and have minimal edible pulp. The majority of the edible fruits are harvested from seedless triploid plants. When the triploids are crossed with diploids the progeny is partly tetraploid (2n = 44) and heptaploid (2n = 77) because of the high frequency of unreduced 3x and 6x gametes and their fruits are also seedless. Some of the related species have chromosome numbers 2n = 14, 18 and 20. ▶seedless fruits, ▶triploidy, ▶sugar beet; Simmonds NW 1966 Bananas, Longman, London.

Band: Refers to an element of the cross-striped chromosome. The banding (perpendicular to the length of the salivary gland chromosomes and continuous across the giant chromosome) may be due to condensation of the juxtapositioned chromomeres or to specific staining of the chromatin. ▶bands of polytenic chromosomes, ▶chromosome banding. The average DNA content in a single natural band of the *Drosophila melanogaster* salivary gland chromosome is 26.2 kb. The total number of salivary chromosome bands is 5,072. The number of distinguishable bands depends on the stage of condensation of the chromosome. The cytologically detectable chromomeres/bands are greater at pachytene than at the metaphase, and in the extended condition structural abnormalities are easier to identify microscopically.

Electrophoretic separation of restriction enzyme digested DNA, or pulsed field electrophoresis separated small chromosomes, as well as various proteins subjected to separation in the electric field, generate bands in the substrate (gel) when visualized either by staining or by special illumination. ▶ **chromosome banding**, ▶ **coefficient of crossing over**, ▶ **electrophoresis**, ▶ **pulsed field electrophoresis**, ▶ **FISH**

Band Cloning: Denotes amplifying DNA bands, extracted from electrophoretic gels, in genetic cloning vectors for molecular analyses. ▶ **cloning vectors**

Band-Morph Mutation: This is distinguished by electrophoretic analysis of the proteins. Mutations resulting in amino acid replacement of different charge appear as mobility difference in the electric field. Although studies of this type were very popular during the 1960s and 1970s, they have very poor resolution because they can detect only 1/4 or less of the mutations. The advantage of this type of research was that large populations could be screened for mutations that would not have necessarily other phenotypic effect. ▶ **electrophoresis**, ▶ **band**; Harada K et al 1993 Jpn J Genet 68:605.

Band III Protein: This is a transmembrane protein consisting of about 800 amino acids. ▶ **spectrin**; Low PS et al 2001 Blood Cells Mol Dis 27:81.

Band-Sharing Coefficient (S_{xy}): This denotes the proportion of shared DNA fragments separated by electrophoresis; $S_{xy} = (2n_{xy})/(n_x + n_y)$ where n_x and n_y are the number of bands in x and y samples and n_{xy} is the number of shared bands. This coefficient may be used to determine the genetic composition of populations on the basis of DNA. In multi-locus forensic tests the British legal system previously used the formula $(0.26)^k$ for calculating the match probabilities of alleles of at least 4 kb in length. 0.26 is an empirical constant and k is the average number of matching alleles. However, this latter formula lacks sufficient robustness. The single locus probes (SLP) based on the profiles of 6–8 short tandem repeat loci (STR) is more popular today. This procedure is useful with as low as 100 pg DNA samples when amplified by PCR. ▶ **DNA fingerprinting**; Zhu J et al 1996 Poultry Sci 75:25.

Band Shifting: ▶ **gel retardation assay**

Banding Pattern: Refers to the distribution of chromosome bands reflecting genetic differences or differences in the expression of genes displaying more or less loose puffs. ▶ **polytenic chromosomes**, ▶ **lampbrush chromosomes**, ▶ **chromosome banding**, ▶ **puff**

Bands of Polytenic Chromosomes: These are deeply stained prominent cross bands on the chromosomes where the chromomeres of the elementary strands are appositioned (see Fig. B11). The salivary chromosomes of *Drosophila* display about 5,000 bands and for a period of time it was assumed that each corresponds to a gene locus. It is now known that the number of genes is about 2.5 times the number of bands. In the region 2B of the X chromosome of *Drosophila* the bands may appear different and rather than being perpendicular to the axis, they may be roughly parallel to the axis. In situ hybridization with molecular probes suggests that this unusual structure is caused by inverted repeats in the DNA. ▶ **polyteny**, ▶ **band**, ▶ **salivary gland chromosomes**, ▶ **coefficient of crossing over for the tip of the X chromosome**

Figure B11. Bands, polytenic

BankIt: This is a GenBank submission form for protein coding sequences. It then generates a GenBank accession number. Its address is: <http://www.ncbi.nlm.nih.gov/BankIt/>. ▶ **GenBank**, ▶ **Sequin**

Bannayan-Riley-Ruvalcaba Syndrome: This is similar to Bannayan-Zonona Syndrome.

Bannayan-Zonona Syndrome: This condition is characterized by autosomal dominant macrocephaly with multiple lipomas and hemangiomas, as well as susceptibility to hamartomatous polyposis cancer. Haplo-insufficiency of PTEN may play a role in its manifestation. ▶ **PTEN**, ▶ **lipomatosis**, ▶ **hemangioma**, ▶ **multiple hamartomas**

BAP: Refers to 6-benzylaminopurine which is a plant hormone. ▶ **plant hormones**

BAP (B-cell receptor associated proteins): Denote three (32, 37, 41 kDa) proteins associated only with IgM membranes. The 32 and the similar 37-kDa molecules form heterodimers and seem to be inhibitors of cell division. BAP29 (240 amino acid) and BAP31 (245 amino acids) are 43% homologous and bind mainly to IgD and somewhat to IgM. ▶ **B lymphocyte receptor**

BAPG: ▶ **bullous pemphigoid autoimmune disease**

Bar: This is a regulator of the Fas- and Apaf-mediated pathways of apoptosis. ▶ **apoptosis**

B

Bar Mutation: The mutation of *Drosophila* (*B*, map position 1–57.0) reduces the eye to a vertical bar with about 90 facets in the male and around 70 in the female compared with 740 in normal males and 780 in normal females; heterozygous females have 360. The *B* mutation is actually a tandem duplication of salivary band 16A, which arises because of unequal (oblique) crossing over.

Thus, the “normal allele” has 16A, *Bar* 16A-16A, *Ultrabar* 16A-16A-16A constitution (see Fig. B12).

Figure B12. *Bar* mutation

The phenotype is actually a position effect and not the cause of a dosage effect as revealed by genetic analyses. The process of unequal crossing over may be repeated and as many as 9 copies of band 16A can accumulate in a single X chromosome. Also, the 16A band may be lost resulting in reversion by the loss of the *roo* transposable element. *B* mutations may also be induced by the P hybrid dysgenesis element whereas chemical mutagens have never produced this mutation. These facts indicate that the *breakage points in the duplications cause the Bar phenotype*. The *Bar* phenotype may be the result of a breakage in a regulatory element or within an intron and causes abnormal fusion of the exons. The *Bar* locus is very large, it spans at least 37 kb DNA. ▶[duplication](#), ▶[position effect](#), ▶[unequal crossing over](#), ▶[intron](#), ▶[exon](#), ▶[CIB](#); Bridges, Sturtevant AH 1925 *Genetics* 10:117; Bridges CB 1936 *Science* 83:210.

Bar-Code, Genetic (molecular): Bar-code generally represents vertical bars of varying widths (two or four) that correspond to digits 0 and 1, and which in turn specify numbers 0 to 9. An optical laser can read the bar-coded information and—through the computer—the scanner can identify various types of information, including properties of a gene, phenotypic expression, etc. Molecular bar-codes can be generated by two ~20-base (20-mer) oligonucleotides (UPTAG,

DOWNTAG) introduced by transformation into special (deletion) cells. These molecular bar-codes can be identified in the genome by microarray hybridization or by sequencing. Also, the growth rate of various deletion strains can be monitored. DNA bar-coding can be used for the identification of species. In animals, mitochondrial cytochrome oxidase I is useful for the identification of species (Hebert PD et al 2004 *PLoS Biol*, 2:e312; Hajibabaei M et al 2006 *Proc Natl Acad Sci USA* 103:968). In plants, an approximately 450-bp intergenic spacer in chloroplasts appeared to be discriminatory (Kress WJ et al 2005 *Proc Natl Acad Sci USA* 102:8369). ▶[DNA chips](#), ▶[targeting genes](#), ▶[signature-tagged mutagenesis](#); Gad S et al 2001 *Genes Chromosomes Cancer* 31:75; Eason RG et al 2004 *Proc Natl Acad Sci USA* 101:11046; identification of various organisms and for taxonomy: <http://www.barcodinglife.org>; <http://www.barcoding.si.edu>.

BARD1 (BRCA1-associated Ring domain protein): This inhibits polyadenylation of mRNA in cooperation with Cstf-50 (cleavage stimulation factor). BRCA1/BARD1 heterodimer modulates Ran-dependent assembly of the mitotic spindle (Joukov V et al 2006 *Cell* 127:539). ▶[cleavage stimulation factor](#), ▶[breast cancer](#), ▶[spindle](#), ▶[RAN](#); Joukov V et al 2001 *Proc Natl Acad Sci USA* 98:12078.

Bardet-Biedl Syndrome (BBS, MKKS): This heterogeneous recessive disease involves retinal dystrophy (retinitis pigmentosa), polydactyly, and other anomalies of the limbs, obesity, underdeveloped genitalia and kidney malfunction, diabetes. Mental retardation is also common. Six to seven chromosomal locations, including (BBS1) 11q13, (BBS5) 2q31, (BBS3) 3p12–p13, (BBS4) 15q23, (BBS2) 16q21, and (BBS6) 20p12 have been reported earlier. The BBS8 locus is at 14q32.11, the BBS10 locus is in chromosome 12. The latter involves a chaperonin (Stoetzel C et al 2006 *Nature Genet* 38:521). The BBS protein has been localized to ciliated structures and to the centrosome (see Fig. B13). The BBS11 locus was assigned to chromosome 9q33 by a high-density single nucleotide polymorphism marker and microarrays; it encodes an E3 ubiquitin ligase (Chiang A et al 2006 *Proc Natl Acad Sci USA* 103:6287). Actually, the other BBS genes seem to affect the same cellular structures (Ansley SJ et al 2003 *Nature [Lond]* 425:628). The major form of BBS shares a chromosomal position with McKusick-Kaufman (MKKS, 20p12) syndrome. One basic problem may

involve a chaperonin that folds improperly several proteins. The core complex of BBS in cooperation with the Rab8 GTPase promotes ciliary membrane biogenesis (Nachury MV et al 2007 Cell 129:1201). ▶kidney diseases, ▶eye diseases, ▶triallelic inheritance, ▶cilia, ▶RAB, ▶McKusick-Kaufman syndrome, ▶chaperonin, ▶Prader-Willi syndrome; Beales PL et al 2001 Amer J Hum Genet 68:606; Myktyyn K et al 2001 Nature Genet 28:188; Katsanis N et al 2001 Hum Mol Genet 10:2293; Badano JL et al 2003 Am J Hum Genet 72:650.

Bare Lymphocyte Syndrome (BLS, 19p12 [RFXANK], 16p13 [MHC2TA], 1q21.1-q21.3 [RFX5], 13q14 [RFXAP]): This is a group of recessive severe immunodeficiency diseases caused by defects in the regulation of the major histocompatibility system by any of the four loci identified earlier. Some forms are due to defect(s) either in the HLA class I or class II genes involving lymphocyte differentiation. Some of the defects involve RFX proteins, which bind to the X box of the MHC2TA promoter. MHC II deficiency may also be due to mutation in MCC2TA transactivator. The MHCII molecules are heterodimeric transmembrane proteins. The current therapy is bone marrow transplantation. In future, gene therapy may be feasible. ▶immunodeficiency, ▶HLA,

▶lymphocyte, ▶MHC, ▶gene therapy, ▶RFX; Reith W, Mach B 2001 Annu Rev Immunol 19:331.

B

Barley (*Hordeum*): This cereal crop is used for feed, food and the brewery industry. The cultivated *H. sativum* is diploid $2n = 14$. Some of the varieties of wild barley are polyploids. The cultivated varieties have either two-row (see diagram; right) or four-row spike (see Fig. B14) or six-row depending on the number of florets fertilized per spikelets and bearing seeds. The diagram of the kernel arrangement (two-row and six-row) on the rachis (the axis of the spike) is presented here. The *vrs1* (*six-rowed spike 1*) gene, responsible for the six-rowed spike in barley, has been isolated by means of positional cloning. The wild type *Vrs1* allele (for two-rowed barley) encodes a transcription factor that includes a homeodomain with a closely linked leucine zipper motif. The expression of *Vrs1* was strictly localized in the lateral-spikelet primordia of immature spikes, suggesting that the VRS1 protein suppresses the development of the lateral rows. The loss of function of *Vrs1* resulted in complete conversion of the rudimentary lateral spikelets in two-rowed barley into fully developed fertile spikelets in the six-rowed phenotype (Komatsuda T et al 2007 Proc Natl Acad Sci USA 104:1424). ▶haploid [*H. bulbosum*], ▶*Hordeum*, ▶homeodomain, ▶leucine zipper, ▶positional cloning; <http://www.barleycap.org/>; <http://www.shigen.nig.ac.jp/barley/Barley.html>; <http://barleygenomics.wsu.edu/>; <http://www.barleybase.org/>.

Barr Body: This dark-stained (heteropyknotic) structure is visible at the periphery of the interphase nuclei of cells that have more than one X chromosome. XY cells do not have a Barr body whereas normal XX female cells have one (see Fig. B16). The number of Barr bodies (named after M.L. Barr) is always one less than the number of X chromosomes, indicating that the non-active X chromosomes remain condensed (dosage compensation). Barr bodies are also present in XXY males. The Barr body is sometimes called sex chromatin. In the leukocytes the Barr body is enclosed in a special nuclear appendage called the “drum-stick” because of its shape. Methylation of CpG dinucleotides is the mechanism of inactivation. ▶[lyonization](#), ▶[methylation of DNA](#), ▶[dosage compensation](#); Heard E et al 1997 Annu Rev Genet 31:571; Hong B et al 2001 Proc Natl Acad Sci USA 98:8703.

Figure B16. Barr body

Barrage: This is the sign of vegetative incompatibility in fungi. At the zone of contact between the two types of mycelia a distinguishable zone is formed as the result of antagonism between the two strains. (Rizet G 1952 Rev Cytol Biol Végét 13:51).

Barrel: Refers to protein β -sheets closing the interior and α chains on the exterior (see Fig. B17). ▶[protein structure](#)

Basal Promoter: This is normally situated in the region –100 bp upstream of the transcription initiation site and contains various regulatory elements of transcription. ►promoter, ►transcription factors, ►core promoter

Basal Transcription Factors: ►transcription factors

BASC: This is one of several similar *Drosophila* genetic stocks, containing the dominant *Bar* (*B*), the recessive eye color allele, *apricot* (*w^a*), and several *scute* inversions. The B and w markers identify

the untreated chromosomes of untreated females and eliminate the cross overs with the treated X chromosomes of males. The mutagenic effectiveness is determined on the basis of the reduced proportion of males in F₂ if a lethal or sublethal mutation was induced in the X chromosome by the treatment. This type of analysis is called Muller-5 technique after H.J. Muller who designed the first stocks. The advantage of these stocks is that both males and homozygous females are completely fertile whereas the XO males are poorly viable and no cross overs appear along the X chromosome. Variegation may occur in some unlinked genes.

Rarely some exceptional females are also detected due to an unequal sister chromatid exchange in the inversion heterozygote females. ►CIB, ►autosomal dominant mutation, ►autosomal recessive mutation; Inoue Y 1992 *Genetica* 87:169; Forbes C 1981 *Mutation Res* 90:255, see Fig. B19.

BASC (BRCA1-associated genome surveillance complex): This includes tumor suppressors, DNA repair proteins, DNA replication factor C, etc. ►breast cancer; Wang Y et al 2000 *Genes Dev* 14:927.

Base: Refers to the lowest part of a structure or a compound or an ion which can combine with protons to yield salt. *Nitrogenous bases* such as the

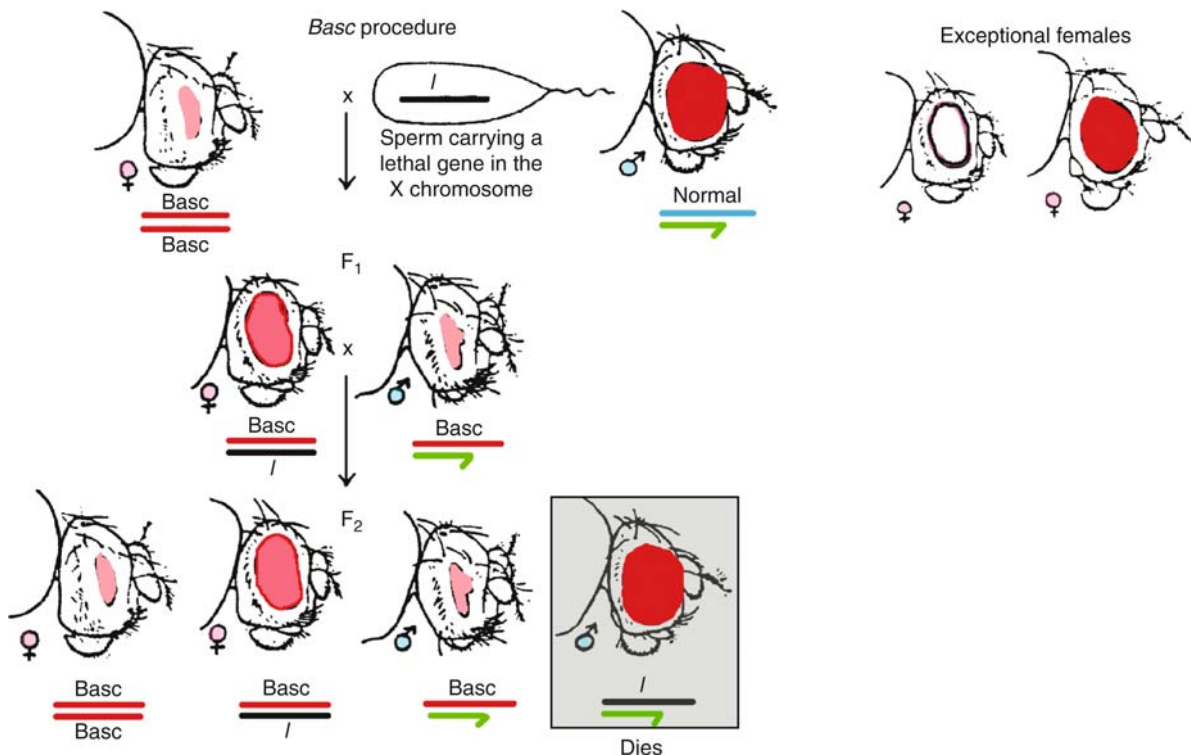

Figure B19. Basc

pyrimidines and purines of nucleic acids. ►[nucleic acid bases](#)

B

Base Analogs: These are nucleic acid bases or nucleosides similar to the normal compounds but cause mutation when incorporated into the DNA either by incorporating in the wrong place or by mispairing with the incorrect base. The most commonly used mutagenic base analogs are 5-bromouracil (thymine analog) and 2-aminopurine (adenine analog). Base analogs expanded by an intercalated benzene ring have been synthesized and the expanded xA and xT analogs form Watson–Crick pairs with the natural complementary base when incorporated into the DNA (see diagram). A single such pair decreases the stability of the double helix but longer tracts are stable. The dxA is a violet-blue fluorochrome (max. emission 389 nm). The dXT appears violet (max. emission 375 nm). When all expanded base analogs are in one strand the binding ability of the natural strand is enhanced making it potentially useful for microarrays, antisense and DNA–RNA analyses (Liu H et al 2003 *Science* 302:868). ►[hydrogen pairing](#), ►[base substitution](#), ►[point mutation](#), ►[universal base](#), ►[microarray hybridization](#), ►[antisense technologies](#), ►[isoguanine](#), ►[modified bases](#), Freeze E 1959 *J Mol Biol* 1:87.

Base Composition: Refers to the percentage of nucleotides in DNA or RNA.

Base Excision Repair (BER): ►[DNA repair](#)

Base Flipping: Some enzymes such as methyltransferases, glycosylases, T4 endonuclease V, *E. coli* phospholyase and endonuclease III must access the bases, which are inside the sugar-phosphate backbone of the B DNA double helix in order to be recognized by the active site of the protein. Some bases are swung out of the helix into an extra-helical position to meet the requirement. Base flipping is important for the hairpin processing reaction in transposition because it performs two opposite but closely related functions. It disrupts the double helix, providing the necessary strand separation and steric freedom, also the transposase appears to position the second DNA strand in the active site for cleavage using the flipped base as a handle (Bischerour J, Chalmers J 2007 *Nucleic Acids Res* 35:2584). ►[methylation of DNA](#), ►[glycosylases](#), ►[endonuclease](#), ►[DNA repair](#), ►[ABC excinucleases](#), ►[photolyase](#), ►[cyclobutane ring](#); Cheng X, Roberts RJ 2001 *Nucleic Acids Res* 29:3784; Patel PH et al 2001 *J Mol Biol* 308:823; Huang N et al 2003 *Proc Natl Acad Sci USA* 100:68; Luo J, Bruce TC 2005 *Proc Natl Acad Sci USA* 102:194.

Base Modifying Agents: Nitrous acid causes oxidative deamination, hydroxylamine converts cytosine into

hydroxylamino-cytosine (a thymine analog), and alkylating agents place alkyl groups at several possible positions to purines and pyrimidines. ►[chemical mutagens](#), ►[base substitution](#), ►[point mutation](#), ►[hydrogen bonding](#)

Base Pair (bp): Refers to hydrogen bonded A = T and G=C in DNA or A = U in double-stranded RNA. (►[mismatch](#), ►[mispairing](#), ►[hydrogen pairing](#), ►[universal bases](#), ►[Watson-Crick model](#))

Base Pair Opening (base flipping): A nucleoside unit swivels out of the DNA helix and inserts into the recognition pocket of a protein. Such nucleoside extrusion and extra-helical recognition may take place by processing the DNA by various glycosylases and endonuclease action. ►[base flipping](#)

Base-Pair Stepping: ►[nucleic acid chain growth](#)

Base Promoter: ►[core promoter](#)

Base Sequencing: ►[DNA sequencing](#)

Base Stacking: The nucleotides in parts of a polynucleotide chain may lie in such a way that the faces of the rings are appositioned (see Fig. B20). The stacking is most likely to occur by non-covalent forces near the chain termini where the bases move somewhat. It imparts some rigidity to the strand(s). The stacking is detectable by physical methods such as circular dichroism and optical rotatory dispersion. Reagents, which weaken hydrophobic reactions, eliminate the stacking, and heating reduces the stacking resulting in hyperchromicity. Destruction of hydrogen bonding also reduces the stacking in double-stranded DNA. Base stacking may occur in double-stranded molecules where the pairing is weakened by deletions or mismatches. ►[circular dichroism](#), ►[optical rotatory dispersion](#), ►[hyperchromicity](#), ►[excimer](#); Kool ET 2001 *Annu Rev Biophys Biomol Struct* 30:1.

Figure B20. Base stacking

Base Substitutions: When a pyrimidine in the DNA is replaced by another pyrimidine or a purine is replaced by another purine the change is a *transition*. When a purine is replaced by a pyrimidine, or vice versa, a *transversion* takes place. These changes cause mutation in the DNA and they may also lead to amino

acid replacement in the protein if the base substitution involves a non-synonymous codon. Many mutagens cause base substitutions, e.g., hydroxylamine (NH₂OH) targets cytosine (C) and hydroxyaminocytosine is formed which is a thymine analog. As a result a C≡G base pair is replaced by a T = A bp. Similarly, 5-bromouracil may cause, through a tautomeric shift, T = A to be replaced by C≡G; and 2-aminopurine, an adenine analog, causes a tautomeric shift that may lead to the replacement of an A = T pair by a G≡C pair. Some other chemicals, e.g., nitrous acid, by deamination, changes cytosine to uracil and converts adenine into guanine. These base substitutions may also cause reversions. A hydroxylamine-induced mutation may be reverted by bromouracil, etc. It is generally assumed that base substitutions occur independently and coincidental double substitutions should be rare. Some genetic repair mechanisms may, however, bring about more than single replacements. A large-scale evolutionary study revealed that double substitutions may occur in the serine codons of primates at the high frequency of 0.1/site/billion years. (►DNA, ►hydrogen bonding, ►point mutation, ►base analogs, ►evolution and base substitutions, ►incorporation error, ►replication error, ►chemical mutagens, ►substitution mutations, ►mutation and DNA replication, ►mutation bias, Freese E 1959 Brookhaven Symp Biol 12:63, base substitution model selection tool: http://darwin.uvigo.es/software/modeltest_server.html).

Base-Call: This process evaluates the nucleotide sequence information using the PHRED program. ►base-calling, ►PHRED, ►PHRAP

Base-Calling: This means identifying the correct nucleotide in a sequence in the DNA. Also, identifying the correct base sequence on the basis of hybridization in microarrays compared to the actual direct sequencing information. Miscalls are false identifications. The multifluorescence discrimination (pulsed multiline excitation, PME) correlates a sequence of excitation pulses from four monochromatic wavelength laser sources with detector response from emission intensities of fluorescently labeled DNA fragments. For this purpose, a new set of dyes has been developed that spans with absorption maxima the entire visible spectrum. This procedure appears superior to the ones previously used (Lewis EK et al 2005 Proc Natl Acad Sci USA 102:5346). ►microarray hybridization, ►PHRAP, ►PHRED; Walther D et al 2001 Genome Res 11:875.

Basedow Disease: ►goiter

Basement Membrane (basal lamina): This is less than 500-nanometer thick laminated condensation of the extracellular matrix (including laminin, collagen IV

and other proteins) on the basal surfaces of epithelia and condensed mesenchyma. The basement membrane is an attachment platform and a barrier to cell mixing. Several human diseases involve anomalies of basement membranes and/or associated proteins. ►extracellular matrix, ►proteoglycan, ►laminin, ►collagen, ►Alport's disease, ►Goodpasture syndrome, ►fibromatosis; Quondamatteo F 2002 Histochem J 34:369; Masunaga T 2006 Connect Tissue Res 47:55.

Base-Pairing: ►hydrogen pairing

Base-Specific Reagents for DNA Single Strands:

1. Dimethylsulfate (DMS) + hydrazine the methylated cytosine is cleaved at the 3' position. 2. DMS alone methylates guanine. 3. Osmiumtetroxide or potassium permanganate oxidizes the C5-C6 double bonds in thymidine. 4. Diethylpyrocarbonate (O[CO₂C₂O₅]₂) preferentially modifies adenine at N-7 although it affects other purines as well. (►DNA sequencing [Maxam & Gilbert method])

Base-Stacking: ►base stacking

Bash (B cell-restricted adaptor protein, BLNK/SLP-64): After ligation Sly tyrosine kinase phosphorylates it and it binds various B cell signaling proteins that control B cell development. Its role is similar to that of SLP-76 for T cells. ►SLP-76, ►B lymphocyte, ►ITIM; Tsuji S et al 2001 J Exp Med 194:529.

Basic Chromosome Number: This is found in the gametes of diploid organisms and it is represented by x; in polyploids the haploid (n) number may be 2x, 3x and so on, depending on the number of genomes contained. The basic number is frequently called a genome. ►chromosome numbers, ►genome, ►polyploid

Basic Copy Gene: It is the silent copy of a *Trypanosoma* gene that is activated by transposition to an activation site in the telomeric region of the chromosome. ►Trypanosomas, ►telomere

Basic Dye: The dye stains negatively charged molecules. ►stains

Basidiomycetes: A taxonomic group of fungi bearing the meiotic products in basidia. ►basidium, ►mushroom

Basidium: This is a fungal reproductive structure generally in the shape of a club where meiosis takes place and then the haploid basidiospores are released infecting the host plants (see Fig. B21). ►stem rust

Figure B21. Basidium with four meiotic spores

B

Basonuclin: This is a cell type-specific Zinc finger protein with a nuclear localization sequence and a serine stripe (serine-rich region). It is in abundance in the human keratinocyte nuclei but in the absence of phosphorylation it is in the cytosol. Basonuclin is also found in the epidermal cells and the germ cells of the testis and the ovary. It binds to the rRNA promoter and apparently regulates rRNA transcription. ▶ [Zinc finger](#), ▶ [nuclear localization signal](#); Tian Q et al 2001 Development 128:407.

Basophil: Refers to a type of white blood cell which is well stainable with basic cytological dyes. These cells contain conspicuous secretory granules and release histamine and serotonin in some immune reactions. Any other (acidic) structure or molecule with an affinity for positive charges. ▶ [granulocytes](#), ▶ [blood](#), ▶ [immune system](#)

Basta: This is a glufosinate ammonium herbicide, pesticide and a selective agent in plant transformation. ▶ [herbicides](#), ▶ [transformation genetic \[plants\]](#); Rathore KS et al 1993 Plant Mol Biol 21:871.

Bastard: This means a hybrid [in German]; and an illegitimate or undesirable offspring [in English].

Bat: *Carollia perpicillata* 2n = 21 in males, 20 in females; *Glossophaga soricina* 2n = 32; *Desmodus rotundus murinus* 2n = 28; *Atropzous pallidus* 2n = 46; *Eptesicus fuscus* 2n = 50; *Myotis velifer incautus* 2n = 44; *Nysticeius humeralis* 2n = 46. They are useful predators of insects but constitute a reservoir of different pathogenic viruses such as SARS, Ebola, Marburg and other strains. (Dobson AP 2005 Science 310:628).

Bateman's Principle: It states that the reproductive success of males shows greater variation than that of females because of greater competition among males and larger number of male gametes.

Batesian Mimicry: This is an adaptive evolutionary device. Certain species develop phenotypic characteristics of sympatric species (models) in order to increase their chances of survival. The models are repugnant (distasteful) to certain ▶ [predators](#), which avoid them, and so the mimickers when mistaken for the models also escape destruction. Batesian mimicry is more common among females than males (butterflies) because females are more often subject to predation than males. (▶ [adaptation](#), ▶ [natural selection](#), ▶ [Müllerian mimicry](#), see Fig. B22).

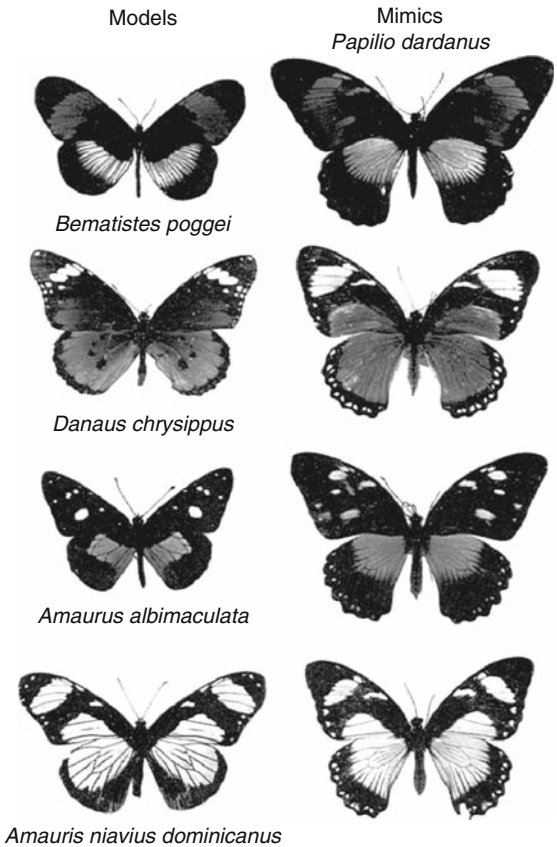

Figure B22. Batesian mimicry. Batesian mimicry in butterflies. (From Sheppard, P.M. 1959 Cold Spring Harbor Symp. Quant. Biol. 24:131)

Batten Disease: This is a recessive (human chromosome 16p12.1–p11.2) juvenile-onset familial amaurotic idiocy caused by lipid accumulation in the nerve tissues and vacuolization of the lymphocytes. Its incidence is $\sim 5 \times 10^{-5}$. The disease seems to be associated with low vacuolar pH. In the yeast *bml* defects chloroquine reverses the phenotype. ▶ [amaurotic familial idiocy](#), ▶ [ceroid lipofuscinosis](#), ▶ [chloroquine](#), ▶ [Vogt-Spielmeyer disease](#), ▶ [PPT](#); Luiro K et al 2001 Hum Mol Genet 10:2123, <http://www.ucl.ac.uk/ncl/>.

Batten-Turner Syndrome: ▶ [myopathy congenital](#), ▶ [human chromosome 16](#)

Bayes' Theorem: The theorem permits the estimation of various conditional probabilities and is used for

decision-making processes. In the simplest general form:

$$P(A|B) = \frac{P[B|A]P[A]}{P[B|A]P[A] + P[B|A']P[A']}$$

Its application in genetics can be illustrated by assuming that there are three individuals, two homozygotes for a semi-lethal dominant factor and one heterozygote for the same semi-lethal and incompletely dominant gene. There are problems with visual classification at an early stage of the development. Assuming that the two homozygotes [A] have 60%, and the heterozygote [A'] is expected to have 80% viability. Thus $P[B|A] = 0.6$, and $P[B|A'] = 0.8$.

The chance of selecting an individual of either genotype is $P[A] = 2/3$ and $P[A'] = 1/3$. If the selected individual turns out to be very weak, and if one is uncertain about the choice, one may want to determine—in view of the information available—the probability of having selected the heterozygote:

$$P(A|B) = \frac{[0.8][0.33]}{[0.8][0.33] + [0.6][0.67]} \cong 0.4$$

Basically, the Bayesian method considers the classical population parameters as random variables with a specific *a priori* probability of distribution. Then the *conditional probability* is estimated on the basis of the *a priori* distribution. The conditional probability is thus a property of a *posteriori* distribution because the accepted or supposed *a priori* distribution is used for the estimation of an existing situation in a population. ▶probability, ▶a priori, ▶prior distribution, ▶conditional probability, ▶risk, ▶inference, ▶Bernoulli process; Shoemaker JS et al 1999 Trends Genet 15:354; Bernardo JM, Smith AFM 1994 Bayesian theory, Oxford University Press, Oxford, UK; Beaumont MA, Rannala B 2004 Nature Rev Genet 5:251.

Bayesian Mapping: This can be applied to QTL. Inferences are made on the basis of the joint posterior distribution of all unknown variables given the prior distribution of all unknowns of the observations. It uses Monte Carlo approximation to the multiple integration required. It may be useful for analyzing complex animal pedigrees. ▶QTL, ▶genetic networks, ▶BAMBE, ▶Monte Carlo method, ▶Bayes' theorem; Yi N, Xu S 2000 Genetics 155:1391.

Bayesian Network: This can represent systems with multiple interactions. It can detect direct molecular interactions and also indirect effects that have not been directly observed. ▶networks, ▶signal transduction, ▶genetic networks; Sachs K et al 2005 Science 308:523.

BB-1: This is the same as B7 or CD80.

BBB (blood-brain barrier): The mechanism seriously limits transport to the central nervous system (CNS) because of the tight junction of the endothelial cells of the brain capillaries. Molecules larger than 180 MW and viruses may be excluded. Lymphocytes may enter the central nervous system but are not retained unless foreign antigens are present. Neurons and some other cells may poorly express MHC proteins and escape the effects of cytotoxic T cells. In such a situation different viruses (rubella, measles, polyoma JC, herpes simplex, rabies, mumps) may infect the brain. In the absence of such a barrier serum may leak into the brain causing edema. Angiotensin may be required to maintain BBB. Antagonists of the hypothalamic growth hormone-releasing hormone such as JV-1-42 (a peptide analog) enter the brain and can accumulate there. Since this hormone is present in several types of cancers there may be an opportunity for the treatment of glioblastomas (Jaeger LB et al 2005 Proc Natl Acad Sci USA 102:12495). Some lipids (but not by water-soluble or protein) molecules may however overcome the barrier if the cargo protein is associated with a carrier such as transferrin (Demeule M et al 2002 J Neurochem 83:924). High doses of the enzyme β -D-glucuronidase injected into the bloodstream of mice, mutant in mucopolysaccharidosis VII, passed through the blood-brain barrier (Vogler C et al 2005 Proc Natl Acad Sci USA 102:14777). Receptors on the blood-brain barrier bind ligands to facilitate their transport to the central nervous system. The use of the lentivirus vector system can deliver the lysosomal enzyme glucocerebrosidase and a secreted form of GFP (green fluorescent protein) to the neurons and astrocytes in the CNS. Fusing the low-density lipoprotein receptor-binding domain of the apolipoprotein B to the targeted protein is useful in delivering to the CNS (Spencer BJ, Verma IM 2007 Proc Natl Acad Sci USA 104:7594). ▶angiotensin, ▶protein transduction, ▶multiple sclerosis, ▶MHC, ▶glucose transporters, ▶GH, ▶gliomas, ▶transferin, ▶enzyme replacement therapy, ▶siRNA; Asahi M et al 2001 J Neurosci 21:7724.

BCL1, BCL2, BCL3, BCL5, BCL6 (B cell lymphoma):

These are leukemia oncogenes but they are also upregulated in various other types of cancers. *Bcl-1* is cyclin D1 (see Fig. B23). *Bcl-2* (18q21.3) suppresses apoptosis (by phosphatase action when bound to calcineurin) as a defense against malignant tumorigenesis and suppresses signaling by NF-AT. BCL2 apparently shuts off the voltage-dependent anion channel on the mitochondrial membrane and prevents the leakage of apoptotic cytochrome c into the cytosol to guard against apoptosis. It also promotes regeneration of severed cells in the central nervous system. The *Bcl-2* protein functions as an ion channel and a docking protein. BCL-2 is located in the outer membrane of the mitochondria, nuclei and the endoplasmic reticulum. *Bcl-6* regulates STAT and cytokine signaling. *Bcl-6* suppresses p53, a pro-apoptotic and cancer suppressor protein in the germinal center B cells (Phanm RT, Dalla-Favera R 2004 Nature [Lond] 432:635). The *Bcl* protein is usually up-regulated in lymphomas, and gene therapy involving deoxyoligonucleotides (such as 5'-TCTCCCAGCGTGCGC-CAT-3') targeted to the *AUG* initiator codon has been used. There are over a dozen members of the *Bcl* family. *Bcl-2* is homologous to *Ced-9* of *Caenorhabditis*. Antimycin A, a complex of highly toxic antifungal substances, inhibitors of electron transport, bind *Bcl* and *Bcl-X* and favor apoptosis and may thus protect against cancerous growth. The *Bcl* proteins can be effectively modulated by engineered BH3 fragments and the so-activated BID protein promotes apoptosis and destroys leukemia cells (Walensky LD et al 2004 Science 305:1466). The anti-apoptotic BCL-2 favors the maintenance of blood cancer, leukemia (Letai A et al 2004 Cancer Cell 6:241). *Bcl-2* interferes with RAD51 controlled recombination that may mediate error-free repair and may thus promote cancer-prone conditions independently from its anti-apoptosis effect. The normally anti-apoptotic *Bcl-2* may interact with Nur77 orphan nuclear receptor and may promote apoptosis. The pro-apoptotic members of the BCL family, BAX and BAK, regulate the inositol triphosphate receptor (IP3R-1) and normally maintain a high calcium level in the endoplasmic reticulum (ER). Mutant BAX and BAK decrease the ER calcium level and the released Ca^{2+} increases mitochondrial permeability leading to apoptosis. BCL2 has the opposite effects (Oakes SA et al 2005 Proc Natl Acad Sci USA 102:105). ►leukemia, ►apoptosis, ►BAX, ►BAD, ►BAK, ►BID,

BCR: Refers to B-cell antigen receptor. ►B lymphocyte

BCR (bcr): The break point cluster region in the Philadelphia chromosome is an area where multiple chromosomal breakages have been observed leading to cancerous transformation (leukemia, ABL). The BCR polypeptide contains 1,271 amino acids and its normal function is a protein serine/threonine kinase.

►Philadelphia chromosome, ►leukemia, ►ABL

B-DNA: This denotes a conformation of the DNA most common in hydrated living cells. ►DNA types

BDNF (brain-derived neurotrophic factor): This is an autocrine growth substance of neurons but it is found in other organs as well. Genetic variant (Val codon 66→Met) predisposes to anxiety and depressive disorders (Chen ZY et al 2006 Science 314:140). ►autocrine, ►neuron, ►TRK, ►ovary, ►Parkinson's disease, ►Rett syndrome, ►anxiety, ►depression; Li Y et al 2005 Nature [Lond] 434:894.

Beacon, Molecular: These are hairpin-shaped single-stranded oligonucleotide genetic probes that become fluorescent after hybridization to the homologous target. One end is covalently bound to a fluorophore and the other end is attached to a non-fluorescent quencher. If the probe does not find homology there is no fluorescence because the quencher prevents it in the hairpin (see Fig. B24). If the probe locates a homologous sequence, unwinding removes the quencher from the vicinity of the fluorophore and the site lights up ✱. ▶[spectral genotyping](#), ▶[molecular beacon](#); Tyagi S, Kramer FR 1996 *Nature Biotechnol* 14:303; Heyduk T, Heyduk E 2002 *Nature Biotechnol* 20:171; Hopkins JF, Woodson SA 2005 *Nucleic Acids Res* 33:5763.

Figure B24. Molecular beacon

Beads-On-A-String: Originally this referred to the (light-microscopically visible) chromosome structure at the pachytene where the chromomeres could be seen as beads-on-a-string. In the 1920s chromomeres were equated with genes, units of function, mutation and recombination. Today, this is also used to describe the DNA strands wrapped around the eight histones (nucleosomes) as seen through an electron microscope. ▶[nucleosome](#), ▶[pachynema](#), ▶[chromomeres](#), ▶[complex locus](#)

Beagle: ▶[copia](#)

BEAMing (beads, emulsion, amplification and magnetics): This is a procedure for the quantification of variation in single DNA molecules among a large number of molecules. The purpose is the detection of SNIPS, rare mutations in genes and transcript of importance for function and disease or state of disease progression in specific tissues. Small numbers of DNA molecules that display variations are amplified by polo. Counting the attached beads on the basis of fluorescent labels using flow cytometry leads to the numbers of variants. ▶[flow cytometry](#), ▶[polo](#), ▶[SNIPS](#); Dressman D et al 2003 *Proc Natl Acad Sci USA* 100:8817.

Bean-Bag Genetics: This phrase was used for characterizing the work of Mendelian geneticists, studying/counting individual genes as they controlled the phenotypes and inheritance. It expressed the contempt of some evolutionists whose interest was in entire

organisms rather than in dissecting the mechanisms of the Mendelian factors by statistical means. With advances in physiological, biochemical and molecular genetics new terms such as “factorial genetics/formal genetic” were proposed for the classical approaches. Today, genetics research relies on the wide-reaching methods and principles based on simple and macromolecules and single molecules, networks of molecules as well as biophysics and cybernetic tools and principles of bioinformatics. The boundaries of modern genetics are unrestricted and genetics has permeated the whole field of basic and applied biology. (Haldane JBS 1964 *Persp Biol Med* 7:343).

Beans (*Phaseolus* spp): These are pulse crops, all with $2n = 2x = 22$ chromosomes, including the most common *P. vulgaris* (French or navy beans) and the *P. lunatus* ▶[Lima bean](#)

Bear: Refers to *Ursus americanus* (black bear) $2n = 74$; *Tremarctos ornatus* (spectacled bear) $2n = 52$.

Beare-Stevenson Syndrome: An autosomal dominant disorder which is characterized by furrowed, corrugated skin (cutis gyrata), head bone fusions, facial anomalies, abnormal digits, umbilical, genital malformations and early death. The basic defect lies in the fibroblast growth factor receptor 2, encoded at 10q26. Some heterogeneity exists. ▶[FGF](#)

Beaver: *Castor canadensis*, $2n = 40$. A large (>80 cm long) brown rodent.

Becker Disease: ▶[myotonia](#)

Becker Muscular Dystrophy (BMD): ▶[muscular dystrophy](#)

Beckwith-Wiedemann Syndrome (EMG syndrome): This disorder is caused by a dominant gene in human chromosome 11p15.5. The symptoms include enlarged tongue (detectable at birth), umbilical anomalies (omphalocele = herniated intestines at the belly button area), hypoglycemia, enlargement of the internal organs (visceromegaly), frequent concomitant kidney and liver anomalies, tumorous striated muscles (rhabdomyosarcoma), etc. It may be associated with trisomy for chromosome 11 and it has been suggested that it is caused by paternal or maternal disomy when the normal (most commonly paternal) chromosome is lost from the trisomic cell lineage, or imprinting. A gene encoding a cyclin-dependent kinase inhibitor ($p57^{KIP2}$) is imprinted and preferentially expressed by the maternal allele may be

B

responsible for some of the cases. Insulin-like growth factor (IGF2) also has a regulatory effect. Deletion, duplication and balanced translocation have been suggested for some cases. It has been shown recently that KVLQT1 gene, encoding a putative potassium channel, and mapped to the 11p15.5 region controls imprinting not only the Beckwith-Wiedemann gene but also the Jervell and Lange-Nielsen syndrome and the LQT heart arrhythmia. ▶disomic, ▶disomic uniparental, ▶Wilms tumor, ▶cancer, ▶Jervell and Lange-Nielsen syndrome, ▶rhabdomyosarcoma, ▶Simpson-Golabi-Behmel syndrome, ▶imprinting, ▶insulin-like growth factors, ▶ion channels, ▶cyclin, p57; LQT; epigenesis; Alders M et al 2000 Am J Hum Genet 66:1473; Blik J et al 2001 Hum Mol Genet 10:467; DeBaun MR et al 2003 Am J Hum Genet 72:156.

Beethoven, Ludwig van (1770–1827): Beethoven was one of the greatest musical geniuses of the eighteenth-nineteenth century. Both his grandfather Louis and his father Johann were outstanding singers in Louvain and Liège. Later his father worked as a musical director (Kapellmeister) in Bonn. His talent was obvious from early childhood (see Fig. B26). Only three of his seven siblings survived to adulthood but none of them had any special musical ability. At the age of 22 he moved from Bonn to Vienna and rose to become a highly esteemed member of the nobility and the imperial court.

Many famous contemporaries were his friends. He was financially independent because of the generosity of his admirers. Beethoven never married because he was plagued by various minor and major illnesses, including gradual loss of hearing leading to near total deafness by the age of 40. Ironically, during this phase, he composed some of his most famous works such as the Emperor concerto, a new version of the opera Fidelio, the seventh and the ninth symphonies. Although he had a platonic relationship with several women, he became isolated

Figure B26. This is the Brunszvik mansion of Martonvásár, Hungary where Beethoven was a guest two times. His bust is in the park at the lake behind the building. Above the spruce tree is the triple window of the music room where he composed the Moonlight Sonata. By the strange fate of life, many years ago author of this book lived in the same elegant room—with beautiful inlaid wood ceiling—for about a month

because he was troubled by his hearing loss (see Fig. B27). ►musical talent, ►genius, ►Bach, ►Mozart, ►Strauss; Mai FM 2007 Diagnosing genius: The life and death of Beethoven, McGill-Queen's University Press, Montreal, Canada.

Beethoven (*Bth*): This is a mouse mutation with dominant progressive hearing loss at the locus homologous to the human gene *TMC1*, causing DFNA36. Beethoven was apparently afflicted by the same mutation. ►deafness

Begonia (*Begonia semperflorens*): This is an ornamental plant, $2n = 34$.

Behavior Genetics: This branch of genetics analyzes the genetic determination and regulation of how organisms behave. Most of the traits (courtship, bird and frog songs) are under multigenic control and they depend to a large extent on the influence of the environment. In a few cases large effects of single genes have also been observed (Hall JC 2002 *J Neurogenet* 16:135). In *Drosophila* the *fruitless* (*fru*) gene is involved in the determination of courtship. The Fru^M transcription factor protein is expressed in about 2% of the neurons of the central nervous system. When the yeast *GAL4* gene is inserted into the *fru* locus Fru^M is expressed in all the peripheral sensory systems involved in courtship. Gal4 is a positive regulatory protein of the yeast galactose gene. Inhibition of Fru^M in the olfactory system components reduces olfaction-dependent courtship. Transient inactivation of all Fru^M -expressing neurons terminates courtship behavior without affecting other behavioral traits. The expression of Fru^M in female flies results in the manifestation of male courtship ritual in females toward other females (Manoli DS et al 2005 *Nature [Lond]* 436:395). The mosquito *Toxorhynchites brevipalpis* “hears” the frequency of the wing beats and both males and females recognize

the opposite sex on this basis (Gibson G, Russell I 2006 *Current Biol* 16:1311).

The Western scrub-jay (*Aphelocoma*), a corvid bird, hides food for future consumption and adopts a very elaborate pattern for protection of the cache (see Fig. B28). The bird can remember which individual saw the cache and alters its tactics to elude potential

Figure B28. Behavior genetics-*Aphelocoma*

thieves (Dally JM et al 2006 *Science* 312:1662). In the honeybee a single gene controls the habit of uncapping the honeycombs containing dead larvae but another gene is required for the removal of the dead brood. If both genes are present the colony becomes resistant to the bacterial disease foul brood because of improved hygienic behavior.

Alcoholism, criminality, etc. in humans may be determined by several genes and by the social environment. The Lesch-Nyhan syndrome is caused by a deficiency of the enzyme hypoxanthine-guanine phosphoribosyl transferase, which renders the salvage pathway of nucleic acid inoperational. As a consequence purines accumulate and uric acid is overproduced leading to gout-like symptoms but more importantly the nervous system is also affected, leading to antisocial behavior and self-mutilation. This gene has been isolated and cloned and may be transferred to the afflicted human body for gene therapy. Since behavioral traits are determined by the nervous system, neurogenetics may provide the answer to many serious conditions such as Alzheimer's disease (an amyloid accumulating presenile dementia), neurofibromatosis (a soft tumor of the nervous system affecting the entire body involving a protein resembling a GTPase activator), etc. Behavioral alteration may result from brain damage without a genetic change. A lesion in the frontal lobe of the brain may result in sociopathy in humans and in macaques (Rudebeck PH et al 2006 *Science* 313:1310).

In recent years progress has been made in the molecular analysis of memory and learning ability through studies of simple organisms such as the slug *Aplysia* and *Drosophila*. Several genes involved in the development of the nervous system of *Drosophila* have been cloned. Recent research has shown that mice without the *fos* gene fail to nurse their pups presumably because of some brain lesions.

B

For genetic and developmental analysis of nerve functions, the nematode, *Caenorhabditis* is particularly well suited because its entire nervous system consists of only 302 cells. In the tobacco hornworm (*Manduca sexta*) the feeding preference depends on an acquired recognition template. The naïve larvae can feed on different plant species but once they have been exposed to a steroidal glycoside (indioside D) present in tobacco leaves, they become “addicted” to that host. Although all biological traits and attributes have some biological basis, the influence of the environment has a very substantial role in the development of behavioral traits. Frequently, for unknown reason, identical behavioral traits are expressed differently in isogenic strains maintained in different laboratories under apparently identical conditions. This fact indicates that genes cannot exonerate criminal behavior, neither should people be condemned on the basis of collective responsibility by supposed sharing of a common gene pool.

Microarray profiles of the brain are associated with behavior (Whitfield CW et al 2003 Science 302:296). Magnetic resonance imaging (MRI) of the brain distinguishes between extrovert and neuroticistic behavior on the basis of humor-driven blood oxygenation level-dependent signals in different regions of the brain (Mobbs D et al 2005 Proc Natl Acad Sci USA 102:16502). The molecular basis of a few mouse behavioral genes is now known. Deletion from the *ROR α* gene causes the *staggerer* phenotype. The *vibrator* mouse carries a retroposon in an intron of the phosphatidylinositol transfer protein. The *weaver* ataxia is a serine→glycine replacement gene in a G-protein-gated inwardly rectifying K-ion channel. The different types of estrogen receptors control mating behavior. Introduction by a viral vector the single gene of the vasopressin V1a receptor into the ventral forebrain of the polygamous species of the Vole substantially increased monogamous behavior (Lim MM et al 2004 Nature [Lond] 429:754). Oxytocin knockout male mice are afflicted by an olfactory recognition problem, a deficit in the amygdala of the brain which can be corrected by injecting oxytocin. *Trpc2* vomeronasal organ-specific neuron ion channel mutant mouse females display unique characteristics of male sexual and courtship behavior such as mounting, pelvic thrust, solicitation, anogenital olfactory investigation, and emission of complex ultrasonic vocalizations towards male and female conspecific mice. The same behavioral phenotype is observed after surgical removal of the vomeronasal organ of adult animals, and is not accompanied by disruption of the estrous cycle and sex hormone levels (Kimchi T et al 2007 Nature [Lond] 448:1009). Galanin, a neuropeptide with inhibitory action on neurotransmission and memory, causes Alzheimer’s disease-like behavior in mice. Enkephalin (opioid

peptide) knockout and/or the loss of its receptor lead to an increase in anxiety. Mutation in the dopamine receptor D2 results in Parkinsonism-like phenotype. The loss of the serotonin receptors increases anxiety. NO synthase knockout mice express greater aggressiveness. Single genes, encoding pheromone-binding protein(s) may regulate complex social behavior, such as recognition of conspecific individuals in social insects (Keller L, Parker JD 2002 Current Genet 12[5]:R180). The nursing of female rabbits and the sucking of pups seem to be regulated by the pheromone 2-methylbutenal (Schaal B et al 2003 Nature [Lond] 424:68). Mice deficient in the TRP2 gene lose their ability to distinguish between sexual types and consequently males mate with both males and females. In the carpenter ants (*Camponotus japonicus*) hydrocarbon blends produced by sensillae of the antennae are the chemical signals for the recognition of nestmates and for the aggressive behavior towards non-nestmates (Ozaki M et al 2005 Science 309:311). Behavior is subject to epigenetic modification. In rats well cared by their mothers during early life the hippocampal glucocorticoid receptor is methylated to a lesser degree than in the neglected pups. This condition persists during the later stages of development. Infusion of L-methionine, a precursor of S-adenosylmethionine and methyl donor for DNA methylation reverses the effect of the maternal behavior on DNA methylation (Weaver IC et al 2005 J Neurosci 25:11045). The higher level of maternal androgens—especially in the later phase of pregnancy—influences social rank and aggressiveness in spotted hyenas (Dloniak SM et al 2006 Nature [Lond] 440:1190). ▶courtship in *Drosophila*, ▶personality, ▶alcoholism, ▶cognitive abilities, ▶autism, ▶addiction, ▶fate mapping, ▶behavior in humans, ▶altruistic behavior, ▶aggression, ▶ethics, ▶instinct, ▶morality, ▶eugenics, ▶avoidance learning, ▶cross fostering, ▶FOS, ▶human intelligence, ▶behavior, ▶affective disorders, ▶Huntington’s chorea, ▶Alzheimer’s disease, ▶mental retardation, ▶attention deficit hyperactivity, ▶dyslexia, ▶homosexual, ▶vomeronasal organ, ▶oxytocin, ▶microsatellite, ▶antenna, ▶sensillum, ▶sex determination, ▶Gal4; Pfaff D 2001 Proc Natl Acad Sci USA 98:5957; McGuffin P et al 2001 Science 291:1232; Toyee AA, Cox R 2001 Curr Biol 2001 11:R473; Krieger MJB, Ross KG 2002 Science 295:328; Bucan M, Abel T 2002 Nature Rev Genet 2002 3:114; Stowers L et al 2002 Science 295:1493; Kucharski R, Maleszka R 2002 Genome Biol 3[2]:res.0007.1; Rankin CH 2002 Nature Rev Genet 3:622; Sokolowski MB 2002 Nature [Lond] 419:893; Sherman G, Visscher PK 2002 Nature [Lond] 419:920; chemical communication; Proc Natl Acad Sci USA 100, Suppl 2 [2003]; application in law, education, employment and insurance: Rothstein MA 2005 Nature Rev Genet 6:793.

Behavior in Humans: For long human behavior has been suspected to be genetically determined but with a few exceptions (Lesch-Nyhan syndrome, Tay-Sachs disease, Huntington's chorea, etc.). However, the genetic control is not completely understood. The majority of the behavioral traits are under the control of several genes. In such instances the tools of quantitative inheritance are needed, such as heritability, comparison of monozygotic-dizygotic twins with the general population and QTL mapping. The approximate ratios of monozygotic:dizygotic concordance are for alcoholism, females (1.1) versus males (1.7), dyslexia (1.7), Alzheimer's disease (2.1), major affective disorders (2.4), schizophrenia (2.7), autism (6.7). Heritabilities determined by intraclass correlation were 0.22 for memory, 0.22 for mental processing speed, 0.38 for scholastic achievement in adolescence, 0.40 for spatial reasoning, 0.42 for adolescent vocational interest, 0.46 for neuroticism, 0.50 for verbal reasoning and 0.52 for general intelligence. [Data based on Plomin, Owen, McGuffin 1994 *Science*:264:1733]. Cognitive abilities are also studied as part of the developmental genetic pattern (longitudinal genetic analysis). Multivariate genetic analysis determines the covariance (►correlation) among multiple traits. Although some genetic effects are specific to certain abilities, the majority of the genetic components have overlapping effects. The studies must also consider in assessing behavioral, cognitive genetic traits that form a continuum and the anomaly in a proband or several individuals may be just the extreme form of a normally existing behavioral pattern. Behavioral traits in general have about 50% or more environmental components. These effects include family relationships and changes in such relationships (e.g., divorce, death, accidents), social environment (economic status, schools, drug use, neighborhood), etc. The quantitative genetic approaches assumes that behavioral traits are complex and are the end product of cooperative action of individual genes, expressed as a phenotypic class rather than one gene-one disorder (OGOD). Some behavioral anomalies may show cosegregation with DNA markers such as those used in QTL analysis. Some mental anomalies, such as phenylketonuria (single recessive defect in phenylalanine hydroxylation) may account for about 1% of the affliction in mental asylums (►the fragile-X syndrome). Over 100 single gene determined human diseases include mental retardation as part of the syndromes. Defects in the X-chromosomally encoded gene product mitochondrial enzyme, monoamine oxidase A (MAOA) was attributed to violent behavior and also to schizophrenia. MAOA degrades serotonin, dopamine and norepinephrine. ►behavior genetics, ►cognitive abilities, ►human intelligence, ►ethology, ►self-destructive behavior, ►personality,

Behcet Syndrome (TAP): This rare disorder is characterized by mouth and genital inflammation in humans. It is probably autosomal dominant.

Behr Syndrome: The disorder leads to recessive infantile optical nerve atrophy. ►optic atrophy

BEL: ►copia

Bell Curve: ►normal distribution

Bellevia: This is a subspecies of lilies ($2n = 8$ or 16) with large and well stainable chromosomes.

Bellophage: Refers to a 1-kb RNA phage, encoding a nucleocapsid protein, a replicase component and an integrase. It has some retroviral-like properties. The small replicase binds to the host DNA polymerase and modifies it in such a way that the enzymes act as an RNA-directed DNA polymerase. Assisted by the integrase, the DNA formed is inserted into the host genome as a prophage. The nucleocapsid, because of its leucine zipper motif, can associate with its helper phage. The helper is originally the *Salmonella* phage Ω but it may recruit for this function adenovirus or influenza virus if mutation alters the leucine zipper. In chickens and some apes the provirus integrates into the mtDNA rather than into the nucleus. Thus it opens the possibilities of inserting foreign DNAs into the mitochondria and chloroplasts for genetic engineering. ►viral vectors, ►transformation of organelles, ►integrase, ►leucine zipper

BEM1: This protein with SH3 domain is involved in signal transduction. ►SH3, ►signal transduction

Bematistes pongei: This is an African butterfly mimicked by *Papilio dardanus*. ►Batesian mimicry

Bence-Jones Protein: Some immunoglobulin heavy chain diseases (HCD) such as the lymphoproliferative neoplasms may only contain the antibody heavy chains (IgM, IgG, IgA), and even those are truncated and are deficient in most parts of the variable region. The γ and α type HCD cells synthesize no light chains but the μ HCD cells secrete an almost normal light chain that is detectable in the urine and it is called Bence-Jones protein. Some of the bone marrow cancer (myeloma) patients also discharge Bence-Jones protein in their urine. These light chain immunoglobulins are generally homogeneous because they are the products of a clone of cancer cells and were historically useful to obtain information on the antibody structure. ►myeloma, ►monoclonal antibody, ►immunoglobulins, ►antibody; Beetham R 2000 *Ann Clin Biochem* 37(5):563.

B

Beneficial Mutation: The majority of new mutations are less well adapted than the prevailing wild type allele in a particular environment or at best they may be neutral. Beneficial mutations are rare because during the long history of evolution the possible mutations at a locus had been tried and the good ones preserved. Nevertheless, if a new mutation has 0.01 reproductive advantage, the odds against its survival in the first generation is $e^{-1.01} = 0.364$. Its chances to be eliminated by the 127th generation are reduced to 0.973 compared to a neutral mutation that would be eliminated by a chance of 0.985. Even mutations with an exceptionally high selective advantage may have a good chance to be lost ($e^{-2} \cong 0.1353$). Under normal conditions the selective advantage(s) is very small and the chance of ultimate survival is $(y) = 2s$ and the chance of extinction is $(l) = 1 - 2s$. In order that the mutation would have more than 50% probability of survival, the requisites must be $(1 - 2s)n < 0.5$ or $(1 - 2s) > 2$. Hence, $-n \ln((1 - 2s)) > \ln 2$ or approximately $-n(-2s) > \ln 2$, and therefore $n > (\ln 2)/2s$ or $\cong (0.6931)/2s$. If $(s) = 0.01$ and $(n) =$ number of mutations, (n) must be larger than $0.6931/(2 \times 0.01) \cong 34.66$. In other words, at least 35 mutational events must take place with at least 1% selective advantage of the mutants over the wild type that one would ultimately survive. If the rate of mutation is 10^{-6} , nearly a population of 35 million may provide such a mathematical chance. Under evolutionary conditions neutral or even deleterious mutations may make it (succeed) by random drift or chance in small populations. ►mutation neutral, ►mutation rate, ►mutation spontaneous, ►mutation in human populations; Fisher RA 1958 The genetical theory of natural selection, Dover, UK; Dobzhansky T, Spassky B 1947 Evolution 1:191; Miura T, Sonigo P 2001 J Theor Biol 209:497.

Benign Hereditary Chorea: This disorder refers to dominant childhood chorea encoded at 14q. ►chorea

Benton-Davis Plaque Hybridization: This process involves the selection of recombinant bacteriophages on the basis of DNA hybridization with ^{32}P probes on an appropriate (nitrocellulose or nylon) membrane. For the screening of a mammalian or other large library, hundreds of thousands of recombinants need to be screened. In a 150 mm Petri dish 5×10^4 plaques may be used. ►DNA hybridization, ►Grunstein-Hogness screening, ►DNA library, ►recombination molecular mechanisms prokaryotes, ►plaque, ►plaque-forming unit; Benton WD, Davis RW 1977 Science 196:180; Lewis JA et al 1983 Mol Cell Biol 3:1815.

Benzimidazoles: These are tubulin-binding/depolymerizing chemicals used as herbicides (trifluralin, oryzalin) or fungicides (benomyl). The oral dose of LD50 for mouse is ~ 2910 mg/kg. ►tubulin

Benzo(a)Pyrene: This is a highly carcinogenic polycyclic hydrocarbon generated by combustion at relatively lower temperatures by polymerization of organic material (see Fig. B29). It is present in automobile emissions, burning of coal, cigarette smoke, fried and grilled meat (in charbroiled T-bone steaks more than 50 $\mu\text{g/kg}$ has been detected, etc.). It has been estimated that 13,000 ton is annually released into the world's atmosphere by these processes. A single 0.2 mg intra-gastric dose per mouse, resulted in 14 tumors in five of the 11 animals treated. Exposure of the skin and inhalation of the fumes substantiated high and rapid carcinogenicity. It is also a promutagen requiring metabolic activation in *E. coli*, yeast, *Drosophila*, various rodents and the plant *Arabidopsis*. Benzo(a)pyrene forms adduct not only with guanine by binding to the N2 position, but also with deoxyadenosine. It also leads to sister chromatid exchange and the formation of micronuclei. Exposure to benzo(a)pyrene results in the expression of cytochrome P450 (cyp1a1) in the skin and liver of mice if the aryl hydrocarbon receptor (AhR) is active. Cyp1a2 gene expression did not need AhR. For carcinogenesis by benzo(a)pyrene AhR is a requisite. ►environmental mutagens, ►carcinogens, ►Ames test, ►bioassays in genetic toxicology, ►sister chromatid exchange, ►micronucleus formation as a bioassay, ►adduct, ►cytochromes; arylhydrocarbon receptor; Chiapperino D et al 2002 J Biol Chem 277:11765.

Figure B29. Benzo(a)Pyrene

Benzyladenine (6-benzylaminopurine): ►plant hormones

BER (base excision repair): ►DNA repair, ►excision repair

Berardinelli Disease: ►lipodystrophy familial

Berardinelli-Seip Congenital Lipodystrophy: This condition is characterized by recessive defects in seipin, an integral membrane protein of the endoplasmic reticulum, leading to neurodegeneration. The symptoms are somewhat similar to those of the Silver syndrome as the same region in human chromosome 11 is involved. ►spinal muscular atrophy, ►Silver syndrome, ►lipodystrophy congenital; Windpassinger C et al 2004 Nature Genet 36:271.

Bergamottin: This is one of the several structurally and functionally related derivatives of furanocoumarins affecting +/- drug transport. It is present in citrus fruits (grapefruit juice) and other natural products (see Fig. B30). ►grapefruit; Ohnishi A et al 2000 British J Pharmacol 130:1369.

Figure B30. Bergamottin

Bermuda Standard: Refers to the 1997 agreement at the 2nd International Strategy Meeting of the human genome sequencing project that provides quality standards. The goals included accuracy at the 1×10^{-4} level of nucleotides and specifying the principles of various technical levels of operations, e.g., using the PHRED and PHRAP computer programs, and restriction enzymes. It also spells out some principles of etiquette. ►human genome projects, ►PHRAP, ►PHRED; see in AltaVista: <http://www.gene.ucl.ac.uk/hugo/bermuda2.htm>.

Bernard-Soulier Syndrome: This refers to 22q11.2 and 17pter-p12 recessive dysfunction of the platelets and thrombocytopenia. It is a potentially lethal bleeding disease. A platelet membrane receptor, glycoprotein Ib-IX-V is absent and the platelets do not agglutinate by interaction with the von Willebrand plasma factor. ►thrombocytopenia, ►platelet, ►von Willebrand disease; Ludlow LB et al 1996 J Biol Chem 271:22076.

Bernoulli Process: Independent experiments, which provide only two outcomes, yes or no, success or failure are called Bernoulli trials, and the two-event classes and their probabilities are called Bernoulli process where p = probability of success and $1 - p = q$ = probability of failure. If in a sequence of 10 trials there are 4 successes, the probability of that sequence is $p^4 q^6$; if

$p = \frac{2}{3}$ then the probability of the sequence becomes

$$\left(\frac{2}{3}\right)^4 \left(\frac{1}{3}\right)^6$$

The general formula becomes:

$$P(r \text{ success} | N, p) = \binom{N}{r} p^r q^{N-r} \quad \{1\}$$

where p = probability of success, r = the exact number of successes and N = the number of independent trials. If it is assumed that one can observe a monogenic segregation where the penetrance of the mutant class

is reduced from 25% to 20%, then the probability of finding a recessive mutant among 3 individuals will be according to $\{1\}$:

$$\begin{aligned} P(1 \text{ mutant among 3 individuals}) \\ &= \binom{3}{1} (0.20)^1 (0.80)^2 \\ &= \left(\frac{3!}{2!(2-1)!}\right) 0.2 \times 0.64 = 0.384 \end{aligned}$$

If the population is increased to say, 210, the chances of finding a mutant increase to 70.

►binomial probability, ►inference

BERT (background equivalent radiation time): If a diagnostic X-ray exam uses 360 mrem it corresponds to 1 BERT/year (approximate average in the USA). Sources contributing to the natural background (in mrem) are: radon (200), cosmic sources (100), medical treatment (39), consumer and industrial products (11), air travel (6) and nuclear industry (<1). The total may vary, however, from 100 to 600 mrem or even more at certain locations. The general public usually overestimates the risk of the nuclear industry and underestimates that from medical diagnosis and treatment. ►rem, ►radiation hazard assessment, ►cosmic radiation, ►risk

Berylliosis (CBD): This is a granulomatous (nodular inflammation) lung disease among people exposed to beryllium dust. Homozygosity of a rare major histocompatibility allele (MHC) predisposes certain individuals to this disease. ►MHC

Best Disease: ►macular dystrophy

BeT (best hit): This is a feature of orthologous sequences displaying homologies among individual genes (COGs) in different species. ►COG

Beta Barrel: ►barrel

Beta Blocker (beta adrenergic antagonist): This drug reduces blood pressure by slowing down the heart rate.

Beta Breaker Amino Acids: These disrupt beta sheets highly likely (Asp, Glu, Pro) or less frequently (Gly, Lys, Ser). ►protein structure, ►prions; Adessi C et al 2003 J Biol Chem 278:13905.

Beta Complex: Refers to one of the alternately distributed translocation complexes of the plant *Oenothera*. ►alpha complex alternative, ►multiple translocations, ►complex heterozygote

Beta Distribution: This distribution is very similar to the binomial probability function. This distribution is continuous whereas the binomial distribution is discrete. $f(x) = \frac{x^{\alpha-1}(1-x)^{\beta-1}}{B(\alpha, \beta)}$. ►binomial distribution

Beta Galactosidase: ►galactosidase; ►Lac operon

B

Beta-Lipoprotein (apolipoprotein, 2p24): This is a component of the low-density lipoprotein fraction (LDL) in the plasma. The ApoB-48 fraction is made in the gut, the ApoB-1000 in the liver by differential processing of the transcript of the same locus. [▶hypobetalipoproteinemia](#), [▶abetalipoproteinemia](#), [▶hyperbetalipoproteinemia](#)

Beta Particles: These electrons are emitted by radioactive isotopes; their mass is 1/1837 that of a proton. The negatively charged form of it is an electron whereas the positively charged is a proton. Beta particles have no independent existence; they are created at the instance of emission. In the biological laboratory the most commonly used isotopes emitting β radiation (with energy in MEV) are H3 (0.018), C14 (0.155), P32 (1.718), S35 (0.167), I131 (0.600 and 0.300 but emits also γ radiations of various energy levels). The mean length of the path of H3 is about 0.5 μ m and that of P32 is about 2600 μ m. [▶linear energy transfer](#), [▶isotopes](#)

Beta Sheets: [▶protein structure](#)

Beta vulgaris: Refers to beets (*Chenopodiaceae*) having basic chromosome number 9. Included in this group are sugar beets, fodder beets, mangold and chards which are all-important food and feed crops. Sugar beets represent a glowing example of the success of selective plant breeding by increasing the sugar content (about 2% in the mid-eighteenth century) by over 10-fold in some modern varieties. The most productive current varieties display triploid heterosis and improved disease resistance and the monogerm “seeds” facilitate mechanization of cultivation, etc. [▶heterosis](#), [▶triploid](#), [▶monogerm seed](#)

Betel Nut (*Arecia catechu*): This seed palm tree is used as a stimulant; $2n = 4x = 32$.

Bet-Hedging: Sexually mature individuals reduce their reproductive potentials due to environmental circumstances. (Menu F et al 2000 Am Nat 155:724).

Bethlem Myopathy: This is a dominant human disorder involving contractures of the joints, muscular weakness and wasting. It is associated with mutations of collagen type VII genes in human chromosomes 21q22.3 and 2q37. [▶collagen](#), [▶laminin](#)

BEV: (Baculovirus expression vector): This is a potential tool to control insect populations by biological means. [▶baculovirus](#), [▶biological control](#), [▶viral vectors](#)

bFGF: Refers to the basic fibroblast growth factor.

BFP (blue fluorescent protein): This is similar to GFP (green fluorescent protein). Excitation at 368 nm causes light emission at 445 nm, which excites the

Ser65Cis mutant of GFP and causes light emission at 509 nm. [▶aequorin](#), [▶EGFP](#)

β -Galactosidase: This enzyme (lactase) splits the disaccharide lactose into galactose and glucose. It can also act on some lactose analogs, e.g., on ONPG (o-nitrophenyl- β -D-galactopyranoside). This substrate (10–3 M or less) when exposed to active enzymes (1010 molecules/mL) yields a yellow product (that has an absorption maximum at 420 nm) and can be used to measure the activity of the enzyme. In cells grown in A medium and with Z buffer the activity of galactosidase is determined by the formula:

$$> 1000 \times \frac{OD_{420} - (1.75 \times OD_{550})}{tx(0.1 \times OD_{660})}$$

where OD is optical density at the wavelength indicated, and t is time of the reaction run in minutes. On a Petri dish the activity of β -galactosidase is detected on EMB agar (containing eosin yellow, methylene blue and lactose) and in case the sugar is fermented, a dark red color develops. Bacterial galactosidase is an inducible enzyme and induction takes place by allolactose that is formed upon the action of the residual few galactosidase molecules in the non-induced cells. A gratuitous inducer (induces synthesis although the enzyme itself is not a substrate) is isopropyl- β -D-thiogalactoside (IPTG). Constitutive mutants of the *E. coli* z gene can be identified on Xgal media containing 5-bromo-4-chloro-3-indolyl- β -D-galactoside dissolved generally in dimethylformamide (20 mg/mL). This compound is not an inducer of the enzyme but it is cleaved by it and thus a blue indolyl derivative is released. [▶Lac operon](#), [▶galactosidase](#)

BGH: [▶bovine growth hormone](#)

β -Glucuronidase: [▶GUS](#)

BH: [▶BAK](#)

BHK: This refers to the baby hamster kidney cell; cultured fibroblasts of the Syrian hamster. [▶hamster](#)

bHLH (basic helix-loop-helix protein): [▶helix-loop-helix](#)

b/HLH/Z Motif: A basic amino acid sequence at the N terminus which is probably required for DNA binding, helix-loop-helix structure, leucine zipper. This general structure is widely found in biologically active proteins involved in DNA binding. [▶binding proteins](#), [▶DNA binding protein domains](#), [▶helix-loop-helix](#)

Bialaphos: This inhibitor is a glutamine synthetase normally produced by *Streptomyces hygroscopicus*.

Upon splitting off two alanine residues it is activated into phosphinotricin. ►herbicides

Biallelic: For gene expression in diploids both alleles must be present. ►allele, Karolinska Institute human bi-allelic sequence: <http://www.kisac.ki.se>.

Bi-Armed Chromosome: This has two chromatids at the opposite sides of the centromere (see Fig. B31). ►telochromosome, ►chromosome morphology

Figure B31. Bi-armed chromosome

Bias: Denotes an average error of an estimate. It is a false difference of an observation from the correct value.

BIBAC (binary bacterial artificial chromosome): This is a plant genetic expression vector that can be propagated in *Agrobacterium tumefaciens* and *E. coli* and it can deliver to plant chromosomes large (160 kb) foreign DNA sequences. ►BAC, ►Agrobacterium, ►transformation, ►vectors

bicoid (*bcd*, 3–48): This is a maternal effect mutation in *Drosophila* (see Fig. B32). The larvae lack a head, thorax, some abdominal segments and duplicate telsons. In the wild type the *bicoid* mRNA is localized in the anterior part of the egg. The mammalian homologs are Pitx1 and Pitx2. Its protein product is in the cleavage embryos in a decreasing anterior-posterior gradient. The Bcd protein—through its binding region, BBR—interacts with d4EHP (an eIF-4E related protein) binds the cap region of *cad* (*caudal*, *Drosophila* gene at 2–55) mRNA and prevents its translation (Cho PF et al 2005 Cell 121:411). Caudal mutations are homozygous lethal because of an abnormal segmentation pattern.

Figure B32. *bicoid*

VPS36 (a component of the ESCRT transport system) functions by binding directly and specifically to stem-loop V of the *bicoid* RNA 3' UTR through its amino-terminal GLUE domain. VPS36 localizes to the anterior of the oocyte in a *bicoid*-mRNA-dependent manner, and is required for the subsequent recruitment of Staufen (a *Drosophila* RNA-binding protein)

to the *bicoid* complex. This function of ESCRT-II as an RNA-binding complex is conserved (Irion U, Johnston D St 2007 Nature [Lond] 445:554). ►left-right asymmetry; Cha B-J et al 2001 Cell 106:36; Houchmandzadeh B et al 2002 Nature [Lond] 415:798.

BID: A pro-apoptotic protein which links proximal signals to the apoptotic pathways (FAS and TNFR). The inactive cytosolic form of BID (p22) is split into the 15-kDa fragment, tBID (truncated BID) that then moves to the mitochondria. Its BH3 domain oligomerizes with BAK and cause mitochondrial dysfunction and the release of cytochrome c. Post-proteolytic *N*-myristoylation triggers the BID-induced apoptosis. When ATM (ataxia telangiectasia mutated) and the related (ATR) kinases phosphorylate BID it can cause cell cycle arrest or by acting on BAX and BAK pro-apoptotic proteins induce apoptosis (Kastan MB 2005 Nature [Lond] 437:1103). One study concluded that Bid has no role in DNA damage or replicative stress-induced apoptosis or cell cycle arrest (Kaufmann T et al 2007 Cell 129:423). ►apoptosis, ►ATM, ►ATR, ►BAK, ►BAX, ►myristic acid, ►Bcl; Wei MC et al 2000 Genes Dev 14:2060; Zha J et al 2000 Science 290:1761.

BiDiI (isosorbide dinitrate and hydralazine): This vasodilator drug is manufactured by Nitro Med, Inc (Bedford, MA), and it is particularly effective in heart failure in the case of some Afro-American individuals with ventricular ejection problems. The label of “ethnic/racial drug” is controversial. ►race, ►ethnicity; Wolf SM 2005 Nature Genet 37:789.

Bidirectional Replication: From the replicational origin the replication moves in opposite directions in the DNA (see Fig. B33). ►replication bidirectional, ►replication fork

Figure B33. Bidirectional

Bidirectional Gene Organization: Genes in large genomes are not dispersed uniformly but form clusters. Among the 144 and 319 known genes of human chromosomes 21 and 22, 22% and 18%, respectively, are divergently arranged within ~1 kb from each other whereas the average spacing distance for all genes is ~85 kb. In most cases the spacing islands of the bidirectional genes carried a CpG island that

B

generally overlapped partially or entirely the first exon or rarely more than one. This organization has regulatory advantage. A study of 23,752 human genes revealed that more than 10% of the genes whose transcription start sites are separated by less than 1000 base pairs are transcribed bidirectionally (Trinklein ND et al 2004 Genome Res 14:62). ▶**operon**, ▶**clustering**; Adachi N, Lieber MR 2002 Cell 109:807.

BIDS: ▶**hair-brain syndrome**

Biennial: Refers to plants with a life span of two years yet the total period is less than two years. These plants germinate in fall and mature and die before the end of the following year.

Bifunctional Antibody: This carries an antibody variable region fragment that secures its ability to recognize certain molecules (antigen). In addition, a fused heterologous component conveys either enzyme activity or carries a toxin or a pro-drug, etc. Such a complex can home in on the cognate molecules and destroy or alter them according to the specificity of the heterologous portion. ▶**bispecific antibody**

Bifunctional Enzymes: These have apparently evolved with the potential to adapt the amino and carboxy terminal tracts to fulfill the metabolic requirements of different tissues. ▶**one gene—one enzyme theorem**; Kitzing K et al 2001 J Biol Chem 276:42658.

Bifunctional Mutagen: ▶**functionality of mutagens**

Big Blue: A commercially available mouse strain that carries the bacterial *LacI* gene (in about 40 copies) as a stably integrated lambda vector, thus it is very useful for the laboratory detection of in vivo mutagenic/carcinogenic effects. The transgene is extracted from mice and with the aid of the λ shuttle vector introduced into *E. coli* bacteria. In the presence of Xgal substrate mutations in the *LacI* gene give rise to blue plaques because of the loss of inhibition of the galactosidase gene, *LacZ*. Thus, mutations in the prokaryotic gene in the animals, activated by the animal metabolism, are screened in bacteria because of the convenience of detection in the prokaryotic system. This system permits the detection of mutation in different animal tissues, e.g., liver, brain, at different developmental stages and under different conditions. ▶ **β -galactosidase**, ▶**Xgal**, ▶**Lac operon**, ▶**Muta Mouse**, ▶**host-mediated assay**; Gossen JA et al 1989 Proc Natl Acad Sci USA 86:7971; Nohmi T et al 2000 Mutation Res 455:191.

BigSeq: A computer program with a similar purpose as Mask, it contains information on millions of contigs. ▶**contig**, ▶**physical map**

Bikont: This eukaryote has two cilium-bearing centrioles (nucleating cone of microtubules) such as plant and protozoa. Unikonts have one cilium on the centriole such as animals, fungi and amoebazoa. ▶**cilia**, ▶**centriole**; Richards TA, Cavalier-Smith T 2005 Nature [Lond] 436:1113.

Bilateral Symmetry: ▶**symmetry**, ▶**zygomorphic** (see Fig. B33), ▶**retinoic acid**

Figure B34. Bilateral symmetry

Bilayer: A bilayer of membranes consists of amphipathic lipids (and proteins) and the non-polar phase faces inward. The majority of cellular membranes are double membranes. ▶**amphipathic**

Bile Salts: These are detergent-type steroid derivatives involved in digestion and absorption of lipids. ▶**lipids**, ▶**cholesterol**; Russel DW 2003 Annu Rev Biochem 72:137.

Bilineality: More than a single locus determines a particular trait and they may segregate independently making chromosomal localization, by genetic techniques, very difficult.

Bilirubin: This bile pigment is formed by the degradation of hemoglobin and other heme containing molecules such as cytochromes. It is circulated in the blood as a complex with albumin and when deposited in the liver it forms bilirubin diglucuronide. It may arise from biliverdin, a breakdown product of heme, through reduction. Bilirubin is a strong antioxidant and may cause brain damage in neonatal jaundice. ▶**hyperbilirubinemia**, ▶**jaundice**, ▶**cholestasis**, ▶**Alagille syndrome**, ▶**Byler disease**, ▶**steroid dehydrogenase**, ▶**steroid reductase**, ▶**Gilbert syndrome**, ▶**cerebral xanthomatosis**, ▶**Crigler-Najjar syndrome**, ▶**Dubin-Johnson syndrome**; Tomaro ML, del C Battle AM 2002 Int J Biochem & Cell Biol 34:216.

Bim: This is a member of the BCL family of proteins. The proteins sharing the Bcl-2 homology domain BH3 promote apoptosis in contrast to other members of the family (e.g., Bax, Bak) that are anti-apoptotic. ▶**BCL**, ▶**BAX**, ▶**BAK**; Chen D, Zhou Q 2004 Proc Natl Acad Sci USA 101:1235.

BimC: This family of motor proteins of the kinesin group is involved in the separation of the mitotic chromosomes by the spindle. ▶motor proteins, ▶spindle, ▶monastrol, ▶mitosis

BimD: A negative regulator of the cell cycle progression in *Aspergillus*, it mediates recombination and chromosome morphology.

BimE: This is an *Aspergillus* protein subunit of the APC complex, it is homologous to APC1. ▶APC, ▶cell cycle

Bimodal Distribution: In this case when the population is represented graphically, it displays two peaks (see Fig. B35). Or, in general, the data are clustered in two modes, in two classes.

Figure B35. Bimodal distribution

BIN: A group of markers (microsatellite DNA) mapped to the same location.

BIN1 (box-dependent Myc interacting protein-1): This is a tumor-suppressor protein (human chromosome 2q14) that interacts with the Myc oncoprotein. It is related to amphiphysin that serves a similar purpose in breast cancer and to the RVS167 cell cycle control gene of yeast. ▶MYC, ▶tumor suppressor; DuHadaway JB et al 2001 Cancer Res 61:3151.

Bin2 (Cct3, TriC): This is synonymous with the CCT γ chaperonin subunit. ▶chaperonins

Bin3 (Cct2): This is synonymous with the CCT β subunit of chaperonins. ▶chaperonins

Binary: Refers to any condition, choice or selection with two possibilities or a numeration system with a radix of 2. ▶radix, ▶founder cells

Binary Variables: These variables are either yes or no (0 or 1); their analysis can be performed by logistic regression or Bernoulli process. ▶logistic regression, ▶Bernoulli process

Binary Gene Expression: The expression is full or none.

Binary Fission: This means splitting into two parts (see Fig. B36). Bacteria, chloroplasts and mitochondria that do not have a mitotic mechanism reproduce in this way after DNA replication has been completed.

Figure B36. Binary fission

Binary Vector: Refers to *Agrobacterium* carrying two plasmids, one has the T-DNA borders and other sequences (special genes, selectable markers) that will integrate into the transformed cell's chromosomes, the other is a helper plasmid carrying the Ti plasmid virulence genes, required for transfer but no part of the latter plasmid is integrated into the host genome during transformation. ▶T-DNA, ▶virulence genes of *Agrobacterium*, ▶transformation genetic, ▶cointegrate vector, ▶agrobacterial vectors; Bevan M 1984 Nucleic Acids Res 12:8711.

Binary Targeting: The specific recombinase gene (*Cre*, *Flp*) is carried by one of the mating pairs and the site-specific recombination site (*loxP*, *FRT*) is present in the other partner. ▶targeting genes, ▶Cre/LoxP, ▶Flp/FRT

Binase: This is a 12-kDa dimeric ($\alpha\beta$) endonucleolytic ribonuclease binding to N-1 of 3'-guanine monophosphate. It has 82% amino acid identity with barnase. ▶barnase; Wang L et al 2001 Proc Natl Acad Sci USA 98:7684.

BIND (Biomolecular Interaction Network Database): <http://www.xml.com/pub/r/1290>.

Bindin: An acrosomal protein that mediates the species-specific binding between gametes during fertilization. Apparently the egg surface has a species-specific bindin receptor. ▶fertilization, ▶acrosomal process, ▶sperm, ▶acrosome; Glaser RW et al 1999 Biochemistry 38:2560; Kamei N, Glabe CG 2003 Genes Dev 17:2502.

Binding Energy: This is derived from the non-covalent interaction between ligand and receptor, enzyme and substrate. ▶ligand, ▶receptor

Binding Proteins: These proteins are of a great variety and they control gene expressions at the level of transcription (transcription factors, hormones, heat-shock proteins, etc.). Most of them bind to upstream consensus sequences. The cap-binding proteins regulate the stability of the mRNA. Some of them are transcription termination factors, such as rho in bacteria or Sal I box binding proteins in the mouse. To study their position and function at the DNA level, footprinting or protein microarrays is undertaken (Ho S-W et al 2006 Proc Natl Acad Sci USA 103:9940). An in vitro method for specific and sensitive solution-phase analysis of interactions between proteins and nucleic acids in nuclear extracts is based on the proximity ligation assay. The reagent consumption is very low, and the excellent sensitivity of the assay enables analysis of as few as 1–10 cells. The method appears highly reproducible, quantitative, and in good agreement with both EMSA (electrophoretic mobility shift assay) and predictions obtained by using a motif finding software. This

B

assay can serve as a valuable tool for characterizing in depth the sequence specificity of DNA-binding proteins and for evaluating the effects of polymorphisms in known transcription factor binding sites Gustafsdottir SM 2007 Proc Natl Acad Sci USA 2104:3067.

Some proteins bind to the cellular membranes and control imports and exports, others mediate signal transduction. These proteins may have a combinatorial hierarchy and are thus capable of influencing a multitude of processes in the cell, far in excess of their individual numbers. Proteins may bind to the DNA in a non-specific manner and this property facilitates the binding to specific nucleotide sequences. Non-specific binding—by electrostatic forces—facilitates the recognition of the specific sites much faster than mere diffusion (Kalodimos CG et al 2004 Science 305:386). Gene expression is controlled primarily by proteins binding non-covalently to the DNA. In general, there is no particular specificity of recognition between amino acids and DNA bases yet some data indicate structural preferences (Mandel-Gutfreund Y et al 1995 J Mol Biol 253:370; Kono H, Sarai A 1999 Proteins 35:114). The interaction is the result of hydrogen bonding between polar atoms of the protein and nucleic acid bases. Therefore unnatural amino acid substitutions may alter the binding specificity (Maiti A, Roy S 2005 Nucleic Acids Res 33:5896). The interaction is not based on one to one relation rather a particular amino acid is more frequently distributed around a particular DNA base. Transcription factors recognize multiple genes, generally within families and this feature is conserved through evolution. Highly conserved bases seem to interact more specifically with particular protein residues. The binding may also be affected by changes in conformation due to mutation at a remote amino acid site. Through laboratory design binding proteins can be created for the regulation of gene function, which is of significance in biotechnology (Desjarlais JR, Berg JM 1994 Proc Natl Acad Sci USA 91:11099; King CA, Berg JM 1995 J Mol Biol 252:1). ▶transcription factors, ▶signal transduction, ▶DNA-binding protein domains, ▶single-strand binding protein, ▶footprinting, ▶EMSA, ▶protein arrays, ▶affinity-directed mass spectrometry, ▶UAS, ▶methyltransferase DNA, ▶protein binding, ▶threading, support vector machine based procedure for predictions: Bhardwaj N et al 2005 Nucleic Acids Res 33:6486; Ren B et al 2000 Science 290:2306; Verdine GL, Norman DPG 2003 Annu Rev Biochem 72:337; Sarai A, Kono H 2005 Annu Rev Biophys Biomol Struct 34:379; DNA and RNA binding server: <http://bioinformatics.ksu.edu/bindn/>, protein-protein binding site prediction: <http://biportal.weizmann.ac.il/promate/>.

Binet Test: ▶human intelligence

Binomial Coefficient: ▶binomial probability

Binomial Distribution: A distribution that is useful in genetics for the direct estimation of segregation ratios in the case of dominance by expansion of $(3 + 1)^n$ where n = is the number of heterozygous loci (note: $3 + 1$ must not be added). By expansion the binomial becomes:

$$1 \times 3^n + [(n!)/1!(n-1)!] \times 3^{n-1} \\ + [n!/2!(n-2)!] \times 3^{n-2} + \dots + [n!/(n-1)!] \\ \times 3^{n-(n-1)} + 1 \times 3^{n-n}$$

The *exponent* of a base gives the number of loci with the dominant phenotype, the *power* identifies the frequency of that phenotype, and the *coefficients* show how many times—quadruple, triple, etc.—dominant phenotypic classes will be expected theoretically. The solution for 4 heterozygous pairs of alleles:

$$(1 \times 3^4) + \left(\frac{4 \times 3 \times 2 \times 1}{1 \times 3 \times 2 \times 1} \times 3^{4-1} \right) \\ + \left(\frac{4 \times 3 \times 2 \times 1}{2 \times 1 \times 2 \times 1} \times 3^{4-2} \right) \\ + \left(\frac{4 \times 3 \times 2 \times 1}{3 \times 2 \times 1 \times 1} \times 3^{4-3} \right) + (1 \times 3^{4-4}) \\ = (1 \times 3^4) + \left(\frac{24}{6} \times 3^3 \right) + \left(\frac{24}{4} \times 3^2 \right) \\ + \left(\frac{24}{6} \times 3^1 \right) + (1 \times 3^0) \\ = (1 \times 81) + (4 \times 27) + (6 \times 9) \\ + (4 \times 3) + (1 \times 1)$$

Translated into genetic language in the case of an Aa Bb Cc Dd heterozygote's F₂ progeny the phenotypic classes will be:

81 ABCD, [27 ABCd, 27 ABcD, 27 AbCD, 27 aBCD], [9 ABcd, 9 AbCd, 9 AbcD, 9 aBCd, aBcD, 9 abCD], [3 Abcd, 3 aBcd, 3 abCd, 3 abcD], [1 abcd] or

81: 108 (4 × 27): 54 (6 × 9): 12 (4 × 3): 1

For the calculation of genotypic classes among the segregants see trinomials and multinomials.

▶Mendelian segregation, ▶Pascal triangle

Binomial Nomenclature: ▶taxonomy

Binomial Probability: P is the complete binomial probability function whereas the $n!/(x!(n-x)!)$ is the binomial coefficient, an integer that shows how many ways one can have x combinations of n , and $p = 0.75$ and $q = 0.25$ (because of the 3:1 segregation). In genetic experiments this shows—if we have

n = independently segregating gene loci, and the inheritance is dominant—how many ways can have x combinations of n ; e.g., if we deal with $n = 5$ loci and we wish to know the chance that at 3 ($=x$) loci the dominant phenotype would appear is then:

$$p = \binom{n}{x} p^x q^{(n-x)} \text{ and } \binom{n}{x} = \frac{n!}{x!(n-x)!}$$

$$[5!/(3!2!)] = (0.75^3)(0.25^2) \cong 0.26367$$

The binomial distribution is obtained from the expansion of the binomial terms $(p + q)^n$; its standard deviation $\sigma = \sqrt{\frac{pq}{n}}$ and $p + q = 1$; n = is the exponent.

►Pascal triangle, ►transmission disequilibrium, ►binomial distribution, ►trinomial distribution, ►Bernoulli process

Binuclear Zinc Cluster: A domain of a DNA-binding transcriptional activator containing 2 Zinc ions about 3.5 Å apart and regulated by 6 cysteines. ►Zinc finger

Bioarrays: Methods/software systems for analysis of microarray hybridization and other high throughput platforms. (Troen C et al 2006 Methods Enzymol 411:99).

Bioassays (biological assays): Used for determining the biological effect(s) of chemicals, drugs or any other factor on live animals, plants, microorganisms and cells.

Bioassays in Genetic Toxicology: Bioassays have been designed to assess mutagenic (and indirectly carcinogenic) properties of factors that human, animal, plant and microbial populations may be exposed to. Their range varies from testing chromosome breakage and point mutations in a wide variety of organisms using different endpoints. All the different procedures cannot be discussed or even enumerated here but the major types of tests include: (i) excision repair, (ii) reversion studies in *Salmonella* and *E. coli*, (iii) sister chromatid exchange, (iv) mitotic recombination, (v) host-mediated assays, (vi) specific locus mutation assays, (vii) micronuclei formation, (viii) chromosome breakage, (ix) sex-linked lethal assays, (x) unscheduled DNA synthesis, (xi) sperm morphology studies, (xii) cell transformation assays, (xiii) dominant mutation, (xiv) somatic mutation detection, (xv) *Arabidopsis* mutagen assays, (xvi) human mutagenic assays, (xvii) mitotic recombination as a bioassay in genetic toxicology, (xviii) *Tradescantia* stamen hair somatic mutation assay is popular for monitoring environmental pollution, (xix) zebrafish assay for mutagens in aquatic media, (xx) mouse lymphoma test. (see the essential features of these tests under the separate entries, ►transgene mutation assay, ►mutation

detection, ►hemiclonal, ►genotoxic chemicals, ►Big Blue ►MutaTM Mouse, ►toxicogenomics; Waters MD, Fostel JM 2004 Nature Rev Genet 5:936.

Bioavailability: The portion or fraction of drugs applied that can be accessed by living cells.

Biobank: A repository that is supposed to collect and maintain information on gene–environment relations in disease, based on large population studies.

Bio-Bar Code, Nano-Particle Based: ►nanoparticle-based bio-bar code

Biocatalysts: Enzymes mediating metabolic processes. They have numerous industrial applications and with the aid of molecular biotechnology means exist for improvement of their efficiency. (Burton SG et al 2002 Nature Biotechnol 20:37).

Biochemical Engineering: Synthesizes proteins and other new molecules in the laboratory without the direct involvement of the classical biosynthetic pathway. The products may have biological value in nutrition, therapeutics, etc. ►antibody engineering, ►nanotechnology, ►bioreactor, ►tissue engineering; unnatural amino acids.

Biochemical Genetics: Studies the genetic mechanisms involved in the determination and control of metabolic pathways. ►inborn errors of metabolism

Biochemical Mutant: The chemical basis of the mutant function is identified. ►auxotroph

Biochemical Pathway: The chemical steps involved in a biological function are represented in a sequence. Enzymes encoded by separate genes usually mediate the individual steps. ►One gene–one enzyme theorem, ►genetic networks, ►transcriptome, Rison SC, Thornton JM 2002 Current Opin Struct Biol 12:374.

Biochips: ►DNA chips, ►protein chips, ►electrical biochip

Biocoenosis (biocenosis): Different organisms living together within the same environment; some of them may be dependent on others for survival or interact in various ways.

Biocomputer: Use approaches different from the digital electronic computing. The input, output software and the hardware are biological molecules without electronic representation. This approach holds promise for the identification of disease conditions. ►DNA computer; Adar R et al Proc Natl Acad Sci USA 101:9960.

Bioconductor: Software for genome analysis (<http://www.bioconductor.org>).

Biocrystalization: DNA may be protected in prokaryotes by co-crystallization with the stress-induced protein Dps. Dps dodecamers protect against

oxidative damage (and nucleases) in a manner similar to ferritins. ► **ferritin**

B

BioCyc: A collection of a set of 160 pathway/genome databases (PGDB) based on the MetaCyc database. ► **MetaCyc**, ► **Pathway Tools**, Karp PD et al 2005 Nucleic Acids Res 33:6083; 142 databases: <http://biocyc.org>; <http://www.org/open-compounds.shtml>, pathway tools for downloading: <http://biocyc.org/download.shtml>.

Biodegradation: Decomposition, destruction of substances by bacterial or other organisms. ► **oil spills**, ► **Pseudomonas**, ► **bioremediation**; <http://umbbd.ahc.umn.edu/>.

Biodiversity: See species extant: <http://www.sp2000.org/>; <http://ip30.eti.uva.nl/BIS/index.php>.

Bioengineering: The replacement of body parts by means of mechanical or biological manufactured devices. (Science 2002 vol 295:998–1031).

Bioethics: The application of ethical principles to biotechnology, medical, genetic and related fields. (► **biotechnology**, ► **embryo research**, ► **nuclear transplantation**, ► **ethics**, ► **informed consent**, ► **human subjects**; Merz JF et al 2002 Am J Hum Genet 70:965; <http://www.bioethics.net>; <http://www.hhmi.org/bioethics>); http://www.ornl.gov/sci/techresources/Human_Genome/elsi/elsi.shtml; <http://www.ornl.gov/hgmis/elsi/elsi.html>; <http://www.nhgri.nih.gov/ELSI/>.

Biofilm: A community of single-cell organisms established as a surface layer with chemical communication among the components. Bacterial aggregates of single or dozens of different species (including also fungi) surrounded by foamy substance and resistant to many types of disinfectants, antibiotics or to antibodies. Within the biofilm, the bacteria may show morphological differentiation depending on actual environment. Also in these cells, different mutations may arise (Kolter R, Greenberg EP 2006 Nature [Lond] 441:300). Aminoglycoside antibiotics can induce biofilm formation and the bacteria become resistant to antibiotics. It appears that an inner membrane phosphodiesterase with substrate for cyclic di-guanosine monophosphate regulates surface adhesiveness and guanosine triphosphate, an inhibitor of this enzyme, reduces biofilm formation (Hoffman LR et al 2005 Nature [Lond] 346:1171). Cells within the biofilm differentiate differently than free-living bacteria. Polymer production suffocates neighboring non-polymer producers and it suggests that polymer secretion provides a strong competitive advantage to cell lineages within mixed-genotype biofilms and global cooperation is not required (Xavier JB, Foster KR 2007 Proc Natl Acad Sci USA 104:876). Engineered bacteriophage T7 containing a biofilm- and *E. coli*-degrading

enzyme eliminates the bacteria ~4.5 orders of magnitude more effectively than non-enzymatic procedures (Lu TK, Collins JJ 2007 Proc Natl Acad Sci USA 104:11197). The polysaccharide (alginate) film may corrode pipes, medical equipment and may be responsible for dental plaques, lung, kidney, prostate, etc. infections and inflammation. The development of the biofilm usually requires quorum-sensing signals. Some fungi (*Candida albicans*) can also form biofilm. ► **algin**, ► **quorum-sensing**, ► **cystic fibrosis**, ► **antibiotics**, ► **antibiotic resistance**, ► **aminoglycosides**; O'Toole G et al 2000 Annu Rev Microbiol 54:49; Whitely M et al 2001 Nature [Lond] 413:860.

Bio-Gel: A commercial ion exchange chromatography medium suitable for the separation of RNA from DNA, purification of oligonucleotides, linkers, etc.

Biogenesis: The cells arise only from cells rather than from non-living organic material. ► **spontaneous generation**

Biohazards: Working with pathogenic organisms or transgenic material containing potentially dangerous genes (coding for toxins). Containment (P1 to P4, the latter the most stringent) is necessary and the appropriate safety regulations must be complied with. Transgenic plants may transmit by cross-pollination the nuclear transgene (e.g., herbicide or antibiotic resistance) to other plants, including weeds. Some of this unwanted transmission problems can be prevented by using transgenic chloroplasts or mitochondria that are only maternally transmitted (Danielle H 2007 Proc Natl Acad Sci USA 104:6879). Information for particular cases can be obtained from the local biohazard committees or from National Institute of Health, Building 31, Room A452, Bethesda, MD 20205, USA. ► **biological containment**, ► **recombinant DNA and biohazards**, ► **laboratory safety**, ► **GMO**

Bioinformatics: The use of computers for developing algorithms, information gathering, storage and analysis of molecular biological data. ► **GenBank**, ► **NCBI**, ► **GSDB**, ► **databases**, ► **image analyzer**, Basset DE Jr et al Nature Genet Suppl Vol 21; Searls DB 2000 Annu Rev Genomics Hum Genet 1:251; Jenssen TK et al 2001 Nature Genet 28:21; Letovsky S (Ed) 1999 Bioinformatics. Databases and Systems 1999 Kluwer, Boston; Davidson D, Baldock R 2001 Nature Rev Genet 2:409; Yandell MD, Majoros WH 2002 Nature Rev Genet 3:601; Kanehisa M, Bork P 2003 Nature Genet 33 (Suppl.):305, <http://www.ncbi.nlm.nih.gov/Tools/index.html>, macromolecular structure, function, taxonomy, sequences: <http://www.ebi.ac.uk/msd-srv/docs/sifts>, bioinformatics assistance: <http://www.ebi.ac.uk/2can/home.html>, HSLS On-line Bioinformatics Resources Collection (OBRC)

contains annotated information and guided links to 1542 open sources bioinformatics databases and software tools: <http://www.hsls.pitt.edu/guides/genetics/obrc>.

Biolistic Transformation: It (biological-ballistic) introduces genes into the nuclei of cells (of the germline) by shooting DNA coated particles into the target cells, propelled by high-power air or helium guns. It is a most useful procedure when other methods of transformation are not sufficiently successful. It can accomplish transformation also in terminally differentiated cells and chloroplasts and mitochondria. High efficiency mitochondrial transformation (100–250 transformants μg DNA) of *Chlamydomonas reinhardtii* with linearized plasmid DNA is feasible. Gene guns are also used for cancer gene therapy and genetic immunization. ▶ [Transformation](#), ▶ [chloroplast genetics](#), ▶ [mitochondrial genetics](#), ▶ [cancer gene therapy](#), ▶ [immunization genetic](#), ▶ [Chlamydomonas](#); Klein TM et al 1987 Nature [Lond] 327:70; Maenpaa P et al 1999 Mol Biotechnol 13:67.

Biological Clock: Frequently called circadian rhythm; it measures in various organisms daily periods and responses to alternation of daily light and dark cycles. The endogenous rhythms also influence gene activity and developmental patterns. ▶ [circadian](#); <http://www.cbt.virginia.edu>.

Biological Containment: The preventive measures to avoid the spread of potentially hazardous organism outside the laboratory. Recombinant DNA-containing organisms with unknown biological impact in the environment may be prevented from spreading accidentally, by using transformation vectors that lack the *bom* and *nic* sites facilitating plasmid mobilization. The cloning bacteria may have an absolute requirement for diaminopimelic acid (lysine precursor), deficient in excision repair (*uvrB* deletion), auxotrophic for thymidine and *rec*[−] (recombination and repair deficient). Thus even after accidental escape, assuming a mutation rate of 10^{-6} for each of the 5 loci, they would require $(10^{-6})^5 = 10^{-30}$ chance to succeed in the environment. 10^{30} *E. coli* bacterial cell number has a mass of about 10^{11} metric tons. The mass of the Earth has been estimated to be 10^{20} tons. ▶ [biohazards](#)

Biological Control: Pathogens or parasites are contained by propagation of their natural enemies or by other pathogens or parasites (e.g., *Aphelinus mali*) or genetically engineered organisms. *Colletotrichum truncatum* fungus is used as weed killer bioherbicide, *Sesbania exaltata*, in various crops such as soybeans, rice and cotton. Attack of plants by armyworm (*Spodoptera exigua*) is concomitant with the oral secretion of *N*-(17-hydroxylinolenoyl)-L-glutamine

[volicitin], which triggers the emission of chemical signals by the plants that attract parasitic wasps, predators of armyworm larvae (see Fig. B37). In some instances, the parasitic wasps are attacked by bacterial symbionts of the host and the presence of the latter may also adversely affect the host's fecundity and longevity. The parasitic wasp *Trichogramma brassicae* spies on mated *Pieris brassicae* butterflies and it is attracted to the pheromone passed from the male to the female to discourage conspecific males. The small wasp (0.5 mm long) then rides on the female and when she lays eggs, the wasp parasitizes them. It is interesting that the wasps show no interest in virgin female butterflies (Fatouros NE et al 2005 Nature [Lond] 433:704). When their roots are attacked by the weevil *Diabrotica virgifera*, wild ancestors and European varieties of maize emit the sesquiterpenoid (E)- β -caryophyllene (see Fig. B38), an attractant for the entomopathogenic nematode, *Heterorhabditis megidis* and it reduces the herbivorous insect population to about half (Rasmann S et al 2005 Nature [Lond] 434:732). Although biological control is frequently considered as the safest method of protection, some biologists worry about the general environmental impact. Some of the control organisms may adversely affect useful native species. ▶ [Bacillus thuringiensis](#), ▶ [genetic sterilization](#), ▶ [Dengue virus](#), ▶ [BEV](#), ▶ [antisense RNA](#), ▶ [conspecific](#), ▶ [parasitoid](#), ▶ [aphids](#); Howarth FG 1991 Annu Rev Entomol 36:485; Pemberton RW, Strong DR 2000 Science 290:1896; Louda SM et al 2003 Annu Rev Entomol 48:365, <http://www.nhm.ac.uk/entomology/chalcidoids>; <http://ipmworld.umn.edu/>.

Figure B37. There are many types of parasitic wasps. The female insect has a long egg depository tube used for placing their eggs into the eggs of another insect

Figure B38. Caryophyllene

Biological Membranes: ►cell membranes**B**

Biological Mutagens: A large number of natural products present in different organisms may be mutagenic for others. Spontaneous mutation may be also increased by endogenous factors such as defective DNA polymerase or defects in the genetic repair system. ►mutator genes, ►transposable elements, ►transposons, ►insertional mutation, ►epigenetics

Biological Systems: ►systems biology

Biological Weapons: It may contain highly pathogenic microorganisms such as *Bacillus anthracis* (anthrax), *Corynebacterium diphtheriae* (diphtheria), *Pasteurella pestis/Yersinia pestis* (bubonic plague), *Francisella tularensis* (tularemia), and various viruses. The *Clostridium botulinum* toxin or castor bean toxin, ricin may also be very dangerous. (The Botox toxin has been used recently for the very questionable cosmetic purpose to reduce facial wrinkles by immobilizing muscles through blocking of acetylcholine at the ends of the motor nerves.) In case the genetic signature of all organisms potentially usable for biological warfare would be available, the rapid identification and effective protection may be facilitated.

The agents are categorized as A if they constitute a national hazard by their easy transmission, have major health impact, possibly increase death rates, and they potentially impacts society to a serious extent. Category B agents constitute somewhat reduced hazards, yet require enhanced surveillance and diagnostic capacities. Category C agents include new pathogens that can be modified for higher disease effectiveness and are potentially hazardous. Research on these agents requires special containment facilities. The availability of genomic sequences of the pathogens facilitates the identification of the organisms and facilitates taking effective defensive measures. ►signature of molecules, ►anthrax, ►*Yersinia*, ►tularemia, ►diphtheria toxin, ►Pox virus, ►*Clostridium botulinum*, ►ricin, ►*Francisella*, ►sarin; Stone R 2001 Science 293:414; Kortepeter MG et al 2001 J Env Health 63(6):21; Hawley RJ, Eitzen EM Jr 2001 Annu Rev Microbiol 55:235; Fraser CM 2004 Nature Rev Genet 5:23, <http://www.virology.net/garryfavwebbw.html>.

Biologics: The material is of biological nature, the processing is biological, the quality of the product is determined by biological methods.

Bioluminescence: ►luciferase, ►aequorin

Biomarker: Any product of the body (e.g., a metabolite) that may respond to adverse environmental effects (carcinogens, mutagens, etc.) or that may be specific for a biological condition, e.g., cancer, other disease,

developmental change or any other function. Biomarkers are important diagnostic and prognostic aids in health and disease. Identification of good biomarkers may facilitate the design of appropriate therapy at a particular stage of a disease. It may help to reveal effective drug targets. If good biomarkers are available, the most likely positive responses may be predicted and unresponsive individuals can be spared from the potential side effects of treatments. Biomarker availability is expected to meet the needs of personalized therapy. Unfortunately, only few effective biomarkers are available for clinical guidance. Gleevec, a tyrosine kinase inhibitor, is a very effective new class of drug against chronic myelogenous leukemia. Gefitinib, also a tyrosine kinase inhibitor capable of blocking epidermal growth factor receptor (EGFR) is used for treating non-small cell lung cancer. Japanese patients respond better to this drug because of differences in missense mutations in those populations compared to people of European descent. Trastuzumab/Herceptin is a monoclonal antibody targeting primarily a tyrosine kinase receptor encoded at 17q12 and involved in certain subtypes of breast cancer. Unfortunately, multiple genes affect the majority of cancers. Therefore only genomic analysis may provide satisfactory approach. Such studies can provide biological signatures for the disease and treatment and are in the frontline of research. The outcome of the research may be affected by genetic, developmental and environmental conditions, the methodology used (proteomics or RNA microarrays) and the statistical analysis employed (t-test or multivariate). (see Dalton WS, Friend SH 2006 Science 312:1165; ►Gleevec, ►Gefitinib, ►Iressa, ►Herceptin, ►Avastin, ►Trastuzumab, ►cancer, ►genetic medicine, ►receptor tyrosine kinases, ►Desatinib, ►Sutent, ►Lepatinib, ►biomarkers in development: http://www.imgenex.com/emarketing/083106_Tissuearray/elucidating_protein_signatures.htm).

Biomaterial: Generally synthetic substances—other than drugs—useful for biological and/or medical devices such as tissue replacement, gene delivery vehicles, diagnostic and array technologies. (see Langer R, Tirrell DA 2004 Nature [Lond] 428:487).

Biometric: An electronic code of human physical features (fingerprints, eye iris scans), and can be used for digital personal identification.

Biometry: Mathematical statistical principles applicable to the study of genetic and non-genetic variation in biology. ►quantitative genetics, ►population genetics

Biomimetic Particles: The system is based on a peptide that recognizes clotted plasma proteins and selectively homes to tumors, where it binds to vessel walls

and tumor stroma. Iron oxide nanoparticles and liposomes coated with this tumor-homing peptide accumulate in tumor vessels, where they induce additional local clotting, and thereby producing new binding sites for more particles. The system mimics platelets, which also circulate freely but accumulate at a diseased site and amplify their own accumulation at that site. The self-amplifying homing is a novel function for nanoparticles. The system enhances tumor imaging, and the addition of a drug carrier function might also be exploited (Simberg D et al 2007 Proc Natl Acad Sci USA 104:932). ►nanoparticles

Biomining: Certain bacteria obtain energy by oxidizing inorganic materials. This process may release acid, which in turn can wash out metals from ores. ►*Thiobacillus ferrooxidans* can release copper and gold, ►*Pseudomonas cepacia* may assist phosphate mining. Eventually this biotechnology may become economical, especially for low-grade ores. Some plants, e.g., Brassica spp, Impatiens spp. may accumulate gold from the soil. ►Bioremediation; Mergeay M 1991 Trends Biotechnol 9:17; Guiliani N, Jerez CA 2000 Appl Environ Microbiol 66:2318.

Biomonitoring: Surveying potential mutagens, carcinogens or other health hazards using biological means such as organismal bio-assays for mutagens, blood cells, human buccal cells, nasal mucosal cells, scalp hair follicles, sputum, detached colon cells, cervical epithelia, exfoliated bladder cells, spermatozoa, bacteria, etc. The tests may involve cytological or molecular methods. ►quantum dots

Bionics: Construction of mechanical devices with the technology of engineering and biology.

Biopanning: The selection by repeated cycles for specific peptides (phage display), interactive ligands, etc. ►phage display, ►ligand; Giordano RJ et al 2001 Nature Med 7:1249; Shadidi M, Sioud M 2004 Methods Mol Biol 252:569.

Biopharming: Producing pharmacological agents by plants and animal transgenic for special genes. ►pharming, ►plant vaccines, ►single-chain Fv fragment; Ma JK-C et al 2003 Nature Rev Genet 4:794.

Biophilia: A hypothesis suggesting an innate human tendency to focus on life and life-like processes and interest in living beings as proposed by E.O. Wilson.

Biophore: A hypothesized hereditary unit of the pre-mendelian era. ►pangenesis

Biophore: A compound or structural element of it that may exert potential biological (carcinogen) activity. ►SAR, ►CASE, ►MULTICASE

Biophysics: The theory and practice of application of physical methods for the study of biological structures (e.g., nucleic acids, proteins) and mechanisms of function (energy conversions, thermodynamics). (<http://www.biophysics.org/education/>).

Biopiracy: The use of human genomic information for commercial purposes without the informed knowledge or consent of the individuals, or the sources of the DNA. ►informed consent

Biopoesis: The evolution of living cells from chemical substances rather than from other cells. ►evolution prebiotic, ►origin of life

Bioprospecting: Searching for natural products (genes) potentially useful for pharmaceutical or agricultural applications. ►biotechnology

Biopterin: A pterin derived co-factor of enzymes functioning in oxidation-reduction processes (see Fig. B39)

Figure B39. Biopterin

Bioreactor: A large-scale (industrial) culture of cells for the purpose of production and extraction of pharmaceuticals, enzymes, polypeptides, biodegradable plastics, etc. The use of transgenic organisms extended the range of utility of these procedures. Some constructions simulate conditions for growth in outer space. *Flow bioreactors* provide a continuous supply of fresh nutrients. In vitro operations may produce human organs, such as bones for therapeutic implantations. Skin and cartilage can already be proliferated outside the body for medical use. ►cell culture, ►chemostat, ►tissue culture, ►transgenic; Baoudreault R, Armstrong DW 1988 Trends Biotechnol 6:91.

Bioreactor: A collaborative software creation initiative for data acquisition, data management, data transformation, data modeling, combining different data sources, making use of evolving machine learning methods, and developing new modeling strategies suitable for computational biology and bioinformatics (Gentlemen RC et al 2004 Genome Biol 5:R80; <http://genomebiology.com/2004/5/10/R80>).

Bioremediation: A procedure of adding organisms to an environment for the purpose of promoting degradation of harmful or undesirable properties of that environment. Some observations indicate that 44 ±18% of polycyclic hydrocarbons of the atmosphere are captured by the vegetation and eventually

B

incorporated into the soil. Many polycyclic hydrocarbons are carcinogenic and mutagenic and pose serious health hazards to people and animals. Their removal from the atmosphere is desirable, however, it is not clear what is the consequence of eating plants that absorbed these semi-volatile compounds. Several organic compounds can be degraded by sequential exposure to anaerobic and aerobic bacteria. Bacterial mercuric ion reductase gene, in a re-engineered form, has been introduced into *Arabidopsis* plants by transformation and the transgenic plants became resistant to HgCl_2 and to Au^{3+} . The transgenic plants evolved substantial amounts of Hg^0 (vapors). *Arabidopsis* plants expressing the yeast gene YCF1 accumulate greater amounts of cadmium and lead and display greater resistance to these toxic metals (Song W-Y et al 2003 Nature Biotechnol 21:914). Plants can extract toxic substances from the soil (phytoextraction) and from water (rhizofiltration), thus facilitate the cleaning up of the environment. By a technique of genetic engineering cytochrome P450 monooxygenase genes can be combined with toluene dioxygenase genes in e.g., *Pseudomonas*. Such bacteria then can degrade polyhalogenated compounds such as 1,1,1,2-tetrachloroethane (a powerful narcotic and liver poison) to 1,1-dichloroethylene and eventually to formic and glyoxylic acids, which are still irritants but occur in natural products of ants and fruits, respectively, but do not pose serious threat at low concentrations. *Dehalococcoides ethenogenes* can degrade vinyl chloride to non-toxic ethane. ►environmental mutagens, ►biomining, ►biodegradation, ►soil remediation; Lovley DR 2001 Science 293:1444; Kramer U, Chardonens AN 2001 Appl Microbiol Biotechnol 55:661; He J et al 2003 Nature [Lond] 424:62; phytoremediation: Pilon-Smits E 2005 Annu Rev Plant Biol 56:15; <http://pdg.cnb.uam.es/MetaRouter>; http://www.pdg.cnb.uam.es/bio_deg_net/MetaRouter.

Bi-Orientation: The sister kinetochores are attached to spindle fibers that connect them to the opposite spindle poles. ►coorientation, ►spindle fibers, ►microtubule, ►kinetochore; Tanaka TU 2002 Current Opin Cell Biol 14:365.

Biosemiotics: The discipline of communication within and among biological systems.

Biosensors: They analyze macromolecular interactions in real time in intact cells. Among the different systems ligand-receptor binding and signal transduction pathways may be the most sensitive, especially when coupled to fluorescent stains. ►ligand, ►signal transduction, ►fluorochromes, ►aequorin, ►surface plasmon resonance; Aravanis AM et al 2001 Biosens Bioelectron 16:571; engineered protein biosensor:

Kohn JE, Plaxco KW 2005 Proc Natl Acad Sci USA 102:10841.

Bioseq: It contains relevant information about a biological sequence beyond what is included in the ASN.1. ►ASN.1, ►gi, ►accession number

Biosphere: The range of habitat of organisms living in and on the soil, in bodies of water and the atmosphere.

Biostratigraphy: The relative dating of the succession of different evolutionary forms of organisms on the basis the paleontological relics.

Bisulfite Reaction: Sodium bisulfite is a mutagen inducing point mutations and chromosomal aberrations. The bisulfite reaction permits also the distinction between cytosine and methylcytosine. In bisulfite-treated single-stranded DNA cytosine is converted into uracil (*bisulfite conversion*) but methylated cytosine is essentially non-reactive. The chemically modified DNA tract can then be amplified by PCR and sequenced to determine the location of the methylated base. A procedure has been worked out to assess the extent of DNA methylation (involved in epigenetic modification), applicable genome-wide (Meissner A et al 2005 Nucleic Acids Res 33:5868). ►methylation-specific PCR, ►methylation of DNA, ►epigenesis; Sasaki M et al 2003 Biochem Biophys Res Commun 309:305.

Biosynthesis: Synthesis of molecules by living cells.

Biota: The community of all living organisms in an environment.

Biotechnology: The purposeful application of biological principles to industrial, medical and agricultural production such as molecular alteration of enzymes, cloned recombinant DNA and its translated products (e.g., human insulin produced by transgenic bacteria), replacement of defective genes by site-specific recombination, gene medicine (introducing transiently into cells genes capable of producing the medication required), transfer desirable genes into domestic animals and plants by genetic transformation to improve their economic value, clean up environmental pollutants by modified microorganism capable of digesting crude oil, etc. The economic importance of the biotechnology industry is indicated by their total value of \$224 billion in 2002, and it employed more than 194,000 people (Rasnick D 2003 Nature Biotechnol 21:355). ►Genetic engineering, ►tissue engineering, ►bioethics, ►bioprospecting, ►genomics, ►GMO; applications to public health: Daar AS et al 2002 Nature Genet 32:229, approval by different social groups: Gaskell G et al 2005 Science 310:1908, agricultural biotech: <http://www.cid.harvard.edu/cidbiotech/homepage.htm>.

Bioterrorism: It produces fear and harm among selected individuals or in the general population or harm plants, animals or the environment with the use of agents like bacteria, viruses, fungi or toxins derived from biological agents. Mechanical detection of explosive devices carried by suicide bombers lack sufficient sensitivity for detection beyond distances of 10 meter and are too bulky and expensive for soft targets (Kaplan EH, Kress M 2005 Proc Natl Acad Sci USA 102:10399). ▶ **Biological weapons**, ▶ **pathogen identification**; Henderson DA 1999 Science 283:1279; Atlas RM 2002 Annu Rev Microbiol 56:167; Fauci AS 2003 Nature [Lond] 421:787; mathematical modeling of food supply poisoning: Wein LM, Liu Y 2005 Proc Natl Acad Sci USA 102:9984, <http://www.health.gov/nhic/Scripts/Hitlist.cfm?Keyword=Bioterrorism>, toxins, virulence factors, antibiotics for biodefense: <http://mvirdb.lnl.gov/>.

Biotic: Related to living organisms.

Biotinidase Deficiency (same as multiple carboxylase deficiency, 21q22.1, 3p25): An autosomal recessive disease yet the heterozygotes may be identified, however, by much less obvious symptoms. The biochemical basis is a deficiency of an enzyme (multiple carboxylase) that splits biocytin (biotin—ε-lysine) and thus generates free biotin from protein linkages. The symptoms that may have late onset or appear in neonates are hypotonia (reduced tension of muscles), ataxia (reduced coordination of the muscles), neurological deficiencies (hearing, vision), alopecia (baldness), skin rash, susceptibility to infections, etc. Generally, administration of biotin alleviates the symptoms and may restore normality. The prevalence varies within the 10^{-5} range. Simple procedure is available for the testing of blood by color on filter paper, without purification. ▶ **genetic screening**, ▶ **biotin**

Biotin: A vitamin, a mobile carrier of activated CO_2 , its major biological role involves pyruvate carboxylase (see Fig. B40). It combines with avidin and thus used for non-radioactive labeling. ▶ **non-radioactive labeling**, ▶ **fluorochromes**, ▶ **biotinylation**; Mardach R et al 2002 J Clin Invest 109:1617.

Figure B40. Biotin

Biotinylation: A very sensitive, non-radioactive labeling generated by incorporation into the DNA, with the aid of nick translation, biotinylated deoxyuridylic or deoxyadenylic acid. Biotin in the DNA has great affinity for streptavidin carrying a dye marker and the labeled DNA can thus be identified in light either cytologically or on membrane filters. ▶ **biotin**, ▶ **fluorochromes**, ▶ **labeling**, ▶ **FISH**; Demidov VV et al 2000 Curr Issues Mol Biol 2:31.

Biotope: A small, uniform ecological niche.

Biotrophic: A parasite living on live host. ▶ **saprophytic**

Biotype: Physiologically distinct race within a species.

BiP: A soluble heat-shock protein 70, a chaperone. It is an immunoglobulin-binding protein. ▶ **heat-shock proteins**, ▶ **Sps70**, ▶ **chaperone**

Biparental Inheritance: The female and male parents transmit the nuclear genes (see Fig. B41), in contrast, cytoplasmic organelles (and their genetic material) are most commonly inherited only through the egg, and therefore, the inheritance is uniparental (through the female). ▶ **allophenic**, ▶ **mtDNA**, ▶ **mitochondrial genetics**, ▶ **chloroplast genetics**, ▶ **meiotic drive**

Figure B41. Bride & groom, ceramics By Margit Kovács

Bipedal: Animals walking on two feet as an evolutionarily developed characteristic.

Bipolar Mood Disorder: A complex human disorder involving manic depression fluctuating with euphoria. Putative genetic determinants have been found in human chromosomes 1p33-p36, 2p, 2q21-q33, 3p14, 3p21, 3q26-q27, 4p15.3-p16.1, 5p15, 6q21-q22, 8q24, 8p21, 10q25-q26, 7, 13q11, 13q31-q34, 14q12-q13, 15, 16, 17q and 18, 21q22. Apparently, a major factor associated with human chromosome

B

22q12 is XBP1 (X box-binding protein transcription factor controlling class II major histocompatibility complex antigens). It involves the control of a heat-shock protein (HSPA5) mediating protein folding in the endoplasmic reticulum (Kakiuchi C et al 2003 Nature Genet 35:171).

By all evidence, several genes contribute to bipolar disorders (Dick DM et al 2003 Am J Hum Genet 73:107; also corrections *ibid.* 73:979). Prevalence of the various manifestations during a lifetime is about 1%. Among artistically creative persons, Hemingway, Gogol, Strindberg, Byron, Goethe, van Gogh, Goya, Donizetti, Handel, Klemperer, Mahler, Schumann and others suffered from this illness to a variable degree (Janka Z 2004 Orvosi Hetilap [in Hungarian]: 145:1709). ▶ [affective disorders](#), ▶ [depression](#), ▶ [manic depression](#), ▶ [lithium](#), ▶ [unipolar depression](#), ▶ [psychoses](#), ▶ [HLA](#), ▶ [QTL](#), ▶ [GSMA](#), ▶ [reelin](#); Kelsoe JR et al 2001 Proc Natl Acad Sci USA 98:585; Cichon S et al 2001 Hum Mol Genet 10:2933; Mitchell PB, Malhi GS 2002 Annu Rev Med 53:173; Segurado R et al 2003 Am J Hum Genet 73:49, review: Belmaker RH 2004 New England J Med 351:476.

Bipolarity: Both strands of the DNA are transcribed in opposite \rightarrow directions.

BIR (chromosome break-induced replication): A mechanism to repair a broken single strand of a chromosome by new DNA synthesis. In haploid budding yeast, Rad51-dependent BIR induced by HO endonuclease requires the lagging strand DNA Pol α -primase complex as well as Pol δ to initiate new DNA synthesis. Pol ϵ is not required for the initial primer extension step of BIR but is required to complete 30 kb of new DNA synthesis. Initiation of BIR also requires the nonessential DNA Pol δ subunit Pol32 primarily through its interaction with another Pol δ subunit, Pol31 (Leydeard JR et al 2007 Nature [Lond] 448:820). (See Kraus E et al 2001 Proc Natl Acad Sci USA 98:8255, BIR in yeast telomere elongation: McEachern MJ, Haber JE 2006 Annu Rev Biochem 75:115).

BIR (baculoviral IAP repeats): N-terminal motifs in the IAP proteins, in one or several copies. The Bir1p protein is an inhibitor of apoptosis and in cooperation with the kinetochore proteins Ndc10p, Cep3p, Ctf13p and Skp1p controls chromosome segregation. ▶ [IAP](#), ▶ [kinetochore](#)

Birch (*Betula*): The silver birch, hardwood tree *B. pubescens* is $2n = 28$ and the *B. verrucosa* is $2n = 56$; $x = 14$ (see Fig. B42).

Figure B42. Birch

BIRN (Biomedical Informatics Research Network, <http://www.nbirn.net/>; <http://birn.ncrr.nih.gov>): Initially it was concerned with neurosciences but now it is extended to a wide range of biological projects. It provides an infrastructure for biology, computer science and statistics with the goal that in the mound of data, a pattern/patterns could be found that would suggest mechanisms of function and facilitate further experimental tests. ▶ [Internet2](#), ▶ [Abilene](#)

Birnavirus: Icosahedral double-stranded RNA virus.

Birth Control: ▶ [contraceptives](#), ▶ [hormone receptors](#), ▶ [sex hormones](#), ▶ [menstruation](#)

Birt-Hogg-Dubé Syndrome: A genodermatosis (genetic skin disease) involving tumorous hair follicles, renal neoplasia, lung cysts and pneumothorax (air accumulation in the serous membrane of the chest). It is linked to the pericentromeric region of human chromosome 17p. (See Schmidt LS et al 2001 Am J Hum Genet 69:867).

Birth Defect: A perinatal anomaly of either hereditary (~6% chromosomal, ~7–8% monogenic, ~20% polygenic) or of extraneous cause (maternal disease, infection or caused by environmental physical or chemical agents).

Birth Rates: ▶ [age-specific birth and death rates](#)

Birth Weight: It may be affected by a number of intrauterine factors such as maternal nutrition, disease, smoking and also genetic causes. Some of the initial relative differences may or may not be eliminated during subsequent development. ▶ [glucokinase](#)

Birth-and-Death Evolution: ▶ [concerted evolution](#)

Bisexuality: May be a case of hermaphroditism or just a behavioral anomaly. In the fruit fly some losses in the brain olfactory centers or receptors lead to a defect of the interpretation of pheromones causing anatomically male flies to court females as well as males. ▶ [pheromones](#), ▶ [hermaphrodite](#), ▶ [homosexual](#), ▶ [olfactory](#), ▶ [olfactogenetics](#), ▶ [sex determination](#)

Bison: American buffalo (*Bison bison*), $2n = 60$.

Bispecific Monoclonal Antibodies (diabody): One of the two arms of the antibody has the recognition site for the surface antigens of a tumor cell, the other for

the antigens of a killer lymphocyte. The bispecific antibody is thus expected to bring these two cells together and destroy the tumor cells. ►antibodies, ►monoclonal antibodies, ►antibody engineering, ►diabody, ►triabody, ►quadroma

Bisphenol: An estrogen and an industrial chemical used in manufacturing polycarbonate food and beverage containers. It can leach out and may be hazardous to developing offspring (see Fig. B43). ►estradiol, ►sex hormones

Figure B43. Bisphenol

Bistable Systems: They can toggle between two alternative steady-states but cannot rest in intermediate states. Such systems have importance for signal transduction, feedback and differentiation. ►signal transduction, ►feedback; Ferrell JE Jr 2002 Current Opin Cell Biol 14:140.

Biston betularia (peppered moth): A frequently used example for adaptive natural selection (see Fig. B44). The moth had predominantly overall grayish tones until the industrial revolution in the vicinity of Birmingham, England deposited black soot on the tree barks and favored the propagation of the dark colored (carbonaria) form of the moth that could hide better from predators. In unpolluted areas the light peppered form remained. These experiments have been subjected to criticism, mainly on ground of flawed methodology because during the decades after the publication of the Kettlewell experiments of the 1950s (Nature 175:943) the dark forms declined. The moth population is actually in a dynamic equilibrium and frequency-dependent selection affects the frequency of different types (Cook LM 2003 Quarterly Rev Biol 78:399). (Cook LM, Grant BS 2000 Heredity 85:580).

Figure B44. *Biston betularia*

Bisulfite (sodium bisulfite, HNaO_3): deaminates cytosine to uracil (Shortle D et al 1981 Annu Rev Genet 15:265).

Bit: A binary digit with a two-way choice such as a value of 1 or 0, on or off, etc. The smallest unit of information a computer recognizes. One byte = 8 bit and 1 kilobyte (K) is 1024 bytes (2^{10}); 1 megabyte (MB) = 2^{20} bytes.

Bithorax: (bx, 3–58.8) ►morphogenesis in *Drosophila* (see Fig. B45), ►Polycomb, Duncan I 1987 Annu Rev Genet 21:285.

Figure B45. *Bithorax*. (From Bridges & Morgan 1923, bx)

Bitmap: Bits representing a graphic image in the memory of a computer.

Bitnote: A message communicated through the computer (e-mail) using the Bitnet system, an IBM mainframe connection to the Internet. ►Internet

BITOLA (Biomedical Discovery Support System): Directs potential relationships between biomedical concepts. The concepts are under Medical Subject Heading (MSH) that is indexed in Medline and HUGO. The system facilitates the discovery of disease–candidate gene relations. Background knowledge and chromosomal locations are included. ►Medline, ►LocusLink, ►HUGO; <http://www.mf.uni-lj.si/bitola/>.

Bitransgenic Regulation: The *A* transgene to be expressed must have its regulator transgene *R* be present in the cell. For normal function, the appropriate ligand(s) must also be available within the cell. ►transgenic, ►ligand; Yao TP et al 1992 Cell 71:63.

Bitscore: The raw quantitated sequence alignment score that indicates the statistical property of the scoring system. It is the likelihood that a query sequence is a genuine homolog of the sequence in the database. The natural logarithm of this likelihood ratio is the bits score. ►Blast, ►likelihood

Bivalent: Two homologous chromosomes, consisting of altogether of 4 chromatids, paired in meiotic prophase. ►heteromorphic bivalent, ►interlocking bivalent, ►chromatid, ►synaptonemal complex

Bivalent Promoters: In embryonic stem cells, bivalent promoters carry both trimethylated lysines at 4 and 27 position of histone 3 (H3K4me3 and H3K27me3).

B

The former is conducive to transcription, the latter to silencing. This combination probably serves to poise key developmental genes for lineage-specific activation or repression, respectively.

Bivariate Distribution: The joint distribution of two random variables.

Bivariate Flow Cytometry: Sorting chromosomes tagged with two fluorochromes (Hoechst 33258), specific for A=T and chloromycin A3, specific for G=C, and excited by laser. flow cytometry, laser; Nunez R 2001 Curr Issues Mol Biol 3:67.

Bivariate Plot: Two-dimensional arrangement of data of two variables.

Bivoltinism: Insects have two generations per year.

Bixin: A pigment extracted from *Bixin orellana*, a tropical American plant and it is used in food and cosmetic industry. It is produced by several steps from lycopene and can now be synthesized in *E. coli* transformed for three genes encoding the critical enzymes. ▶lycopene; Bouvier F et al 2003 Science 300:2089.

BK Virus: It has 80% homology to Simian virus 40 with a somewhat different host range (human, monkey, hamster and other rodent cells). It may occur as an episomal element in two dozen to hundreds of copies. Its autonomous replicon may be useful for propagating DNA and genes in human cell cultures.

BKM Sequences: tetranucleotide GATA and GACA repeats in the W chromosomes (comparable to the Y chromosome) of birds and reptiles, occasionally in other eukaryotic chromosomes. ▶satellite DNA, ▶tetranucleotide repeats, ▶Y chromosome

Black Box: A slang expression for equipment that is too complicated inside to be generally understood. Figuratively, a living cell was considered to be a black box because some of its functions were observed yet all the mechanisms that drove these functions were not fully understood. Geneticists knew segregation of genes and chromosomes but the molecular mechanisms underlying these processes were largely shut inside the “black box” until the discoveries of DNA replication, transcription, translation, gene regulation, cell cycle, etc.

Black Locust (*Robinia pseudoacacia*): A leguminous tree with fragrant flowers; $2n = 20$.

Black Pepper (*Piper nigrum*): Southeast Asian spice. Basic chromosome number probably 12, 13, or 16, and $2n = 46, 52, 104$ and 128 have been reported.

Bladder Exstrophy: An apparently recessive familial disease with poor penetrance. A defect of the hindgut

(cloaca) results in open lower abdominal wall, pubis, lower urinary tract and the genitalia. The expressivity varies.

β-Lactamase: An enzyme (synonym: penicillinase) capable of cleaving the β-lactam ring of antibiotics of the penicillin family (see Fig. B46). Their activity is determined by the R-group attached to the lactam ring. The majority of the synthetic penicillins are not susceptible to penicillinase action. The coding gene was originally detected in Tn3. The ampicillin resistance gene in the pBR322 plasmid codes for 263 amino acid residue pre-protein containing a 23 amino acid leader sequence, which directs the secretion of the protein into the periplasmic space of the bacterium. The transcription of the gene starts counterclockwise at pBR322 coordinate 4146 and ends at 3297. Its mRNA in vitro contains a 5'-pppGpA terminus. The tetracycline resistance gene in pBR322 is transcribed from another promoter clockwise, starting at coordinate 244 or 245. The *Tc^R* gene encodes a polypeptide of 396 residues. Penicillinases occur naturally only in bacteria with peptidoglycan cell wall. The lack of the enzyme, in the absence of antibiotics, is inconsequential for the bacteria. The β-lactamase genes are used extensively in vector construction (to convey antibiotic resistance) and for the detection of insertional events that inactivate the enzymes. The lactamase enzyme can be used for real time monitoring gene transcription. A substrate (e.g., cephalosporin) complexed with a fluorochrome (7-hydroxy-coumarin) upon hydrolysis may generate a wavelength shift (from blue to green) in the emission of the substrate located in the plasma membrane. With aid of a cell sorter, transcription can be monitored in single cells. β-Lactamase is inhibited by clavulanic acid (an oxygen containing β-lactam). ▶antibiotics, ▶Tn3, ▶periplasma, ▶vectors, ▶cell sorter, ▶fluorochrome, ▶coumarin, ▶penicillin, ▶PBP; Daiyasu H et al 2001 FEBS Lett 503:1; Jacoby GA et al 2005 New Engl J Med 352:380.

Figure B46. β-Lactamase

Blank Allele: It is not expressed.

BLAST (basic local alignment search tool): It is used for comparison of nucleotide sequences in apparently related (homologous) DNA (Altschul SF et al 1990 J Mol Biol 215:403) or for amino acid sequences in proteins (for DNA BLAST and for proteins PSI-BLAST: Altschul SF et al 1997 Nucleic Acids Res 25:3389). E-mail address blast@ncbi.nlm.nih.gov. ▶DNA sequencing, ▶MegaBLAST, ▶homology, ▶evolutionary tree, ▶FASTA, ▶BLOSUM, ▶databases; Trends Supplement [Elsevier Science] 1998; Wolfsberg TG, Madden TL 1999 In: Ausubel FM et al (eds) Short protocols in molecular biology, Wiley, New York, p.18-1, <http://www.ncbi.nlm.nih.gov/BLAST/>, WU-BLAST: <http://blast.wustl.eduftp://ftp.ncbi.nih.gov/blast/executables/LATEST/>.

Blast Cell: A cell, which may give rise to a progeny cell(s) different from itself.

BLASTP: BLAST for proteins. ▶BLAST

Blastema: A group of cells resembling stem cells in function and instrumental in tissue or organ regeneration. Hsp60 is required for regeneration of animal organs from blastema. Mutation in Hsp60 leads into mitochondrial defects and apoptosis (Makino S et al 2005 Proc Natl Acad Sci USA 102:14599). ▶chaperonin, ▶apoptosis, ▶regeneration in animals

Blastid: The site in the fertilized egg where cellular organization takes place.

Blastocoele: ▶Blastula

Blastocyst: An early embryonal stage (of about 60 cells in mammals) when the blastocoele is enveloped by a trophoblast cell layer, a pre-implantation stage of the animal zygote when the zona pellucida (the envelop of the egg) is still visible and the blastula begins to develop its inner cell mass (see Fig. B47). Before implantation the blastocysts sheds the zona pellucida. The mode of implantation is somewhat different in different mammals. ▶blastocoele, ▶trophoblast, ▶blastula, ▶stem cells, ▶uterus; Wang H, Dey SK 2006 Nature Rev Genet 7:185.

Figure B47. Blastocyst

Blastocyte: An undifferentiated cell of an early zygote.

Blastoderm: A single layer of cells at the embryonic stage of insects surrounding a fluid-containing cavity (blastocoele) at the blastula stage of cell divisions.

Blastoma: A cell in the early stage of differentiation or a neoplastic tissue containing embryonic cells.

Blastomeres: The large fertilized egg through cleavage divisions produces smaller cells, the blastomeres. These divisions are extremely fast and during the short process RNA synthesis ceases and protein synthesis depends on reserve mRNAs. Individual blastomeres of the mouse are already different at the two-cell stage as detectable by the localization of the Cdx2 transcription factor. This cell gives rise to the trophectoderm during the following divisions (Deb K et al 2006 Science 311:992). ▶blastoderm, ▶cleavage, ▶founder cells, ▶Cdx2, ▶trophectoderm, ▶oviduct, ▶morula

Blastopore: Located near the site of the gray center of the animal pole where invagination of the blastula begins and eventually encompasses the vegetal pole. The *dorsal lip* of the blastopore organizes gastrulation. ▶blastula, ▶animal pole, ▶vegetal pole, ▶gastrulation, ▶organizer

Blastula: A product of the cleavage of the early zygote when it becomes a spherical structure in which the blastoderm envelops the blastocoele cavity. ▶blastocoele

BLASTX: A computer program for gene and protein searches. (Nature Genet. 3:266 [1993]).

BLAT: A computer program for aligning nucleotide or amino acid sequences. (Ogasawara J, Morishita S 2003 J Bioinform Comput Biol 1:363).

Blattner Number: Refers to the position of genes in the sequenced genome of *E. coli* bacterium. ▶*E. coli*, Blattner FR et al 1997 Science 277:1453; Riley M, Serres MH 2000 Annu Rev Microbiol 54:341; Liang P et al 2002 Physiol Genomics 9:15; <http://genprotec.mbl.edu/>.

Blau Disease: A form of ulcerative colitis (intestinal inflammation) under the control of more than a single gene. Its symptoms overlap with those of Crohn disease. ▶Crohn disease; Miceli-Richard; C et al 2001 Nature Genet 29:19.

Blebistatin: (-)-blebistatin is an inhibitor of myosin II of mammals and thus the contraction of the cytokinesis cleavage furrow without affecting the assembly of the contractile ring. ▶cytokinesis, ▶myosin; Straight AF et al 2003 Science 299:1743.

Bleeder Disease: ▶hemophilia, ▶antihemophilic factors

bullosa the larger vesicles appear in clusters on the palms, soles, neck and around the mouth apparently due to a mutation in the keratin 14 gene. Another epidermolysis bullosa appears to be due to deficiency of galactosylhydroxyllysyl glucosyltransferase. In one form, a human chromosome 12-coded gelatin-specific metalloprotease deficiency may be involved. A mottled type (pigmented spots) displays recurrent blistering beginning at birth and premature aging. The epidermolysis bullosa with absence of skin and deformity of nails has a perfect penetrance. The autosomal recessive types: epidermolysis bullosa dystrophica (human chromosome 11q11-q13) is caused by excessive collagenase activity affecting primarily the hands, feet, elbows and knees at birth or infancy but may affect other organs too. The epidermolysis bullosa letalis may kill infants within about three weeks after birth but occasionally some survive to the first decade of life. In some forms the distal opening of the stomach (pylorus) may be constricted and atrophied and in other forms congenital deafness, muscular dystrophy may appear. X-linked epidermolysis with multiple complications (baldness, hyperpigmentation, dwarfism, microcephaly [small head], mental retardation, finger and nail malformation, and death before adult age is also known.) ►keratosis, ►ichthyosis, ►skin diseases

BLK: ►SRC oncogene family

BLM: ►Bloom syndrome

Bloch-Sulzberger Syndrome: ►incontinentia pigmenti

Block: A group of related sequences in proteins or DNA stretches between recombination sites. (Kimmel G, Shamir R 2005 Proc Natl Acad Sci USA 102:158; protein block database: <http://motif.stanford.edu/eblocks/>).

Block Design: Generally each treatment is present in every block (complete block) where the treatments may be randomized. In the incomplete block design, not all treatments are present in each block because of the large number of treatments causes technical difficulties. In the latter cases mathematics is used for compensation.

Block Mutation: It affects more than a single nucleotide in the cell, e.g., deletion; such mutations may not yield wild type recombinants if the defects overlap.

Blocked Reading Frame: Translation is interrupted by nonsense codons. ►nonsense codons

Blocking Buffer: 3% BSA (bovine serum albumin) in phosphate buffered saline containing also 0.02% sodium azide. BSA blocks the binding sites on nitrocellulose filter that are not occupied by proteins

transferred from (SDS polyacrylamide) gels. ►gel electrophoresis

Blocks: An Internet tool for the search of functional DNA motifs: blocks@howard.fhcrc.org or <http://blocks.fhcrc.org>.

Blog: Informal communication through the Internet about various topics from science to politics. The site <http://scienceblogs.com/> contains an index of blogs of possible interest to science. More information about blogging: Bonetta L 2007 Cell 129:445.

Blood: The fluid that carries nutrients and oxygen by circulating through the blood vessels in the animal body. It is composed of red (non-nucleated mature erythrocytes) and white (nucleated leukocytes) cells. The white cells include granulocytes, neutrophils, eosinophils and basophils, B and T lymphocytes and natural killer cells. The differentiation of these various types of cells from the multipotential hematopoietic stem cells is determined by a combination of growth factors, such as interleukins, stem cell factors, colony stimulating factors, etc. In the lymphoid developmental path the Pax5 gene and its product BSAP (B-cell-specific activator protein) plays a key role. The blood contains also platelets (thrombocytes) and the blood plasma, the non-corpusculate yellowish fraction. In *Drosophila* there are crystal cells (contain defense enzymes), plasmatocytes (the main phagocytotic defense cells) and lamellocytes (develop from plasmatocytes with similar functions). See these cell types, ►hemolytic disease, ►ABO blood group, ►blood groups, ►macrophages, ►dendritic cells, ►immune system, ►hematopoiesis, ►Pax, ►anti-hemophilic factors, ►B lymphocyte, ►T cell, ►erythrocyte, ►leukocyte, catalog of blood proteins relevant to disease: <http://bpb.nci.nih.gov/>; www.plasmaproteomedatabase.org, biology and disease: www.blood.interhealth.info/, blood cell development: <http://hembase.niddk.nih.gov>.

Blood Brain Barrier: ►BBB

Blood Clotting Pathways: These are the intrinsic pathway involving the successive participation of the Hagemann factor (XII), plasma thromboplastin antecedent (PTA XI), Christmas factor (IX), anti-hemophilic factor (VIII), Stuart factor (X), phospholipid and proaccelerin and the extrinsic clotting pathway requiring proconvertin (VII), Stuart factor (X), proaccelerin and calcium ions. With the aid of lentiviral vectors directed to the liver of mouse, the human Factor IX gene can be expressed and stably maintained for months. ►antihemophilic factors, ►tissue factor, ►vitamin K; Tsui LV et al 2002 Nature Biotechnol 20:53.

B

Blood Coagulation: ►blood clotting pathway, ►anti-hemophilic factors, ►aspirin

Blood Formation (hematopoiesis): During early embryonic development the yolk and the aorta-gonad-mesonephros (AGM) region are involved, later the function in the embryo is switched to the liver and after birth, the bone marrow is involved.

Blood Groups: An incomplete list of the types found in this volume: ABO, ABH, Ahonen, Colton, Diego, Dembrock, Duch, Duffy, En, Gerbich, I system, Kell-Cellano, Kidd, Lewis, Lutheran, LW, MN, Newfoundland, OK, P blood group, Radin, Rhesus, Scianna, Ss, Webb, Wright, Yt, and Xg. These are distinguished mainly by the epitopes on the erythrocytes. ►epitope, ►erythrocyte

Blood Pressure: The pressure of the blood on the blood vessels (arteries). ►hypertension

Blood Transposable Element: ►copia

Blood Typing: Identification the blood group a person belongs to. ►blood groups

Bloom Syndrome (BS, BLM): Semi-recessive human dwarfism; increases the frequency of chromosomal aberrations (particularly sister chromatid exchanges), and various forms of cancer (leukemia), sensitive to sunlight (red blotches over face) and usually shorter than normal life expectancy. It was attributed to a DNA ligase I deficiency but the cloning and sequencing of the gene indicates that this is not the primary defect rather a DNA helicase-like protein (RecQ family, homolog of budding yeast genes SGS1 and SRS2), encoded in human chromosome 15q26.1, is involved. The DRAFT protein complex is shared by Fanconi anemia and Bloom syndrome (Meetei AR et al 2003 Mol Cell Biol 23:3417). SGS1 mutations greatly enhance gross chromosomal aberrations and the rate of recombination. The wild type SGS1 represses chromosomal aberrations. The *Drosophila* homolog is Dmblm. In BS sister chromatid exchange and mitotic recombination are elevated but genetic repair seems to be normal. In Dmblm, an extra copy of Ku70 compensates for sterility. The BS helicase physically interacts with the Werner syndrome helicase. ►DNA repair, ►xeroderma pigmentosum, ►Fanconi anemia, ►Werner syndrome, ►Cockayne syndrome, ►Rothmund-Thomson syndrome, ►carcinogenesis, ►light-sensitivity diseases, ►co-suppression; Ku, Luo G et al 2000 Nature Genet 26:424; Myung K et al 2001 Nature Genet 27:113; von Kobbe C et al 2002 J Biol Chem 277:22035.

BLOSUMS: Amino acid substitution matrices used to determine evolutionary changes in proteins [Henikoff S, Henikoff JG 1992 Proc Natl Acad Sci USA

89:10915]. ►BLAST, ►FASTA, ►evolutionary clock, ►SSPA

Blotting: Macromolecules separated by electrophoresis in agarose or polyacrylamide are transferred to a cellulose or nylon membrane and immobilized there for further study. ►Southern blot, ►Northern blot, ►Western blot, ►colony hybridization, ►immunoprobe

BLOTTO (Bovine Lacto Transfer Technique Optimizer): A 5% solution of non-fat, evaporated milk in 0.02% sodium azide (NaN₃). [It may contain RNase activity]. In 25-fold dilution, it may be used for blocking background annealing in Grunstein-Hogness hybridization, Benton-Davis hybridization, dot blots, and non-single copy Southern hybridization. ►Denhardt reagent, ►heparin, ►Grunstein-Hogness screening, ►Benton-Davis plaque hybridization, ►dot blot

Blue Grass (*Poa pratensis*): Lawn and pasture plant; 2n = 36–123 in the polyploid series.

Blue Diaper Syndrome: An intestinal failure to transport tryptophan and *Pseudomonas aeruginosa* bacteria convert the amino acid into indole, which upon oxidation stains bluish. ►amino acidurias

Blue Light Response: Photomorphogenetic reaction (of plants) to illumination in the range of 400–500 nm wavelength. ►photomorphogenesis, ►cryptochromes

Blueberry (*Vaccinium* spp): A fruit shrub with x = 12; *V. corymbosum* (high-bush blueberry) is tetraploid, the *V. angustifolium* (low-bush blueberry) is diploid.

Bluescript M13: A 2.96 kb genetic vector containing the bacteriophage M13 replication origin and a polycloning insertion site flanked by T7 and T3 phage promoters in opposite orientation and useful for generation of single-stranded DNA or RNA complementary to the double-stranded DNA insert. Several variations exist (e.g., (ZAP, bluescript SK). The name comes from the bacterial Lac fragment that upon expression of (β-galactosidase in Xgal medium forms an easily detectable blue color. ►Xgal; Short JM et al 1988 Nucleic Acids Res 16:7583; Snead M et al 1988 Methods Mol Biol 81:255.

Blunt End: The blunt-end of double-stranded DNA is generated by non-staggered cut and it terminates at the same base pair across both strands of the double helix (see Fig. B50). Bacterial DNA polymerase I (Klenow fragment) or phage T4 DNA polymerase can also generate 3' blunt ends of DNA by 5'→3' exonucleolytic activity. ►blunt end ligation

Figure B50. Blunt end

Blunt-End Ligation: T4 phage DNA ligase joins non-staggered DNA ends or adds chemically synthesized duplexes to double-stranded blunt ends. ▶DNA ligases, ▶linker

BLUP (best linear unbiased prediction): A statistical procedure based on covariance analysis of gametic genetic disequilibrium of QTL and other types of markers in multibreed populations. (Wang T et al 1998 Genetics 148:507, ▶multibreed, ▶QTL)

BLYM: Chicken bursal lymphoma oncogene, located to human chromosome 1p32. It is homologous to transferrin, a glycoprotein with important role in the synthesis of ribonucleotide reductase, and thereby in DNA replication and mitosis. ▶oncogenes, ▶lymphoma, ▶transferrin

BLYS (B lymphocyte stimulator): A human chromosome 13q34-encoded protein of the tumor necrosis factor family is involved in B cell proliferation and immunoglobulin secretion. ▶B lymphocyte, ▶TNF

BMI: ▶body mass index

BMK1 (big MAP kinase): ▶ERK

BMP: ▶bone morphogenetic protein

BMT: Transformed monkey cell line expressing the T antigen of SV40, driven by a mouse metallothionein promoter. ▶SV40, ▶metallothionein

BMYC: Oncogene isolated from rat has extensive homology to the MYC oncogene but it maps to a different location than the other members of the MYC family LMYC, NMYC, PMYC, RMYC. (▶MYC and other members of the family, ▶oncogenes)

BNA: ▶locked nucleic acids

Bni: A member of the formin proteins involved in polar morphogenesis and cytokinesis of eukaryotic cells. Bni1 protein is associated with CDC42 protein, with actin, profilin and Bud6. ▶actin, ▶profilin, ▶CDC42, ▶Bud

Bob: ▶OBF

BOB': ▶att sites

BODIPY: ▶fluorochromes

Body Map (human and mouse gene expression database): Abundance of mRNAs in different tissues of the body. It reveals also the functional relatedness of genes by the similarity of expression profiles. (See Kawamoto S et al 2000 Genome Res 10:1807; <http://bodymap.ims.u-tokyo.ac.jp>; <http://bodymap.jp/>).

Body Mass Index in Humans (BMI): BMI is determined as a measure of obesity by the formula: weight in kg/height in meter². In morbid obesity BMI > 40 kg/m². Obesity (BMI>30) is detrimental to health although for centuries it was associated with fertility (see Fig. B51). The body mass index does not take into account unusually strong muscle development and in such cases does not provide good measure of obesity. Correlation of BMI between monozygotic twins is about 0.74 versus 0.32 for dizygotic twins indicating very high heritability. The correlation among parents and biological offspring were found to be 0.19 versus adopted children 0.06 indicating the major role of hereditary factors. The pro-opiomelanocortin locus in human chromosome 2p21 is a significant contributor to body mass according to some studies. Perola M et al 2001 Am J Hum Genet 69:117) failed to detect any linkage to BMI by QTL in Finnish populations. ▶obesity, ▶leptin, ▶melanocortin, ▶morbidity, Barsh GS et al 2000 Nature [Lond] 404:644.

Villendorfl Venus
ca. 15000 B.C.

Figure B51. Fertility goddess from Willendorf, Austria ~15,000 B.C. (From Gowans CS 1974 Stadler Symp 6:113)

Body Plan (bauplan): The three-dimensional organization of the body of an organism, e.g., mammals are bilaterally, incomplete symmetrical quadripeds, star fish has five-fold symmetry.

Body Size: In insects a balance between ecdysone and insulin signals determines body size. Ecdysone is produced by the prothoracic gland and its size is controlled by activated RAS or PI3K although RAF also regulates body size by activation ecdysone-dependent genes (See Caldwell PE et al 2005 Current Biol 15:1785). ▶ecdysone, ▶RAS, ▶PI3K, ▶size, ▶body mass, ▶Kleiber's rule

bol: ▶boule

Boltzmann Time Warping: ►dynamic time warping**B**

bom: A bacterial gene (basis of mobilization), required for the transfer of plasmids. ►plasmid mobilization, ►mob, ►Hfr

Bombardia lunata: An ascomycete, $n = 7$.

Bombay Blood Type: A relatively rare blood type discovered in India and subsequently on the Reunion Island in the Indian Ocean. This blood type has two main forms determined by the recessive alleles h (for H type red cell antigen). In the h/h se/se individuals also the enzyme fucosyltransferase 1 is inactive; in the h/h Se/se individuals a weak expression of the H antigen may be observed; Se is apparently coding for fucosyltransferase 2. ►ABH antigen, ►Secretor, ►Lewis blood group, ►fucose

Bombesin (protein, $C_{71}H_{110}N_{24}O_{18}S$): Bombesin modulate smooth muscle contraction, hormone traffic, metabolism, hyperglycemia, hypertension and eating behavior. ►obesity, ►ovarian cancer

Bombyx mori: ►silkworm

BONCAT (bioorthogonal noncanonical amino acid tagging): A method for detection and separation of newly synthesized proteins in response to environmental cues. The metabolic machinery incorporates azides and ketones and subsequent ligation with reactive probes facilitates their detection. Azidohomoalanine can be introduced into mammalian cells and the tagged proteome can be separated by affinity chromatography and identified by tandem mass spectrometry (Dieterich DC et al 2006 Proc Natl Acad Sci USA 103:9482). ►azide, ►ketone, ►homoalanine, ►affinity chromatography, ►tandem mass spectrometry

Bond Energy: It is required to break a chemical bond. Such bonds in the piconewton range are important in biology and are represented by protein and nucleic acids interactions, receptor-ligand pairs and covalent bonds. Measurement of the forces involved may be important for, e.g., detection of DNA base mismatches and for proteomics. ►atomic force microscope, ►newton; Albrecht C et al 2003 Science 301:367.

Bone Development: A complex process that involves signaling, molecules, growth hormones, transcription factors, etc. ►osteoblast, ►osteoclast; Kronenberg HM 2003 Nature [Lond] 423:332; Boyle WJ et al 2003 Nature [Lond] 423:337; Harada S-i, Rodan GA 2003 Nature [Lond] 423:349.

Bone Diseases: ►collagen, ►campomelic dysplasia, ►achondroplasia, ►hypochondroplasia, ►pseudoachondroplasia, ►osteogenesis imperfecta, ►SED, ►PAPS, ►osteoporosis, ►osteosarcoma, ►osteolysis, ►Paget disease, ►osteopetrosis, ►diastrophic

dysplasia, ►chondrodysplasia, ►dyssegmental dysplasia, ►dyschondrosteosis, ►dwarfism, ►adactyly, ►brachydactyly, ►polydactyly, ►syndactyly, ►exostosis, ►trichorhinophalangeal syndrome, ►ectrodactyly, ►Ellis-van Creveld syndrome, ►Holt-Oram syndrome, ►Hay-Wells syndrome, ►head/face/brain defects, ►pynodysostosis, ►osteochondromatosis, ►Larsen exostosis Alagille syndrome, ►spondylocostal dysostosis, ►spondylo-metaphyseal dysplasia, ►spondyloepiphyseal dysplasia, ►Greig's cephalopolysyndactyly syndrome, ►craniometaphyseal dysplasia, ►Pallister-Hall syndrome, ►Townes-Brocks syndrome, ►Robinow syndrome, ►acromesomelic dysplasia, ►acrodysostosis, ►acheiropodia, ►nail-patella syndrome, ►sympalangism proximal, ►radioulnar synostosis, ►synostosis, ►cleidocranial dysplasia, ►Waardenburg syndrome, ►Stickler syndrome, ►hypophosphatemia, ►Kniest dysplasia, ►Marfan syndrome, ►osteolysis, ►osteopetrosis, ►osteoporosis, ►sclerosteosis, ►scoliosis, ►Camurati-Engelmann disease, Kornak U, Mundlos S 2003 Am J Hum Genet 73:447.

Bone Marrow: The red spongy tissue inside the bones gives rise to lymphocyte stem cells and erythrocytes; the yellow bone marrow is mainly made of fat cells (see Fig. B52). Hematopoietic stem cells egress from the bone marrow by signals from the sympathetic nervous system (Katayama Y et al 2006 Cell 124:407). From the stromal cells of the bone marrow, stem cells can be isolated that can generate muscle cells at very good efficiency (89%) and suitable also for the development of neural and other types of cells under appropriate conditions and can be exploited for repairing degenerated tissue. It has the advantage that these stem cells would not be rejected if taken from the same individual and would avoid some ethical objections to the use of embryonic stem cells (Dezawa M et al 2005 Science 309:314). It has been claimed that stem cells exiting from the bone can end up in the ovaries and produce oocytes. Newer experiments challenged this claim (Powell K 2006 Nature [Lond] 441:795). ►stem cells, ►thymus, ►sympathetic nervous system, ►hematopoiesis

Figure B52. Bone marrow is in the inner cavity (light brown)

Bone Morphogenetic Protein (BMP): A maternally expressed factor in *Xenopus* embryos; in addition to bone differentiation it is involved in dorso-ventral organization of the embryo. Osteoblast differentiation

and proliferation is controlled by BMP and Smad. BMP-1 is a procollagen protease (PCP) that assembles collagen within the extracellular matrix. The other BMPs belong to the transforming growth factor (TGF- β) family. BMP-4 regulates apoptosis in neural crest cells affecting skeletal bone and muscle formation. BMP-3 is a negative regulator of bone density. The growth/differentiation factors of mouse (GDF) belong to this family and their mutation shortens the limb bones (brachypodism) without affecting the axial skeleton. The CBFA-1 gene seems to be a major factor in ossification. BMP is the vertebrate homolog of decapentaplegic (dpp) in *Drosophila*. The Sog (short gastrulation) and the Chd (chordin) proteins in vertebrates and invertebrates negatively regulate the BMP/Dpp system, respectively. The metalloprotease Xld (Xolloid)/Tld (tolloid) release the Bpm/Dpp from inactive complexes. Thus, a balance between Sog/Chd and Xld/Tld determines a morphogenetic gradient. Noggin, gremlin, chordin and follistatin inhibit BMP and dorsalize the embryo. The process is, however, more complex since that other serine protease(s) may also be involved (astacin, furin). The Kuz metalloprotease (a reprolysin) regulates the Notch cell surface receptor by proteolytic cleavage. BMP in coordination with other signal proteins regulates the specification of teeth development: $Msx-1^+$ ($Barx-1^-$) activity state leads to the development of incisors whereas $Msx-1^-$ ($Barx-1^+$) state promotes molar formation in the oral mesenchyme in mouse. ► [fibrodysplasia ossificans progressiva](#), ► [pulmonary hypertension](#), ► [decapentaplegic](#), ► [furin](#), ► [Notch](#), ► [organizer](#), ► [noggin](#), ► [GLI](#), ► [Smad](#), ► [osteoclast](#), ► [osteoblast](#), ► [collagen](#), ► [brachydactyly](#), ► [tooth](#), ► [hepcidin](#); Olsen BR et al 2000 Annu Rev Cell Dev Biol 16:191; Ray RP, Wharton KA 2001 Cell 104:801; Khokha MK et al 2003 Nature Genet 34:303.

Bonferroni Correction: Guards against type I error at some α values (false positives). In case of a small number of tests it is satisfactory and simple. It is frequently used when multiple hypotheses are tested: $p_{\text{corrected}} = 1 - (p_{\text{uncorrected}})^n$ where p is the values of the hypotheses and n is the number of hypotheses. The basic assumption is that all alternatives are equally likely and the results are tested against this hypothesis. ► [significance level](#), ► [error types](#), ► [test significant difference](#); Altman DG 1991 Practical statistics for medical research, Chapman & Hall, London; Hochberg Y 1988 Biometrika 75:800.

Bonobo (*Pan paniscus*): Pygmy chimpanzee is an ape closest to humans after chimpanzee. ► [chimpanzee](#)

Book Syndrome: An autosomal dominant defect of tooth development, high degree of sweating and premature loss of hair color. ► [hair color](#)

Bookmark: Indicates an address on the Internet or other items in the computer where you wish to return.

Bookmarking: The mechanism responsible for preventing compaction of a specific gene region during mitosis (Xing H et al 2005 Science 307:421).

Boolean Algebra: Developed by George Boole (1815–1864) for the use of formal logic. He supposed that in binary forms thinkable objects could be defined. Thus, if x = horned and y = sheep then by selecting x and y the class of horned sheep is defined. Also $1-x$ would define all things of the universe that are not horned, and $(1-x)(1-y)$ would identify all things that are neither horned nor sheep. This approach defines sets and subsets in discrete forms without intermediates, yet capable of defining mutual relationships. Using simple symbols, syllogisms could be developed in mathematical forms. Learning of concepts by humans appears to be proportional to its Boolean complexity, i.e., to the length of the shortest logically equivalent proposition. The switch-gear of the telephone systems and the modern digital computers were developed on the basis of the Boolean binary logic. Boolean logic is employed in devising cellular automaton networks and some information retrieval system, e.g., PubMed is operated on the basis of Boolean principles. DNA-based digital logic circuits have also been designed for the detection of complex enzyme-free nucleic acid circuits for the monitoring of complex gene expression patterns (Seelig G et al 2006 Science 314:1585). ► [automaton](#), ► [networks](#), ► [synthetic genetics](#), ► [PubMed](#)

Bootstrap: A statistical device that was introduced for computer operations (versus the classical type computations). The standard error by the classical method is computed as:

$$se(\bar{x}) = \left\{ \sum_{i=1}^n (x_i - \bar{x})^2 / [n(n-1)] \right\}^{1/2}$$

in comparison, with the bootstrap procedure:

$$se[t(x)] = \left\{ B [t(x^{*b}) - \bar{t}]^2 / (B-1) \right\}^{1/2}$$

where $se[t(x)]$ is the standard error of the bootstrap statistic, $t(x)$, B = bootstrap samples of size n from the data, \bar{t} is the average of the B bootstrap replications ($\bar{t}(x^{*b})$). The bootstrap algorithm can be applied to the majority of statistical problems and it is widely used for estimating the confidence level in evolutionary trees. The data points x_i need not be single numbers, they can be vectors, matrices or more general quantities, such as maps, graphs. The statistic $t(x)$ can be anything as long $t(x^*)$ can be computed for every bootstrap data set x^* . Data set x does not have to be a random sample from a single distribution.

B

Regression models, time series, or stratified samples can be accommodated by appropriate changes. For details and specific references see Efron B, Tibshirani RJ 1993 *An Introduction to the Bootstrap*. Chapman & Hall, New York. ▶jackknifing; Kerr MK, Churchill GA 2001 *Proc Natl Acad Sci USA* 98:8961; Davison AC, Hinkley DV 1997 *Bootstrap methods and their application*, Cambridge University Press, Cambridge, UK.

Bora Bora: ~220 kb centromeric sequences in *Drosophila*. ▶centromere

Border Sequences: ▶T-DNA

Borjeson Syndrome (Borjeson-Forssman-Lehman syndrome): Face, nervous system, endocrine defects, hypogonadism, assigned to human chromosome Xq26-q27. ▶RBM, ▶head/face/brain defects

Borna Virus: An enveloped negative-strand, non-segmented RNA virus with inverted terminal repeats (see Fig. B53). Its genome is replicated and transcribed in the nucleus of warm-blooded animals, including humans. Viral replication is controlled by genome trimming. From the 5' end one or four bases can be eliminated in the hairpin structure limiting genome amplification but not protein synthesis. From three transcription units it transcribes mRNA for six proteins by overlapping open reading frames, read-through transcription signals and alternative splicing of the polycistronic transcripts. Infection of the nervous system of newborn rats results in inflammation and causing mood disorders reminiscent of schizophrenia and autism of humans. In adult animals, uncoordinated movement and serious weight loss were observed. (Diagram is modified after Schneider U et al 2005 *Proc Natl Acad Sci USA* 102:3441).

Figure B53. Borna virus

Borrelia: Spirochete bacteria; about 28 species (*B. burgdorferi*, *B. hermsii*, etc.) are responsible for relapsing fever or Lyme disease and other human ailments all over the world. The *Borrelia burgdorferi* genome B31 contains 910,725 bp linear DNA and 17 linear and circular plasmids. This bacterium, like *Mycoplasma genitalium*, has no genes for cellular biosynthetic functions but there are 853 genes for transcription, translation, transport and energy metabolism. The filamentous bacteria are 8 to 16 µm long flagellate cells infectious for birds and mam-

mals. Their generation time is about 6 hours and in about 5 days within a single animal their population may exceed 10^6 cells and that coincides with the major symptoms (erythema migrans [enlarged red spots]) of the infection. Within weeks or months, the bacteria may invade all major organs of the body, primarily the joints and cause arthritic symptoms. If untreated, Lyme disease may be fatal. Intravenous injection of rocephin or other antibiotics (also orally administered doxycycline) may be the cures although some of the effects may persist for years. The vectors of the bacteria are the *Ixodes* arthropods (ticks) that live on grasses and low-growing bushes in wildlife (deer, mice, birds) frequented rural and suburban areas. The salivary protein Salp15 of *Ixodes scapularis* interacts with the surface protein of *B. burgdorferi* and protects the spirochete from the mammalian host antibodies (Ramamoorthi N et al 2005 *Nature [Lond]* 436:573). The bacterial σ^{54} , a RNA polymerase subunit deficient *Borrelia* cells can invade the tick but they are not infectious (Fisher MA et al 2005 *Proc Natl Acad Sci USA* 102:5162). The tick receptor (Trospa) that is required for spirochetal colonization (Pal H et al 2004 *Cell* 119:457). The *Bb* gene of *Borrelia* is required for the persistence of the bacteria in ticks and subsequent productive infection of the mammalian cell. The BptA a putative lipoprotein is a likely virulence factor for *Bb* (Revel AT et al 2005 *Proc Natl Acad Sci USA* 102:6972).

Identification of the disease is difficult because of the complexity of the symptoms. Serological detection encounters problems because the outer membrane of the bacteria displays variable serotypes. *Borrelia*s harbor several copies of approximately 23–50-kb linear plasmids with genes for Vmps/Vsps (variable major proteins). Transposition within and recombination between the plasmids assures great antigenic variation in these organisms. New serotypes appear at an estimated frequency of 10^{-4} to 10^{-3} per cell per generation. This fact accounts for the difficulties in developing effective immunosera and no acceptable vaccine is available (Abbott A 2006 *Nature [Lond]* 439:525). An attenuated strain of *Mycobacterium bovis*, the bacillus Calmette-Guerin (BCG) may serve as a suitable vector for the *B. burgdorferi* surface protein antigen A and may secure more than a year long protection by mucosal delivery. About 10% of Lyme disease patients appear resistant to antibiotic treatment and display arthritis symptoms long after spirochetal DNA in fluids of the joints is no longer detectable. The arthritis is an immune response to the outer surface protein A (OspA) of the bacterium. Actually, OspA-reactive type 1 T helper lymphocytes are found in the joints many years after the infection is cured. OspA has

homology to human leukocyte-function associated antigen-1 (hLA-1). Thus, it seems that the apparently antibiotic-resistant individuals have an autoimmune reaction to this major histocompatibility class peptide encoded by the dominant DRB*0401 allele. OspA is up-regulated when *Borrelia* is in its tick host and down-regulated when it is in a mammalian host. Before the bacterium enters the mammalian host, the host neuroendocrine stress hormones, epinephrine and norepinephrine, specifically bound by *B. burgdorferi*, and result in increased expression of OspA. This recognition is specific and blocked by competitive inhibitors of human adrenergic receptors. Propranolol significantly reduced uptake of *B. burgdorferi* by feeding ticks and decreased expression of OspA in the bacteria recovered from ticks that fed on propranolol (anti-hypertension drug)-treated mice (Scheckelhoff MR et al 2007 Proc Natl Acad Sci USA 104:7247). ▶serotype, ▶antigen, ▶serum, ▶mucosal immunity, ▶Ixodoidea, ▶σ, ▶BCG, ▶HLA, ▶autoimmune disease, ▶arthritis, ▶leptospirosis; Ohnishi J et al 2001 Proc Natl Acad Sci USA 98:670, Kumaran D et al 2001 EMBO J 20:971; Revel AT et al 2002 Proc Natl Acad Sci USA 99:1562.

Borromean Rings: Interlocked rings. DNA may be arranged this or more complex ways (see Fig. B54). The simplest representation.

Figure B54. Borromean rings

Bos taurus (cattle): $2n = 60$. ▶cattle

Boss: A transmembrane protein product on the R8 photoreceptor in the eyes of *Drosophila*, encoded by gene boss (bride of sevenless, 3.90.5). It is the ligand and activator for the receptor tyrosine kinase, encoded by the sev (sevenless, 1–33.38) gene. ▶sevenless, ▶son-of-sevenless, ▶rhodopsin, ▶receptor tyrosine kinase, ▶daughter of sevenless

Botany: A basic scientific field concerned with plants. (See herbaria and botanists: <http://www.nybg.org/bsci/ih>; all plants: <http://plants.usda.gov/>; Plant Name Index: <http://www.ipni.org>).

Bottleneck Effects: If the size of the population is periodically reduced substantially, genetic drift may alter gene frequencies. Usually bottlenecks reduce variation. Occasionally after bottlenecks, an increase of variation has been reported, and it was attributed to dominance and epistasis. Bottleneck effect is quite common in the transmission of mtDNA because only a small portion of it is passed through the germline and the heteroplasmy may be altered. ▶genetic drift, ▶mtDNA, ▶heteroplasmy; Galtier N et al 2000 Genetics 155:981.

Bottom-Up Analysis: ▶top-down analysis

Bottom-Up Map: It relies on STS-based information. These are useful for relatively short chromosomal distances. Two STSs are “singly linked” if they share at least one YAC and “doubly linked” in case they share at least two YACs. Single linkage is generally not useful because of the high degree of chimerism among the YACs. In the first step, STS are assembled into doubly linked contigs. Then, the doubly linked contigs are ordered either on the basis of radiation hybrids or traditional genetic recombination information. Finally, single linkage can also be used to join contigs to the same short genetic region. ▶mapping genetic, ▶STS, ▶contig, ▶radiation hybrid, ▶bottom-down mapping, ▶YAC; Carrano AV et al 1989 Genome 31:1059.

Botulin (botulinum): Highly toxic product of *Clostridium* bacteria (lethal dose 1 ng kg^{-1}) and frequent cause of potentially lethal food poisoning. It is approved for treatment of strabismus and blepharospasm (a nervous eyelid problem), and it is also a cosmetic treatment of “crow’s feet” facial, signs of aging. It is also a potential biological weapon. The botulinum neurotoxin A enters neurons by binding to synaptic vesicle protein (SV2) isoforms (Dong M et al 2006 Science 312:592). Botulinum toxin also binds synaptotagmin II (Jin R et al 2006 Nature [Lond] 444:1092; Chai Q et al 2006 Nature [Lond] 444:1096). ▶strabismus, ▶synaptotagmin; Moore A 2002 EMBO Reports 3:714.

Boule (bol): An autosomal gene in *Drosophila* encoding a cell cycle protein regulating G2-M transition. It is homologous to the human Y-chromosomal gene DAZ responsible for azoospermia. Its suspected function is translation and localization of mRNA. ▶infertility, ▶fertility, ▶azoospermia, ▶cell cycle, ▶twine, ▶pelota, ▶Dazla

Boundary Element (barriers): Limits the function of cis-regulatory elements or the spread of heterochromatinization. ▶insulator, ▶heterochromatin, ▶RAP, ▶CTCF

B

Bouquet (polarization): In leptotene the chromosomes are attached by their ends to a small area of the nuclear membrane (spindle pole body) while the rest of the chromosome length is looped across the nucleus (see Fig. B55). Meiotic proteins Bqt1 and Bqt2 tether the telomeres to the spindle pole body (fungal organ comparable to the centrosome). These proteins form a connecting bridge between telomere protein Rap1 and Sad1, a spindle pole protein (Chikashige Y et al 2006 Cell 125:59). ▶meiosis, ▶leptotene stage, ▶spindle pole body, ▶horsetail stage

Figure B55. Bouquet

Bovine: Animals of *Bos taurus* (cattle) group. ▶*Bos taurus*, ▶cattle

Bovine Growth Hormone (BGH): A somatotropin; it has been commercially produced by genetic engineering and it boosts significantly milk production. ▶somatotropin

Bovine Papilloma Viral Vectors: By genetic manipulations and with pBR322 bacterial plasmid sequences added, they can be converted into a shuttle vector carrying genes between mouse and *E. coli*. ▶transformation genetic, ▶vectors, ▶viral vectors, ▶shuttle vector

Bovine Papilloma Virus (BPV): A papova virus (about 7.9 kbp DNA), responsible for wart in animals. The BPV69T segment of their genome (5.5 kbp) has been used as a large capacity vector, which can multiply into 10 to 200 copies. It can stay as an episome or can be integrated into the chromosomes of mammals.

Bovine Spongiform Encephalopathy (BSE): ▶encephalopathies, ▶Creutzfeldt-Jakob disease, ▶Alzheimer disease, ▶prions, ▶scrapie

Bowel Disease (chronic inflammatory bowel disease): ▶CIBD, ▶CARD15, ▶Crohn disease

Bowman-Birk Inhibitors: These are prepared from plant tissues and can bind and inhibit simultaneously or independently, trypsin and chymotrypsin. They may decrease cancer development in animals exposed to alkylating agents or displaying sporadic tumorous growth. (Witchi H, Espiritu I 2002 Cancer Lett 183[2]:141).

Bow-Tie: A system with various inputs and outputs connected by a node, resembling a bow-tie.

Box: Generally used for a consensus sequence in the DNA, such as a homeobox; domains of the internal control regions (box A, box, B, box C) that are the sequences where transcription factors bind. Sometimes protein boxes are also distinguished.

Box Genes: Clustered mutations in exons or introns (in mosaic genes of mtDNA). ▶mtDNA

β-Pleated Sheet: Extended polypeptide chains in parallel or antiparallel arrangement linked by hydrogen bonds between the amino and carboxyl groups. ▶protein structure

BP (B.P.): Before present, for archeological age.

bp: Base pair.

BPV: ▶bovine papilloma virus

BR RNP (Balbiani ring ribonucleoprotein): Transcripts of the Balbiani ring and associated with about 500 protein molecules of a total molecular size of 106 daltons. ▶Balbiani ring

Brachmann-De Lange Syndrome: ▶De Lange syndrome

Brachydactyly: Abnormally short fingers and toes controlled by autosomal dominant genes (see Fig. B56). In Type E the metacarpus and metatarsus (the bones between the wrist and the fingers of the hand and the corresponding bones in the foot) are shortened. In still other types nervous defects, hypertension, shortening the bones of the arm accompanies the hand and foot problems. The expression may vary. Most commonly the middle bones (phalanx/phalanges) are affected (Type A); in some cases not all the fingers express the gene. In type B (9q22, receptor tyrosine kinase ROR2), in addition to the middle phalanges, the terminal ones are also short or absent. In type C more than 3 phalanges may appear. Type D involves short and flat terminal phalanges of the big toe and the thumb. In Type E the metacarpus and metatarsus (the bones between the wrist and fingers of the hand and the corresponding bones in the foot) are shortened. In still other types nervous defects, hypertension, shortening the bones of the arm accompanies the hand and foot bone problems. In an autosomal recessive form the brachydactyly involves also small head (microcephaly). In another recessive form primarily the great toe is affected but the proximal (near the wrist) joints do not move. The dominant brachydactyly with severe hypertension gene has been assigned to human chromosome 12p. Brachydactyly type A-1 is due to mutation in the Indian hedgehog gene. Brachydactyly type A2 (4q21-q25) is due to mutation in bone morphogenetic protein receptor

1B (Lehmann K et al 2003 Proc Natl Acad Sci USA 100:12277). ►polydactyly, ►syndactyly, ►car-tilage, ►bone morphogenetic protein, ►Robinow syndrome, ►hedgehog; Schwabe GC et al 2000 Am J Hum Genet 67:822; Gao B et al 2001 Nature Genet 28:386.

Figure B56. Brachydactyly

Brachymeiosis: When the second meiotic division is missing. ►meiosis

Brachyury: A homozygous (*TT*) dominant lethal (after 10 days of conception) gene in mice. The *Tt* heterozygotes are viable and have reduced tail (tailless), the homozygous *tt* also dies in 5 days. The different alleles of the complex locus have different effects of the development. The anomaly (chromosome 17) involves a genetic defect in the notochord development. The somites undergo differentiation but resorbed before birth. There are defects also in the posterior parts (limbs, allantois, umbilical vessels). The *t* alleles may display meiotic drive and from the male *t*/+ heterozygotes more than 90% of the progeny may receive the *t* allele. The distortion of the transmission (TRD) is controlled by at least six loci that do not normally recombine because of the presence of inversions. The *t* complex occupies about 1/3 of chromosome 17 and generally is inherited as a block because the region includes at least four inversions. The rare recombinants are called “partial *t* haplotypes.” Females display normal transmission and fertility. In addition, there are at least 16 lethality loci within the *t* haplotype but these are not the primary causes of the distorted segregation. The *Tcd1*, *Tcd2* and *Tcd3* distorters act in response to the *Tcr* responders and can affect the transmission of any chromosome of mouse. The distorted segregation is due to the cis-acting so-called *T* complex responder (*Tcr*). The *Tcr*^f (acts only in cis) males avoid distortion and can fertilize the females but show the abnormal transmission. The distorted ratio is due to the *Smok* (sperm motility kinase) located at the C-terminus of the ribosomal *Rsk3* kinase. *Smok* apparently phosphorylates the axonemal dynein of

the microtubules. The *T* complex distorters (*Tcd*) are transacting factors, which increase transmission of the *tcr*-bearing chromosome. Despite the preferential transmission of the *t* haplotype by the heterozygous males, the populations carry only 10–25% *t* haplotypes. The brachyury transcription factor is embedded by its carboxy-terminal into the minor groove of the DNA contacting a guanine residue but it is not bending the DNA. It is an important transcription factor for mesodermal specification. The *t* haplotype carries four Rho-GTPase-activating loci (*Tapgap-1*) whereas the wild type has only one. Brachyury-like anomalies occur also among cats, dogs, sheep, cattle and pigs (see Fig. B57). ►Manx in cat, ►meiotic drive, ►killer spore, ►somite, ►notochord, ►haplotype, ►axoneme, ►dynein, ►TCP-1, ►Holt-Oram syndrome; Schimenti J 2000 Trends Genet 16:240; Lyon MF 2003 Annu Rev Genet 37:393; Bauer H et al 2005 Nature Genet 37:969.

Bradford Method (Anal Biochem 72:248): The Bradford protein assay, for 1 to 100 µg protein. Prepare a standard solution (0.5 mg/mL) of bovine serum albumin (BSA) and make a dilution series 5 to 20 µL and dilute to 100 µL with 0.15 M NaCl. Prepare also 0.15 M NaCl blanks. Make a series of dilutions also from the unknown quantity of the protein to be

B

tested. Add 1 mL Coomassie brilliant blue to all and mix thoroughly. After 2 min determine absorption at 1-cm path-length at 595-nm wavelength in a spectrophotometer and extrapolate the concentration of the sample from the standard series. ►Lowry test, ►Kjeldahl method

Bradykinin: ►kininogen

Bradytelic Evolution: Evolution at very slow pace involving species whose adaptive environment extends over very long (geological) periods. In contrast, the tachytelic evolution is progressing at a fast pace whereas the horotelic evolution appears to show an average rate. ►evolution

BRAF: A cytoplasmic serine/threonine kinase that is mutant in 66% of melanomas but it occurs at lower frequencies in other cancers. Inhibition of MEK abrogates BRAF tumor growth (Solit DB et al 2006 Nature [Lond] 439:358). BRAF mutations occur in the majority of probands with the cranio-facio-cutaneous syndrome without an apparent increased frequency of cancer. ►RAS, ►MEK, ►cranio-facio-cutaneous syndrome, ►melanoma; Davies H et al 2002 Nature [Lond] 417:949.

Brain, Human: A very complex structure and here only a few major landmarks are outlined as reference to several entries dealing with the central nervous system. The seven-layered hippocampus, consisting of “gray matter” is not shown although this is the most important area at the basal-temporal region involved in memory and learning. The functional areas of the brain can be identified by the increased blood flow upon stimulation by using positron emission tomography or functional magnetic resonance imaging. Microelectrodes applied to individual nerve cells reveal electrical activity at a single cell level. Since the mammalian brain contains thousands of distinct neuronal glial cell types, their synthesis requires separate transcription factors and the study of Gray PA et al (2004 Science 306:2255) found by in situ hybridization that that 349 genes in the brain displayed restricted expression pattern reflecting the anatomical organization of the mouse brain (see Fig. B59).

Figure B59. Major areas of the human brain

The new Allen Brain Atlas (ABA) allows one to view all the locations at which any of the more than 20000 genes in the mouse brain are activated, down to cellular-level resolution. The site allows one to search any anatomical region of the brain for any gene or combination of genes. The activated genes can be viewed with tools that can zoom from a whole-brain section down to a single cell while retrieving data at multiple levels of resolution (Markram H 2007 Nature [Lond] 445:160). The current technology visualizes the expression of single genes per cells but eventually larger the parts of the transcriptome might be visualized. Newly developed image-based informatics tools allow global genome-scale structural analysis and cross-correlation, as well as identification of regionally enriched genes. Unbiased fine-resolution analysis has identified highly specific cellular markers as well as extensive evidence of cellular heterogeneity not evident in classical neuroanatomical atlases. The new methods enable global analysis and mining for detailed expression patterns in the brain. The entire Allen Brain Atlas data set and associated informatics tools are available through an unrestricted web-based viewing application (Lein ES et al 2007 Nature [Lond] 445:168; <http://www.brain-map.org>).

The brain size of hominids (1,200–1,600 cm²) approximately tripled in less than 3 million years of evolution. Brain volume and cognitive abilities seem to be positively correlated ($r = +0.4$) yet the correlation between brain size and cognitive performance is very low within families. The heritability of brain size of humans is very high and evolutionarily it has reached a plateau because the pelvic size of the mothers is restrictive in order to assure uncomplicated

child delivery. The positive correlation may be mainly non-genetic and influenced by socioeconomic status, cultural influences, etc. (See figure; ►memory, ►cerebellum, ►EQ, ►IQ, ►nerve function, ►tomography, ►nuclear magnetic resonance spectrography, ►human intelligence, ►brain scan, ►chimpanzee ►language, ►EPH, ►blood-brain barrier, ►microcephaly, ►encephalon; Nichols MJ, Newsome WT 1999 Nature Suppl 402:C35; brain evolution: Gilbert SL et al 2005 Nature Rev Genet 6:581; computer modeling of the brain: Herz AVM et al 2006 Science 314:81; neuronal networks: Destexhe A, Contreras D 2006 Science 314:85; computational models of cognition: O'Reilly RC 2006 Science 324:91; gene expression: <http://www.loni.ucla.edu>; <http://www.loni.ucla.edu>; mouse brain: <http://www.mbl.org>; expression pattern of ~21,000 mouse genes in the brain: <http://www.brain-map.org/>; <http://www.brainatlas.org>; <http://www.trans.nih.gov/bmap>; brain maps of different vertebrates: <http://www.brainmaps.org/>).

Brain Scan: Uses various sophisticated technologies such a functional magnetic resonance imaging (fMRI) and other technologies well as statistics to monitor sensorimotor and cognitive processes to shed light on human motivation, reasoning, emotions, possibility of deceptions and social attitudes. It reveals activation in different critical regions of the brain. It is becoming also a clinical tool of neurology. Some unresolved ethical issues still remain regarding the interpretation and validity of the data so obtained. ►brain human, ►tomography, ►nuclear magnetic resonance spectrography; Illes J et al 2003 Nature Neurosci 6:205; Check E 2005 Nature [Lond] 435:254.

Branch Migration: During the process of molecular recombination the exchange point between two fixed sites of the DNA single strands can move left or right when the two single strands are separated they can simultaneously reassociate in an exchanged manner in both double helices. This strand invasion brings about heteroduplexes. In *E. coli* the RuvA (a specificity factor) and RuvB (an ATPase) proteins (induced by ultraviolet radiation damage to the DNA) bind to the Holliday junctions and increase the length of the heteroduplex. RuvA and RuvB drive helical rotation of the DNA at the rate of about 8.3 bp/second (Han Y-W et al 2006 Proc Natl Acad Sci USA 103:11544). In eukaryotes, Rad54 and Rad51 operate homologous recombination at the Holliday junctions. Mismatches in the synaptic strands may interfere with

branch migration. ►Holliday model, ►Holliday junction, ►heteroduplex, ►recombination molecular mechanisms, ►mismatch repair; Ruv ABC; Walker box; Putnam CD et al 2001 J Mol Biol 311:297; Constatinou A et al 2001 Cell 104:259; Fabisiewicz A, Worth L Jr 2001 J Biol Chem 276:9413; Karymov M et al 2005 Proc Natl Acad Sci USA 102:8186.

Branch Length: of an evolutionary tree may be determined by the least square method or by using the maximum likelihood principle. ►evolutionary tree, ►least squares, ►maximum likelihood principle

Branch Point Sequence: Short RNA tract YNCURA Y, (Y stands for pyrimidine, R for purine and N can be either) in the primary transcript near (18–38 base upstream) to the 3' end of an intron (AG) of mammals. After exon1-intron boundary is severed and the intron end is released with a 5'-GU pair at the end, it forms then a loop as it folds back by G making a 2'→5' bond with the A shown bold above. Subsequently, a cut is made at the 3' end of the intron, the intron is released, and the exon1 is attached to exon 2. ►introns; Peled-Zehavi H et al 2001 Mol Cell Biol 21:5232.

Branched Chain Amino Acids: ►isoleucine-valine biosynthetic steps

Branched RNA: An intermediate of RNA splicing. ►introns

Branchio-Otorenal Syndrome (BOR): A human chromosome 8q13.3 dominant syndrome with incomplete penetrance and expressivity. It involves defects in the appearance of the ears, underdevelopment of the middle ear structures (malleus, incus, stapes) and the inner ear (cochlea) resulting in mild to severe hearing loss. This is accompanied by under-development of the kidney and the urinary tract. A variant form without the kidney symptoms maps to 1q31. The prevalence of BOR is $\sim 4 \times 10^{-4}$. The gene bears homology to the *Drosophila* gene *eyes absent* (*eya*). The 61.2 kDa Eya protein seems to be a transcriptional coactivator. (See Kumar S et al 2000 Am J Hum Genet 66:1715).

Brassica oleracea (cabbage, kale): Vegetable crops. Basic chromosome number is controversial 5 or 6 although cabbage is $2n = 18$ (C genome) and there are some indications of being an amphidiploid. ►turnip, ►swedes, ►rapes, ►mustards, ►radish, ►watercress; Howell EC et al 2002 Genetics 161:1225; Lukens L et al 2003 Genetics 164:359; annotated genomes of the species: <http://hornbill.cspg.latrobe.edu.au>; <http://brassica.bbsrc.ac.uk>; *Brassica*, strawberry: <http://bioinformatics.pbcbasc.latrobe.edu.au/index.htm>.

B

Brassica rapa: (*syn. B campestris*; mustard; genome AA; $2n = 20$): Sequence-tagged linkage map is available (Kim JS et al 2006 Genetics 174:29).

Brassinolide: ►brassinosteroids (see Fig. B60).

Figure B60. Brassinolide

Brassinosteroids (BR): Synthesized through the pathway campesterol→ campestanol→ cathasterone→ teasterone→ 3-dehydroteasterone→ typhasterol→ castasterone→ brassinolide. Uridine diphosphate glycosyltransferase mediates the glycosylation in the last two steps of this pathway in *Arabidopsis* (Poppenberger B et al 2005 Proc Natl Acad Sci USA 102:15253). The latter compound has been shown to remedy de-etiolation, derepression of light-induced genes, miniaturizing, male sterility and other symptoms of stress-regulated genes. These brassinosteroids bear close similarity to ecdysones, the animal molting hormones. The phytoecdysones were known for two decades in plants. All these plant hormones interact with each other in various ways and regulate signal transduction and gene activities. Unlike most animal steroid hormones, plant hormones are of small molecular size (except brassinosteroids) generally in the range of 28–350 Da. Brassinolide has a MW of about 480. A putative brassinosteroid receptor kinase shows similarities to the *ERECTA* and *CLAVATA1* gene products of *Arabidopsis* and share leucine-rich repeat with disease-resistance genes. Brassinosteroids bind to BRI1 leucine-rich receptor kinase in the outer plasma membrane (Kinoshita T et al 2005 Nature [Lond] 433:167). The *BES1* locus of *Arabidopsis* regulates the level of brassinosteroids and the response to light. BES1 interacts with the helix-loop-helix protein BIM1 and binds to an E box in some brassinosteroid gene promoters and regulates their transcription (Yin Y et al 2005 Cell 120:249). BES1 is constitutively localizes to the nucleus and its activity there is modulated by BIN2 kinase (Vert G, Chory J 2006 Nature [Lond] 441:96). Another protein BZR1—when receives the brassinosteroid signal—turns some genes off although it controls homeostasis of BR (He J-X et al 2005 Science 307: 1634). BRI1 is a serine/threonine kinase cell surface receptor of

brassinosteroids, and its coreceptor is BAK1. BKI1 (brassinosteroid receptor kinase inhibitor) is a negative regulator of signaling (Wang X, Chory J 2006 Science 313:1118). Removal of its C-terminus results in increased phosphorylation and increased activity. Ligand binding relieves inhibition of kinase activity (Wang X et al 2005 Developmental Cell 8:855). Ca^{2+} /calmodulin are important for brassinosteroid biosynthesis and growth (Du L, Pooviah BW 2005 Nature [Lond] 437:741). Brassinosteroids appear to be rate-limiting for auxin-responsive gene expression (Mouchel CF et al 2006 Nature [Lond] 443:458). ►plant hormones, ►de-etiolation, ►photomorphogenesis, ►hormones, ►steroid hormones. ►epidermis; Szekeres M et al 1996 Cell 85:171; Clouse SD, Sasse JM 1998 Annu Rev Plant Physiol Mol Biol 49:427; Neff MM et al 1999 Proc Natl Acad Sci USA 96:15316; Kang J-G et al 2001 Cell 105:625; Li J, Nam KH 2002 Science 295:1299; Yin Y et al 2002 Cell 109:181; Bishop GJ, Koncz C 2002 Plant Cell 14:S97; brassinosteroid signaling: Belkadir Y, Chory J 2006 Science 314:1410.

BRCA1 (breast cancer antigen): An exclusively nuclear located protein. ►breast cancer

BrdU: bromodeoxyuridine. ►bromouracil, ►hydrogen pairing, ►chemical mutagens

Breakage and Reunion: The broken chromatids or DNA single strands are broken at the position of chiasmata, and reunited in an exchanged manner during genetic recombination. This process is a physical event not requiring (normally) DNA replication as it was one time hypothesized with the copy choice idea. Recently, it was found that recombination takes place also by replication. ►recombination molecular models, ►recombination by replication, ►Holliday model; Creighton HB, McClintock B 1931 Proc Natl Acad Sci USA 17:492; Stern C 1931 Biol Zbl 51:547; Meselson M 1964 J Mol Biol 9:734.

Breakage–Fusion–Bridge Cycles: May cause variegation in the tissues because some of the genes may not be present in one of the daughter cells whereas the other cell receives two copies. If this dominant gene determines color, its presence is immediately recognized in the cell lineages. In telomerase-deficient and p53 mutant mice, epithelial cancer development is promoted by breakage-fusion-bridge cycles (see Fig. B61). In *Saccharomyces cerevisiae* dysfunctional telomeres may increase mutation rate ten to hundred fold. (See Fig. B62, ►Ac-Ds, ►cancer, ►telomerase, ►centromere silencing, ►p53; McClintock B 1941 Genetics 26:234; Hackett JA et al 2001 Cell 106:275).

Figure B61. Breakage-fusion-bridge cycles may occur in the endosperm of maize plants if the end of the chromosomes is broken. The genetic and cytological consequences of such events are diagramed here. The relative size of the sectors (detectable when appropriate color markers are used) indicates the developmental time of the cycle. Early events involve large sectors, late events are indicated by small sectors. If the event occurs repeatedly, several sectors are observed. In case the two centromeres move toward the same pole no bridge is formed and an intact dicentric chromatid is recovered. In case double bridge is formed and both chromatids break, two monocentric (most commonly defective chromosomes) go to the poles. The breakage-fusion-bridge cycle may not continue in the tissues of the growing plants because of apparent healing of the broken ends. The healing is attributed to the acquisition of new telomeres. (Photographs by courtesy of Barbara McClintock)

Breakpoint Mapping: ► inversions

Breast Cancer (BRCA): Breast cancer is one of the most common diseases of women. The development of the disease proceeds through multiple steps. The pre-malignant stage is an atypical ductal hyperplasia. It progresses into the preinvasive stage of localized ductal carcinoma, which may change into invasive carcinoma, a potential lethal condition. Recently, for the better definition of these stages at the cell, rather than tissue level, microarray technology is combined with laser-capture microdissection. Although these different stages do not display significant differences in the pattern of gene expression, different grades of tumors are associated with distinct gene signature patterns and thus have predictive value regarding the condition of the disease (Ma X-J et al 2003 Proc Natl Acad Sci USA 100:5974). There is over 10% chance that the survivor to age 90 or over will develop breast cancer and ~5–10% of the cases are caused by mutation either in the BRCA1 or BRCA2 genes. Based on 22 studies involving 8,139 index cases, with unselected family with history of female (86%) and male (2%) breast cancers or epithelial ovarian cancers (12%) were evaluated. The average cumulative risks in BRCA1 carriers for breast cancer by age 70 were 65% and for ovarian cancer 39%. For BRCA2 the same risks were 45% and 11%, respectively (Antoniou A et al 2003 Am J Hum Genet 72:1117).

Deficiency of BRCA2 leads to impaired homologous recombination but maintains normal non-homologous end joining (Xia F et al 2001 Proc Natl Acad Sci USA 98:8644). Fusion of Replication Protein A to BCR2 repeats reduced mutagenic recombination and promoted repair (Saeki H et al 2006 Proc Natl Acad Sci USA 103:8768). Even in non-hereditary (sporadic) cases of breast cancer, the BRCA1 gene is frequently lost or is inactive or rearranged. BRCA1, actually a tumor suppressor

Figure B62. Left side is colorless. The right side is colored because of the AA gene

B

(in human chromosome 17q21), is responsible for 25% of the cases diagnosed before age 30. BRCA1 along with CREB is part of the pol II holoenzyme. It activates transcription when it is associated by its C-terminus with RNA helicase A and pol II. In BRCA1 of the 12 RNA polymerase subunits the activation of hRPB2 and hRPB10 α are most critical. Predisposition to breast cancer is inherited as a dominant trait but the somatic expression (manifestation of cancer) requires that in these heterozygotes the normal allele would be lost or inactivated during the lifetime of the individual who inherited one BRCA susceptibility allele. The BRCA1 reading frame encodes 1,863 amino acids (22 exons) with a Zn finger domain at the NH₂ end. Amino acids 1,528 to 1,863, i.e., the C-terminal domain appear to be a transcriptional activator. The primary single transcript is 7.8 kb and is expressed primarily in the testis and the thymus but also in the breast and ovary. The transcript displays alternative splicing. Mice mutant in *Brcal* also develops increased risk for breast cancer because progesterone receptors are overexpressed in mammary epithelial cells. Treatment of *Brcal*/p53-deficient animals with the progesterone antagonist mifepristone can prevent tumorigenesis (Jovanovic PA et al 2006 Science 314:1467).

Gene Id4 is an important negative transcriptional regulator of BRC1 expression. BRCA1 is an important component of the 18-protein complex (SWI/SNF) involved in chromatin remodeling. BRCA1 strongly binds DNA and protects it from nucleolytic attack without sequence specificity and it is involved in double-strand DNA repair. BRCA1 binds to BRG1. As a transcription factor, it enhances the expression of several genes including p53. The BRCA1 sequences are well conserved in mammals but absent in chicken. The defects in the gene varies in the different kindreds from 11 bp deletion to frame shifts, nonsense, missense mutations or other alterations causing instability. The phenotype of the patients varies between the kindreds indicating that the specific mutations at the locus may affect its expression. It was noteworthy that there were female carriers of the mutation(s) who by age 80 failed to develop breast or ovarian cancer. Apparently, the expression is affected to some extent by extraneous genetic and environmental factors. Receptor-associated protein 80 (RAP80) is a BRCA1-interacting protein in humans. It contains a tandem ubiquitin-interacting motif domain, which is required for its binding with ubiquitin in vitro and its damage-induced foci formation in vivo. RAP80 specifically recruits BRCA1 to DNA damage sites and functions with BRCA1 in G2/M checkpoint control (Kim H et al 2007 Science 316:1202).

The BRCA1 protein may also be aberrantly localized in the cytoplasm and complicates the expression pattern. BRCA2 in human chromosome

13q12-q13 encodes 3,418 amino acids within a 6-cM region, is also a dominant early onset disease, responsible for about 45% of all *hereditary* breast cancers. Its highly conserved third exon is homologous to the c-Jun oncogene where the JNK protein binds. The 18–60 amino acid residues are potential activation sites. On both sides of exon-3 are inhibitory regions (IR1 & 2). It does not create a substantial risk for ovarian and other cancers but the chance for breast cancer in males may be slightly elevated, in contrast to BRCA1. Deletions 185delAG in BRCA1 and deletion 617delT in BRCA2 occur with carrier frequencies of 1.09% and 1.52%, respectively in Ashkenazy Jewish populations. The BRCA2 protein is cytoplasmically located. Its nuclear localization factor resides within the C-terminal 156 amino acids, and deletion in that region (e.g., 617delT) prevents the translocation of the protein to the nucleus and it consequently loses its ability to suppress tumorigenesis. The PALB2 protein normally binds BRCA2 and its mutation reduces its ability to bind and causes deficiency in homologous recombination and cross-link repair. Its mutation increases familial occurrence of breast cancer as well as prostate cancer (Erkko H et al 2007 Nature [Lond] 446:316). In 36% of the BRC families, chromosomal rearrangements (deficiencies, duplications) may be present (see Fig. B63).

Figure B63. Breast cancer pathway. (Modified after Nass, S.J. et al. 1998 Nature Medicine 4:761)

The normal allele of BRCA1 transactivates the cyclin-dependent protein kinase inhibitor p21^{WAF1/CIP1} without the cooperation of p53 and thus the entry into the S-phase of the cell cycle is prevented. This process, however, depends on the normal allele of p21. BRCA1 appears to be involved in transcription-coupled repair of oxidative DNA damage and the defective BRCA1 conveys hypersensitivity to ionizing radiation and hydrogen peroxide. Human Cds1 phosphorylates the BRCA1 protein at serine 988 after DNA damage and assists cell survival. The BRCA2 appears to be a cofactor of the radiation hypersensitivity genes Rad51 mediating double-strand DNA repair by homologous recombination or transcription-coupled repair upon phosphorylation by ATM or ATR (an ataxia telangiectasia mutated and RAD3-related protein). The BRCA2 tumor

suppressor is essential for error-free repair of double-strand breaks of the DNA. The repair is mediated by RAD51, which is attracted to the break-point by BRCA2. BRCA2 has eight ~30-amino acid repeats, which bind RAD51 and the ~700-amino acid domain binds to single-strand DNA. RAD51 elongates by polymerization the BRCA2-nucleated repairing DNA filament, which then ties the single strand to the double-strand DNA at the new junction (Yang H et al 2005 Nature [Lond] 433:653). BRCA2 has been localized to the midbody during cytokinesis and its defect results in chromosomal instability and aneuploidy (Daniels MJ et al 2004 Science 306:876). BRCA1 and BRCA2 proteins apparently interact in the cell. The Brc3 and Brc4 peptides of Brca2 protein and several low-penetrance genes are of potential importance. Homozygosity of mutant (truncated) BRCA2 (unexpectedly) also blocks cell proliferation and causes chromosomal breakage but mutations in spindle assembly checkpoint genes (p53, Bub1, Mad3L) relieve this growth arrest and restart (neoplastic) proliferation (Lee H et al 1999 Mol Cell 4:1). BRC2 (384 kDa) also involves double-stranded DNA repair (Yang H et al 2002 Science 297:1837). Normally BRC2 binds RAD51 protein, which mediates homologous pairing and recombinational repair. CDK-dependent phosphorylation of Ser 3291 site of RAD51 increases as cell proceeds toward mitosis. C-terminal damage of BRC2, however, may limit phosphorylation and interaction of BRC2 and RAD51 and leads to predisposition to radiation sensitivity and cancer because of the lack of repair (Ezashi F et al 2005 Nature [Lond] 434:598; Galkin VE et al 2005 Proc Natl Acad Sci USA 102:8537).

One of the remaining types of breast cancer is supposed to be due to a mutation in the *KRAS2* (Kirsten sarcoma) gene in human chromosome 6 when at codon 13 a G → A transition takes place resulting in Gly → Asp substitution. Ductal breast cancer was attributed to the loss of genes in human chromosome 1q21ter but also chromosomes 2, 14 and 20 were implicated. In families with high incidence of breast cancer a small secreted protein gene, expressed only in human breast cancer, was mapped to chromosome 21q22.3. **BASE** (breast cancer and salivary gland expression) a secreted protein (20q11.21), is associated with many breast cancers but not with normal tissues (Egland KA et al 2003 Proc Natl Acad Sci USA 100:1099). A dominant gene product serologically reacts with murine monoclonal antibody DF3. In the region of chromosome 17p13.3, the *TP53* regulator of tumor protein p53 was found but it could not be ruled out that a regulator exists 20 megabases telomeric to *TP53*. AIB1 steroid receptor (20q, member of the SRC-1 family oncogenes) is either amplified or overexpressed in the tumors. AIB1 seems to be a co-activator. Some observations

suggest that loss of BRCA1 may lead to perturbation and destabilization of the inactive X chromosome and that explains why this disease occurs in females (Ganesan S et al 2002 Cell 111:393). Although BRCA1 and BRCA2 are the major suppressors of breast cancer, loss of heterozygosity at 1p, 1q, 3p, 6q, 7q, 8p, 11p, 13q, 16q, 17p, 17q, 18q, 19p, 21q and 22q may also affect the development of the cancer (Miller RJ et al 2003 Am J Hum Genet 73:748).

Some forms of breast cancer also affects males and the incidence of breast cancer in Klinefelter (XXY) men is almost as high as that in women. It appears the BRCA2 carrier males have increased risk for prostate and pancreatic cancer and possibly also bone and pharynx cancer (van Asperen CJ et al 2005 J Med Genet 42:711).

Some types of breast cancers are associated with cancers in other organs. *FOXC2* transcription factor, which is involved in specifying mesenchymal cell fate during embryogenesis, is associated also with the metastatic capabilities of cancer cells. *FOXC2* expression is required for the ability of murine mammary carcinoma cells to metastasize to the lung, and overexpression of *FOXC2* enhances the metastatic ability of mouse mammary carcinoma cells (Mani SA et al 2007 Proc Natl Acad Sci USA 104:10069). The risk of recurrence of breast cancer among first-degree relatives may be as high as 50%. In a transgenic mouse model, in the HER2-induced mammary tumors the increased level of the transcriptional repressor Snail, involved transition from epithelial-to-mesenchymal cells and higher relapse of cancer (Moody SE et al 2005 Cancer Cell 8:197). The risk of breast cancer is increasing with age, unmarried status, obesity, radiation exposure, etc. Several environmental chemicals (heterocyclic amines, o-toluidine, dibromoethane, glycidol, etc.) may cause breast cancer. In North America, the lifetime risk of breast cancer in females is about 10%. Of all breast cancer incidences about 5–10% is due to inherited causes. Genetic testing is now available for BRCA1 and BRCA2 for women who on the basis of family history have an increased risk for developing the disease. Unfortunately, individuals appearing negative in the standard test may be false negatives because rearrangements at these loci (~12%) remain undetected. Furthermore CHEK2, TP53 and PTEN mutations (~5%) also increase the risk, and members of the high-risk families should be tested for these mutations (Walsh T et al 2006 J Am Med Assoc 295:1379).

The incidence of breast cancer rises steeply between ages 25 to 50 and levels off after apparently because of the petering level of estrogens. Chromosomes 2q35 and 16q12 harbor estrogen receptor susceptibility (Hunter DJ et al 2007 Nature Genet 39:870). The development of breast cancer for BRCA1 and BRCA2 carrier females by age 70 is 28–87% and for ovarian cancer ~25–30%. The male

B

carriers also have an increased risk for breast, prostate, colon, pancreas, gall bladder, bile duct, stomach cancers and melanoma (Liede A et al 2000 *Am J Hum Genet* 67:1494). The contralateral occurrence of breast cancer is much higher than the prevalence of breast cancer in the general population. BRCA1 gene is responsible partly also for ovarian and prostatic cancers. DNA repair defect seems to be involved. BRCA1 forms a complex with proteins hRAD50-hMRE11-p95. BIC (breast cancer information core) address: <http://www.breast-cancer-network.info/breast-cancer-information-core.html>, environmental risk factors: <http://envirocancer.cornell.edu/>. Breathing Of DNA: A reversible, short-range strand-separation below the melting temperature. ►[melting temperature](#)

Breeding System: Mating within a population may be random (each individual has an equal chance to mate with any member of the opposite sex) or it may be self-fertilization (in monoecious species) or inbreeding (in dioecious species). Also random mating and inbreeding both take place within the group. The term breeding system denotes these alternatives.

The predominant breeding system of a few plant species is tabulated (A: apomictic, D: dioecious, I: self-incompatible, M: monoecious, O: outbreeding, S: selfing)

Table B6. Predominant breeding system in selected plant species

| | | | |
|------------------|------------------|-------------------|-----------------|
| Alfalfa O-S | Cherry O-I | Mulberry D | Rubus O |

Breeding Value: The quantitative value a genotype, judged on the basis of the mean performance of the offspring. Actually, it is twice the mean deviation of the offspring from the mean of the parental population. The doubling is used here because each parent contributes a haploid gamete to the offspring and thus half of its genes. Breeders frequently call it the additive effect. The observed performance of individuals is called the *phenotypic value* (P) that is measured as the mean value of the population. The average value of two homozygotes is called the *midpoint*. It is equal to zero (only in case when the frequency of the two alleles is equal, 0.5) because the two parents deviate from it by a quantity of (+a) and (−a), by definition, and their sum cancel out each other. The *genotypic value* of the heterozygotes is designated by (d). In the absence of dominance $d = 0$, with complete dominance $d = a$, with overdominance $d > a$:

Table B7. Calculating breeding value

| | | | |
|------|-------|------|----|
| aa | 0 | Aa | AA |
| ← −a | → ← | +a → | |
| | ← d → | | |

The mean value (\bar{x}) is usually calculated as the weighted mean, i.e., multiplied by the genotypic frequencies in the population. If the population is in equilibrium, the mean is:

$$\bar{x} = p^2(a) + 2pq(d) + q^2(-a) + 2pq(d) = (a)(p + q)(p - q) + 2pq(d) \text{ and because } p + q = 1, \\ \bar{x} = (a)(p - q) + 2pq(d) \text{ and if several loci are involved, } \bar{x} = \sum [(a)(p - q) + 2pq(d)].$$

►gain; heritability, ►OMIA, ►Hardy-Weinberg equilibrium, ►merit; Falconer DS, Mackay TEC 1996 Introduction to quantitative genetics. Longman/Addison Wesley, White Plains, New York.

Brefeldin A (γ ,4-dihydroxy-2-[6-hydroxy-1-heptenyl]-4-cyclopentanecrotonic acid λ lactone): An inhibitor of passing peptides from the endoplasmic reticulum and Golgi complex. In the absence of brefeldin, yeast cells suffer chromosome instabilities. ►ARF, ►translocase, ►ARNO; Wigge PA et al 1998 J Cell Biol 141:967; Lang BD et al 2001 Nucleic Acids Res 29:2567.

Bremsstrahlung (brake radiation, [from German words]): Electromagnetic radiation resulting from retardation or acceleration of a high-energy particle.

BRENDA: A database of at least 40000 enzymes and 6900 organisms. Nomenclature, reaction and specificity, structure, isolation and stability information is presented. ►Recon; ►http://www.brenda.uni-koeln.de.

BRF: The binding factor in RNA synthesis initiation.

BRG1 (BRAHMA related gene-product): A 1613 amino acid, DNA-dependent human ATPase, active in SWI/SNF, RSC mediating chromatin remodeling. ►chromatin remodeling, ►SWI/SNF, ►BRAHMA; Strobeck MW et al 2001 J Biol Chem 276:9273; Barker N et al 2001 EMBO J 20:4935; ►breast cancer

Bric: ►Byler disease

Bridge: Anaphase tie between separating centromeres in dicentric chromosomes (see Fig. B64). ►breakage-fusion-bridge, ►inversion

Figure B64. Bridge. Meiotic anaphase single and double bridges and 1 or 2 chromatid fragments resulting from 2 and 4 strand recombination in a paracentric inversion heterozygote (Courtesy of Dr. Arnold Sparrow)

BRIDGE: β -lactamase Reporter for Imaging Downstream gene expression. ► β -lactamase

Bridge Protein: Facilitates the interaction between viral particles and cell surface receptors.

Bridging Cross: If two genetically distant sexually incompatible species (A and B) are to be selected for gene transfer by sexual means. The problems can possibly be overcome by first mating one of the species with an intermediate compatible form (C) and then cross the hybrid (A \times C) to the other (B). C serves as the bridge.

Bright Paramecia: ►symbionts hereditary

Bright-Field Microscopy: Ordinary light microscopy. ►dark-field microscopy, ►fluorescent microscopy, ►phase contrast microscopy, ►Nomarski, ►stereomicroscopy

Brim: Break repair induced mutation. ►DNA repair, ►DNA repair

Bristle: ►chaetae

Britten & Davidson Model: This model was suggested as a working hypothesis in the 1960s for interpreting the processes involved in the regulation of eukaryotic

B

gene functions. The external stimuli were supposed to be directed to *sensor* genes that activated *integrator* genes that in turn transmitted the signals to *receptor* genes, which affected then the *structural* genes, coding for protein. These systems might have operated then in series of interacting batteries. (Britten RJ, Davidson EH 1969 Science 165:349; Britten RJ 1998 Proc Natl Acad Sci USA 95:9372).

BRM: Animal chromatin remodeling ATPases of ~1,600 amino acids. ▶chromatin remodeling, ▶BRAHMA, ▶BRG1; Banine F et al 2005 Cancer Res 65:3542.

Brn: Eukaryotic transcription factors with POU domain controlling terminal differentiation of sensorineural cells. They are homologous to unc-86 in *Caenorhabditis*. ▶POU, ▶unc-86

Broad Bean (*Vicia faba*): $2n = 2x = 12$ and large chromosomes has been used extensively for cytological research (see Fig. B65). It is an important crop in cool climates. ▶favism, ▶*Vicia faba* for karyotype

Figure B65. Broad bean

Broad-Betalipoproteinemia: A hyperlipoproteinemia. ▶apolipoproteins, ▶hyperlipoproteinemia

Broad Sense Heritability: ▶heritability

Brody Disease (ATP2A1): A rare recessive disease encoded in human chromosome 16p12.1-p12.2, and it involves impairment of muscle relaxation, stiffness and cramps in the muscles. The basic defect is associated with the muscle sarcoplasmic reticulum calcium ATP-ase (SERCA1). ▶neuromuscular diseases, ▶sarcoplasmic reticulum, ▶Darier-White disease

Broken Tulips: Variegation (sectors) in the flowers is caused by viral infection (see Fig. B66). These sectorial tulips have commercial value in floriculture. In the seventeenth and eighteenth century the bulbs were so highly valued that they fetched gold of equal weight. ▶symbionts hereditary, ▶infectious heredity

Figure B66. Broken tulip

Bromodomain: A more or less cylindrical shape association of four helices of about 100 amino acids that form the docking sites in the chromatin for a large number of proteins (see Fig. B67). The lysine-acetylated H3 and H4 histones may be fitting into the bromodomains and are the conditions for gene transcription in eukaryotes. Bromodomains appear to anchor histone acetylase to the chromatin. ▶chromatin remodeling, ▶histones, ▶histone methyltransferases, ▶histone acetyltransferases, ▶p300, ▶SAGA, ▶PCAF, ▶SNF, ▶TAF, ▶TAF_{II}250; Ornaghi P et al 1999 J Mol Biol 287:1; Dhalluin C et al 1999 Nature [Lond] 399:491; Zeng L, Zhou M-M 2002 FEBS Lett 513:124.

Bromophenol Blue: ▶tracking dyes

Bromouracil (BU): A pyrimidine base analog that is mutagenic in prokaryotes because it may lead to base substitution after tautomeric shift. When incorporated into eukaryotic chromosomes it may cause breakage upon exposure to light. On this basis, it has been successfully used as a selective agent in animal cell cultures. The non-growing mutant cells failed to incorporate it and survived while the growing (wild type) cells were killed upon illumination. Eosinophil peroxidase may produce 5-bromodeoxycytidine and the latter is incorporated into DNA as 5-bromodeoxyuridine, which by mispairing with guanine may become mutagenic. ▶base substitution, ▶tautomeric shift, ▶hydrogen pairing, ▶chemical mutagens, ▶eosinophil; Benzer S, Freeze E 1958 Proc Natl Acad Sci USA 44:112.

Figure B67. Bromouracil

Bronchitis: Inflammation of the air passages and lung.

Bronze Age: About 5000 years ago marked the development of crafts and urbanization.

Brood: The offspring of a single mating or the cluster of eggs (clutch) laid by a bird or reptile.

Brown Fat: Adipose tissue that mainly dissipates heat. Humans with pheochromocytoma have large deposits of brown fat. ▶adipocyte, ▶pheochromocytoma

Brownian Ratchet: A hypothesis explaining transport of molecules into the mitochondria by Brownian movement (thermal agitation of molecules). Mitochondrial Hsp70-bound ATP complex associates with Tim proteins and nuclear encoded pre-proteins destined to mitochondria slide into import channels. The Mge1 protein initiates the ADP exchange and thus prevents backward movement and the protein is imported into the organelle. ▶mitochondrial import, ▶Mge1, ▶ADP, ▶ATP; Brokaw CJ 2001 Biophys J 81:1333.

Brownian-Zsigmondy Movement: Colloidal particles in solution may be in a continuously-agitated motion due to collision with the medium. It can microscopically be observed also in the cytosol of living cells.

Browsers: They provide comprehensive views by Internet access on genes, annotations, genomic regions, chromosomes and other important aspects of genomes. (UCSC Genome browser: <http://genome.ucsc.edu>; Hsu F et al 2005 Nucleic Acids Res 33:D54; National Center for Biotechnology: <http://www.ncbi.nlm.nih.gov>; Wheeler DL et al 2005 Nucleic Acids Res 33:D39; ENSEMBLE browser: <http://www.ensembl.org>; Hubbard T et al 2005 Nucleic Acids Res 33:D447; Revised and updated list appears annually in the first issue of Nucleic Acids Research).

Bruce: A 528 kD peripheral membrane protein of the trans-Golgi network and functions as an inhibitor of apoptosis. ▶trans-Golgi network, ▶apoptosis; Bartke T et al 2004 Mol Cell 14:801.

Bruce Effect: The termination of pregnancy in mice by olfactory influence on a pregnant female of a male that is genetically different from the inseminator. ▶olfactogenetics, ▶pheromones; Rajendren G, Dominic CJ 1987 Exp Clin Endocrinol 89:188.

Brucella: Bacteria responsible (for brucellosis) abortion and infertility of animals and serious febrile infection of male and female humans. *Brucella suis* 3.31 Mb and *B. melitensis* 3.29 Mb DNA have been completely sequenced. (See DelVecchio VG et al 2002 Proc Natl Acad Sci USA 99:443; Paulsen IT et al 2002 Proc Natl Acad Sci USA 99:13148; genome: <http://bbrp.llnl.gov/bbrp/html/microbe.html>).

Brugada Syndrome (SCN5A, 3p21): A dominant LQT-type heart disease (idiopathic ventricular fibrillation) due to defect in exon 28 of a sodium channel (SCN5A) gene. SUNDS (sudden unexplained nocturnal death syndrome) relatively common in

Southeast Asia is controlled by an allelic gene. ▶LQT, ▶heart diseases, ▶ion channels; Vatta M et al 2002 Hum Mol Genet 11:337.

Brush Border: A dense lawn of microvilli on the intestinal and kidney epithelium that facilitates absorption by increasing the surface. ▶microvilli

Bruton's Tyrosine Kinase: ▶BTK, ▶agammaglobulinemia

Bryophytes: Mosses, liverworts and hornworts. They are green plants similar to algae but the organization of their body is more complex. Their gametangia is either unicellular or multicellular and show some cell differentiation. They usually have haploid and diploid life forms. The majority of them are terrestrial. ▶alga

BS: ▶Bloom syndrome

BSAP: ▶pax

BSE (bovine spongiform encephalopathy): ▶encephalopathies, ▶Creutzfeldt-Jakob disease

BSL (biological safety level): BSL is specified by governmental regulations, BSL-1 is the minimal and BSL-4 is the most stringent, depending on the hazards involved.

bT: as a prefix for *Bos taurus* (bovine) DNA or protein.

BTB: Protein domains named for the *Drosophila* transcription factors Bric-a-brac (bab), Tramtrack (ttk) and Broad-Complex (BR-C) that associate with cullins, ubiquitin ligase and are required for the degradation of the meiotic spindle and the assembly of the mitotic spindle. BTB is an adaptor for the SCF complex. ▶cullins, ▶ubiquitin, ▶SCF, ▶spindle; Pintard L et al 2003 Nature [Lond] 425:311; Xu L et al 2003 Nature [Lond] 425:316.

BT2: same as TFIIH. ▶transcription factors

BTG: Antiproliferative protein encoded in human chromosome 1q32. Its synthesis is regulated by p53. ▶p53

BTK (Bruton's tyrosine kinase): It belongs to a family of non-receptor tyrosine kinases. Its deficiency results in immunodeficiency by blocking differentiation of B lymphocytes. Syk and Lyn activate BTK with the mediation of BLNK. BTK phosphorylates transcription factor TFII-1 and loss of the TFII-1 gene results in Williams-Beuren mental defect. TFII-1 acts as a negative regulator outside the nucleus and interferes with calcium entry (Caraveo G et al 2006 Science 324:122). ▶agammaglobulinemia, ▶Sky, ▶Lyn, ▶B lymphocyte receptor, ▶Williams syndrome; Liu W et al 2001 Nature Immunol 2:897.

βTrCP: A ubiquitin ligase, frequently associated with SCF and regulates by degradation of diverse

B

metabolic and developmental pathways. ►ubiquitin; Zhang J et al 2003 Proc Natl Acad Sci USA 100:14127.

BUB1, BUB2: These are checkpoint proteins arresting mitosis when the spindle attachment assembly is defective or there are problems with sister chromatid separation. ►cell cycle, ►meiosis I, ►MAD, ►p53; Krishnan R et al 2000 Genetics 156:489; Geymonat M et al 2002 J Biol Chem 277:29439; relation to p53: Gjoerup OJ et al 2007 Proc Natl Acad Sci USA 104:8334.

Bubble: A bubble is formed when at replication the two strands of the DNA separate or when transcription begins on DNA. Re-annealing the bubble at promoter clearance is called bubble collapse (Pal M et al 2005 Mol Cell 19:101). ►promoter clearance

Bubonic Plague: ►Yersinia

Buccal Smear: A sample of the epithelial cells from the inner surface of the cheek is spread onto microscope slides and used for rapid determination of the number of Barr bodies with 4–5% error rate. This procedure (mucosal swab) is non-invasive and the sampling is painless. The cells so sampled may also be used for DNA analysis by PCR after a rapid (ca. 1 hr) extraction. ►Barr body, ►PCR

Buckwheat (*Fagopyrum*): A feed and food plant ($2n = 2x = 16$). Eaten by animals or by humans, it may increase sensitivity to light and skin rash (see Fig. B68). ►favism

Figure B68. Buckwheat

Bud (budding protein of yeast): A cytoskeleton assembly-mediating protein family. Bud proteins associated with GTPase activating protein (GAP) are required for axial and bipolar budding patterns. ►Bni, ►cytoskeleton, ►profilin, ►polarity embryonic

Bud Scar: A chitin ring formed at the junction of the mother and daughter yeast cells that persists even after separation of the two cells. The number of bud scars may indicate the number of cell divisions (age) of the cell as well as polyploidy which is characterized by a different pattern of the bud scars.

Bud Sport: Genetically different sector (due to somatic mutation) in an individual plant (chimera).

Budding: Asexual reproduction by which the cell's cytoplasm does not divide into two equal halves, yet the bud after receiving a mitotically divided nucleus eventually reproduces all cytoplasmic elements and grows to normal size. Budding of enveloped viruses takes place by acquiring their membrane of lipid bilayer and proteins. They direct their surface glycoproteins into one or another type of cell membrane. They are pinching off either from the cell surface or into the cell lumen. The lipids of the bilayer come from the cell whereas the virus DNA specifies the proteins. ►Saccharomyces cerevisiae; retrovirus budding: Fisher RD et al 2007 Cell 128:841.

Budding Yeast: ►Saccharomyces cerevisiae (see Fig. B69).

Figure B69. Budding yeast

BUdR (5-bromodeoxyuridine): Animal cells deficient in thymidine kinase enzyme are resistant to this analog. It is a base analog mutagen, substituting for thymidine and may cause mutation. Its mutagenic efficiency is low, especially in eukaryotes although if cells with BUdR substituted chromosomes are exposed to visible light, chromosome breakage is induced. When chromosomes with BUdR substitutions, at least in one of the strands, are exposed to low LET ionizing radiation, double-strand breaks occur in proportion of the amount of substitutions. The presence of reducing agents (e.g., e^-_{aq}) favors breakage. ►bromouracil, ►base substitution mutation, ►sister chromatid exchange, ►hydrogen pairing

Buerger Disease: Autosomal recessive predisposition to thromboangiitis (inflammation of the blood vessels); its frequency is relatively high in some oriental ethnic groups.

Buffalo: Asiatic swamp buffalo (*Bubalus bubalis*) $2n = 48$, the Murrah buffalo (*Bubalus bubalis*) $2n = 50$, the African buffalos (*Syncerus caffer caffer*) $2n = 52$, and the *Syncerus caffer nanus* is $2n = 54$.

Buffer: A chemical solution capable of maintaining a level of pH within a particular range depending on the components of an acid-base system. Also a special storage area in the memory of a computer from where the information can be utilized at different rates by different programs; e.g., the printer can store information faster than it can print it.

Buffer Sequences: To avoid the loss of indispensable 5' and 3' tracts from linearized transforming DNA,

protective sequences may be added to the constructs. These buffers should not have cryptic splice or regulatory sites. Introns may be used.

Buffering, Genetic: A homeostatic mechanism that is supposed to maintain the function of genes at a certain level. ▶Redundancy (duplications), ▶feedback, ▶epistasis, ▶temperature-sensitivity, ▶modifier genes, ▶signal transduction, ▶chaperones, ▶apoptosis, etc. may mediate it. (Kitami T, Nadeau JH 2002 *Nature Genet* 32:191).

Bufo vulgaris (toad, $2n = 36$): A primarily terrestrial small frog species and it lives in water environment during the mating season. (▶*Rana*, ▶*Xenopus*, ▶frog, ▶toad)

Build: The sequence of the human genome. The most complete sequence in 2004 is denoted as Build 35. (See *Nature [Lond]* 431:931).

Bulge: Unpaired stretches in the DNA. They are involved in binding of regulatory protein domains, in enzymatic repairs, slipped mispairing in the replication of microsatellite DNA, intermediates in frame shift mutations and essential elements for naturally occurring antisense RNA ▶DNA repair, ▶binding proteins, ▶mismatching, ▶frame shift mutation, ▶microsatellite, ▶antisense RNA

Bulimia: A psychological disorder involving excessive eating and self-induced vomiting based on serotonergic abnormality. ▶anorexia, ▶obesity, ▶serotonin, ▶addiction; Bulik CM et al 2003 *Am J Hum Genet* 72:200.

Bulked Segregant Analysis: It is used in mapping recombinant inbred lines. The individuals in the population are identical at a particular locus but unlinked regions in the chromosomes are represented at random. ▶RAPD

Bulk-Flow Model: It postulates that targeting signals does not regulate export of molecules from the endoplasmic reticulum. Experimental evidence indicates, however, that even the constitutively excreted proteins carry some target specificities. ▶endoplasmic reticulum

Bulking: A plant breeding procedure when selection of segregants after a cross is delayed to later generations when the majority of individuals become homozygous by continued inbreeding. The number of heterozygotes by F_n is expected to be $0.5(n-1)$ for a particular locus where n stands for the number of generations selfed. Note: the F_1 is produced by crossing therefore we use $n - 1$. ▶inbreeding progress of, ▶inbreeding rate

Buller Phenomenon: When from dikaryotic mycelia nuclei may move into monokaryotic ones. ▶di-mon

Bullous Pemphigoid Autoimmune Disease: A human chromosome 6p12-p11 dominant autoimmune disease manifested as vesicles on the skin. It is based on a defect involving the ca. 230 kDa glycoprotein (antigen BPAG1e). This antigen affects also the nerve fibers. ▶filament, ▶autoimmune disease

Bundle: Protein α -helices running along the same axis. ▶protein structure

Bundle Sheath: Cells wrapped around the phloem bundles. Their chloroplasts do not show grana and synthesize carbohydrates through the C3 pathway although the other chloroplasts in the same plant operate by the C4 system. ▶chloroplasts, ▶C3 plants, ▶C4 plants

Bungarotoxin: ▶toxins

Buoyant Density: A molecule (e.g., DNA) suspended in a salt density gradient (such as a CsCl solution, spun for 24 hr at 40,000 rpm in an ultracentrifuge tube) comes to rest in the salt gradient at the position where the medium (CsCl) density is identical to its own. The buoyant density of, e.g., *Chlamydomonas* nuclear and chloroplast DNA is 1.724 and 1.695, respectively. Higher buoyant density reflects higher G + C content in the DNA. The refractive index determined by a refractometer, capable of 5-digit resolution, can be used to determine the density (ρ) of a cesium chloride solution in any sample withdrawn from the centrifuge tube. The relevant relationships at 25°C are the following:

Table B8. Determining Buoyant Density

| CsCl Weight% | Density g/mL | Refractive Index | Molarity |
|--------------|--------------|------------------|----------|
| 50 | 1.5825 | 1.3885 | 4.700 |
| 55 | 1.6778 | 1.3973 | 5.481 |
| 56 | 1.699 | 1.3992 | 5.651 |
| 57 | 1.7200 | 1.4012 | 5.823 |
| 58 | 1.7410 | 1.4032 | 5.998 |

The density of *E. coli* DNA is about 1.710 and that of *Mycobacterium phlei* is 1.732 and a deoxy A-T polymer has a (ρ) value of 1.679. Since none of these values are directly readable from the tabulation, interpolation is required that can be done by graphic representation. ▶density gradient centrifugation

Buphthalmos: ▶glaucoma

Burbank, Luther (1849–1926): American breeder credited with the production of over 800 new varieties and strains of plants, mainly in Santa Rosa, California. In addition, his success had a stimulating

B

effect on the development of plant breeding. Regrettably, his mystic, Lamarckian ideas also hindered scientific plant breeding. (See Crow J 2001 Genetics 158:1391).

Burden of Proof: The responsibility of proving the validity of an assertion, e.g., that a genetically modified organism or a drug is hazardous or harmful.

Burdo: A “graft hybrid” between tomato and nightshade (*Belladonna*), forming a periclinal chimera. The graft hybrids were assumed to be the result of fusion between the cells of different species combined at the site of the grafting. From this site then somatic hybrid cells regenerated into plants. ▶periclinal, ▶somatic cell hybrids; Winkler H 1907 Ber Dtsch Bot Ges 25:568.

Burkitt's Lymphoma: A human cancer caused frequently by the Epstein-Barr virus is most common in central Africa but occurs in other parts of the world, involved in nasopharyngeal (nose and throat) carcinoma and neoplasias of the jaws and the abdomen. It frequently involves a translocation between human chromosomes 8 (c-myc oncogene) to 14 (immunoglobulin promoter). The receptor of the Burkitt's lymphoma is activated by a chemokine that is targeted to B cells in the lymphoid follicles. The Epstein-Barr virus positive lymphomas display elevated amount of reactive oxygen species (ROS), a likely contributing factor to cancer (Cerimele F et al 2005 Proc Natl Acad Sci USA 102:175). ▶Epstein-Barr virus, ▶chemokine, ▶B cell, ▶lymphoma, ▶methylation of DNA, ▶immunoglobulins, ▶myc

Bursa: Generally a sac like pouch; the bursae Fabricius are located in the intestinal tract of birds and produce the B lymphocytes. ▶lymphocytes

Burst Size: The average number of phage particles released by the lysis of bacteria.

Bus: It is the circuit system in a computer that transmits information within the hardware or cables that link together various devices with the computer.

Bushmen: A designation for nomadic people who live in the wilderness (bush), such as the Australian aborigines or people in the Kalahari Desert. The anthropological characteristics are shared within the group but there is no known evolutionary relationship among the Bushmen inhabiting different geographical regions.

Busulfan (C₆H₁₄O₆S₂, most common trade name myleran): It is antineoplastic/carcinogenic chemical (see Fig. B70). It is a mitotic germ cell toxicant; eliminates primordial follicles. It is also a chemosterilant pesticide. ▶Myleran

Figure B70. Busulfan

Buzzword Index (BWI): BWI indicates the varying trends of use of certain terms in the science literature.

$$BWI = Ln(n)X \frac{(n+1)/(N+1)}{(n^*+1)/(N^*+1)}$$

Where n is the number of times the term was mentioned in the past year and n^* is the number of times the word was mentioned during the past 10 years. N and N^* are similarly calculated on the basis of the occurrence of the word “biology” and this normalizes the score with respect to the general growth of biology papers. (Adopted from Jensen LJ et al 2006 Nature Rev Genet 7:119).

BvgS: *Bordetella pertussis* (bacterial) kinase affecting virulence regulatory protein BvgA. ▶pertussis toxin

Bypass Replication: It is capable of bypassing a DNA defect and continues the process beyond it. It does not lead to permanent repair. ▶DNA repair

Byr 2: A serine-threonine kinase of *Schizosaccharomyces pombe*. An analog of RAF. ▶raf, ▶signal transduction, ▶serine/threonine kinase

Byler Disease (PFIC1, 18q21): Progressive intrahepatic cholestasis. It is apparently allelic to the benign recurrent intrahepatic cholestasis (BRIC). Bile acid secretion is defective due to defect(s) in the ATP-binding cassette (ABC) transporter. ▶cholestasis, ▶Alagille syndrome, ▶ABC transporter

Bystander Activation: A hypothesis for the origin of autoimmune reaction. Viruses may induce inflammation resulting in cytokine production. The cytokines may reactivate dormant T cells with low activation threshold and these T cells may then attack self-antigens that normally escape their attention. Non-malignant immune cells infiltrating follicular lymphoma have profound effect on the development of this type of cancer (Dave SS et al 2004 New England J Med 356:2159). ▶self antigen, ▶immune response, ▶autoimmune disease, ▶immune tolerance, ▶bystander effect; Fournie GJ et al 2001 J Autoimmun 16:319.

Bystander Effect: Genetic vectors targeted to a particular cell type do not spread to neighboring cells, yet their synthesized transgene product (e.g., a toxin) may diffuse and also kill the surrounding cells. The bystander effect is a complex result of intercellular communication through gap junctions, apoptotic cell

death, release of cytokines, blocking of angiogenesis, etc. ►gene therapy, ►cancer gene therapy, ►Mo-MuLV, ►transgene, ►gap junctions, ►cytokines, ►apoptosis, ►angiogenesis, ►vectors, ►radiation response, ►radiation hazard; Zheng X et al 2001 Mol Pharmacol 60:262.

Byte: A computer unit of information consisting of a number of adjacent bits. Most frequently 1 byte is

8 bits that represent a letter or other characters that the computer uses. ►bit

B

bZIP: basic leucine zipper. ►leucine zipper, ►DNA-binding protein domains

B-Zip Protein: A DNA binding, protein contains a basic amino acid zipper domain. ►binding proteins

Historical vignette

William Bateson, the most ardent Mendelian, among many of his original contributions, discovered that the interactions among gene products modify the Mendelian ratios without compromising the validity of the basic principles. In 1926 TH Morgan eulogized Bateson with these words: "His intellectual rectitude was beyond all praise and recognized by friend and foe alike" (*Science* 63: 531).

Bateson enjoyed popularity in America and was personally familiar with most of his American colleagues. In 1922, at the University of Pennsylvania, he concluded a memorial lecture with the following warning:

"I think we shall do genetical science no disservice if we postpone acceptance of the chromosome theory in its many extensions and implications. Let us distinguish fact from hypothesis. It has been proved that, especially in animals, certain transferable characters have a direct association with particular chromosomes. Though made in a restricted field this is a very extraordinary and most encouraging advance. Nevertheless the hope that it may be safely extended into a comprehensive theory of heredity seems to me ill-founded, and I can scarcely suppose that on a wide survey of genetical facts, especially those so commonly witnessed among plants, such an expectation would be entertained. For phenomena to which the simple chromosome theory is inapplicable, save by the invocation of a train of subordinate hypotheses, have been there met with continually, as even our brief experience of some fifteen years has abundantly demonstrated" (*J. Genet.* 16: 201 [1926]).

W. Bateson
1922

C

C: An abbreviation of cytosine. ► [cytosine](#)

3C: ► [chromosome conformation capture](#)

4C (circular chromosome conformation capture):
► [chromosome conformation capture](#)

C6: Rat glioma cell line (tumor of tissues supporting the nerves). ► [glioma](#)

C6: Fungal zinc-binding protein cluster.

c25: A prolactin/cycloheximide responsive transcription factor similar to IRF-1 (interferon regulator factor); controls proliferation and anti-proliferation responses in cells. ► [transcription factors](#), ► [IRF](#), ► [interferon](#)

C α: The carbon atom(s) of amino acids to which an amino group, carboxyl group, hydrogen atom or a side chain is attached.

C Amount of DNA: Content of DNA in the gametes is 1C; it is 2C in the zygotic cells before S phase, 4C after S phase. The 1C amount actually means that the chromosomes have only one chromatid containing a single DNA double helix. After replication, each chromosome becomes double-stranded, i.e., composed of two chromatids held together at the centromere. The 4C stage usually is an indication of a diploid or zygotic cell. ► [cell cycle](#), ► [C value paradox](#)

C Banding: A type of banding pattern near the centromere (and some other limited areas, such as telomeres) obtained after staining chromosomes with the Giemsa stain (a mixture of basic dyes), particularly when, prior to staining, the chromosomes were exposed to the protease trypsin (see Fig. [C1](#)). ► [chromosome banding](#), ► [G banding](#), ► [R banding](#); Chen TR, Ruddle FH 1971 Chromosoma 34:51.

Figure C1. C banding

C.E.: Common Era; designation of historical time of, e.g., archeological sites.

C genes: Genes coding for the constant region of the antibody molecule (such as C μ , C δ , C γ , C ϵ , C α). ► [immunoglobulins](#); ► [antibody](#)

C1 Inhibitor: A proteinase inhibitor of the serpin family; it is a regulator of blood clotting. ► [serpin](#)

C Kinase: A Ca²⁺-dependent protein kinase attached to the plasma membrane. Diacylglycerols and/or phosphatidylserine may activate it. It may be indirectly involved in +/- regulation of genes. ► [RACK](#)

C Period: A full cycle of the replication of DNA measured in time units.

C₃ Plants: These plants produce three-carbon molecules (phosphoglycerate) as the first step in photosynthesis. By genetic engineering some of the C₄ enzymes can be expressed in C₃ plants. ► [Calvin cycle](#), ► [photosynthesis](#); Matsuoka M et al 2001 Annu Rev Plant Physiol Mol Biol 52:297.

C₄ Plants: The first products of their carbon fixation are four-carbon molecules (oxaloacetate, malate, aspartate); their photosynthetic efficiency is greater than that of C₃ plants. ► [C₃ plants](#)

C Terminus: The carboxyl end of a polypeptide chain. ► [collinearity](#), ► [amino end](#)

C Value: The amount of DNA in a single chromatid or chromosome before the DNA has replicated. Thus, the C value in the gametes is 1, in the diploid zygote it is 2, and after S phase before cell division takes place it may be 4 C. ► [genome](#); Plant DNA C Value Database: <http://www.rbgekew.org.uk/cval/database1.html>; Animal Genome Size Database: <http://www.genomesize.com/>.

C Value Paradox: The lack of relationship between evolutionary status (complexity of an organism) and its genome size, e.g., the size of the genome of the plant *Fritillaria* is $\sim 3 \times 10^8$ kbp whereas that of *Homo* is $\sim 3 \times 10^6$ kbp. ► [copy number paradox](#), ► [genome](#), ► [pseudogenes](#), ► [redundancy](#), ► [repetitious DNA](#), ► [junk DNA](#), ► [gene number paradox](#), ► [N value paradox](#), ► [H value paradox](#); Petrov DA 2001 Trends Genet 17:23; Gregory TR 2001 Biol Revs 76:65.

C₆ Zinc Cluster Protein: A group of transcriptional activators. Their DNA binding sites have the conserved CGG...CCG triplets and, in-between, a number of other bases in the different members of the family. Furthermore, there is a 19-amino acid carboxy-terminal region at the zinc cluster side, containing the linker and the beginning of the dimerization element that directs the protein to its preferred site. ► [transcription factors](#), ► [transcriptional activator](#), ► [zinc finger](#); Akache B et al 2001 Nucleic Acids Res 29:2181.

CAAT Box (CCAAT): A consensus sequence in the untranslated promoter region of eukaryotic genes, recognized by transcription factors. Housekeeping

genes may not have this box or a TATA box. ►C/EBP, ►AP, ►G box, ►asparagine synthetase, ►promoter, ►TATA box, ►housekeeping genes

C

CaaX Box: A membrane-binding protein motif.

CAB: ►chlorophyll-binding protein

Cabbage: ►*Brassica*

CaBP (calcium-binding protein): An endoplasmic reticulum chaperone protein (49 kDa) with two thioredoxin kind domains. ►PDI, ►chaperones

CAC (chromatin assembly complex): Includes histones H3 and H4 and the chromatin assembly factor. CAC subunits are p160, p60 and p48. ►histones, ►nucleosome, ►CAF, ►chromatin

Cacajo: ►Cebidae

Cacao (*Theobroma cacao*): A tropical plant; also a source of chocolate and cocoa derived from the dried oily cotyledons of the seed. The economically useful species are $2n = 2x = 20$. In the flavonol-rich content, epicatechin actively increases nitric oxide synthesis in the body causing vasodilation and this is beneficial for atherosclerosis. (Schroeter H et al 2006 Proc Natl Acad Sci USA 103:1024).

Cache: A memory in the computer that increases the speed and efficiency of the machine.

Cachectin: A hormone-like protein product of the macrophages which releases fat and lowers the concentration of fat synthetic and storage enzymes. It is encoded by a gene situated within the HLA cluster in human chromosome 6p21.3. ►HLA, ►macrophage; Jue DM et al 1990 Biochemistry 29:8371.

CACHET (condensation of amplification circles after hybridization of encoding tags): ►padlock probes

Cachexia: A condition of emaciation, of the wasting away of muscles. It may be caused by a 24 kDa proteoglycan as the consequence of cancer or other debilitating conditions. Tumor necrosis factor α may have an important role in it. The proteasome activity is aided by glucocorticoids, but NF- κ B aids the process by down-regulating MyoD, which replenishes muscle fibers. ►proteoglycan, ►TNF, ►NF- κ B, ►proteasome, ►MyoD, ►obesity; Rubin H 2003 Proc Natl Acad Sci USA 100:5384.

CACN1A4: α subunit of a brain-specific voltage-gated neuronal calcium ion channel, encoded at human chromosome 19p13.1. ►migraine, ►ion channels, ►spinocerebellar ataxia

Caco: Colon adenocarcinoma, a malignant adenoma. ►adenoma, ►carcinoma

Cactus: A protein product of the *cact* gene of *Drosophila* (2–52) which controls dorsoventral differentiation by maternal effect in the embryo. Its action is similar to Dorsal. The protein Toll dissociates Cactus from Dorsal and subsequently Dorsal moves into the nucleus. Pelle (serine/threonine kinase) and Tube mediate the signals from Toll to the Dorsal-Cactus complex (morphogenesis in *Drosophila*).

CAD (caspase-activated DNase): Degrades chromatin by cleavage between the histone-DNA complex of the nucleosomes during apoptosis. ►caspase, ►DNase, ►nucleosome, ►chromatin, ►ICAD, ►acinus, ►apoptosis, ►ICAD, ►endonuclease G; Enari M et al 1998 Nature [Lond] 391:43.

CAD (coronary artery disease): ►coronary heart disease

CAD: A three-enzyme complex trifunctional protein catalyzing the first three steps in the *de novo* pyrimidine pathways (carbamoyl phosphate synthetase II, aspartate transcarbamylase, and dihydroorotase). All the three identical polypeptide subunits (Mr 230,000, each) have active sites for the three reactions. In the Syrian hamster, the gene coding for it is 25 kbp; it has 37 introns and the mRNA transcript is 7.9 kb. When amplified, this complex is 500 kbp. The synthesis of carbamoyl phosphate synthetase II is stimulated by the epidermal growth factor (EGF) and ERK MAP kinase system. ►pyrimidine, ►EGF, ►signal transduction; Chen S et al 2001 Proc Natl Acad Sci USA 98:13802.

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy): A complex syndrome encoded in an 800 kb region of human chromosome 19p13.2-13.1 (Notch3). It involves diffuse white matter in the brain, defects in the brain blood vessels, stroke, progressive mental illness, paralysis of the face, headaches, severe depression, etc. The basic defect is in a glycosylated transmembrane receptor protein, homologous to Notch of *Drosophila*. ►Notch, ►presenilins, ►morphogenesis in *Drosophila*, ►Alzheimer disease, ►transmembrane proteins, ►stroke, ►brain human, ►migraine, ►leukoencephalopathy

Cadastral: Within a topological boundary. Cadaster originally meant land maps for taxation generated in detail and at various scales, e.g., 1 inch on paper corresponding to yards or furlongs on the land.

Cadherins: Cell adhesion molecules (glycoproteins) dependent on the presence of Ca^{2+} . The quantity and quality of cadherins determines how cells of the same type stay together and how different types segregate during embryonic development, i.e., the nurse cells, follicle cells, and the embryo segregate to different

poles in the egg chamber of *Drosophila* (see diagram at maternal effect genes). Cadherins alone do not determine the specificity of cell sorting (Niessen CM, Gumbiner BM 2002 J Cell Biol 156:389). Cadherins are encoded in human chromosome 16q22.1. The human protocadherins genes PCDH α , β , γ are in chromosome 5q31, but PCDH7 is at 4p15 and PCDH22 is at Yp11.2. Protocadherin genes are found also at 13q21.1 and at 10q21-q22. The protocadherins are classified as nonclassic cadherins because—unlike the classic cadherins—they do not interact with catenins. They have a basic role in normal development and a reduction in their level increases the invasiveness of many types of cancerous growths. They have membrane-spanning and cytoplasmic domains. The former assures cell-to-cell contacts, the latter attaches to the cytoskeleton. Dominant negative cadherin mutants develop Crohn's disease-like symptoms, spina bifida and adenomas. Dysadherin, a 178 amino acid cell membrane glycoprotein, down-regulates E-cadherin and promotes metastasis. ▶Crohn's disease, ▶adenoma, ▶spina bifida; ▶integrin, ▶catenin, ▶gastric cancer, ▶deafness, ▶Usher syndrome, ▶snail, ▶pattern formation during development, ▶p38; Nollet F et al 1999 Mol Cell Biol Res Comm 2:77; Poser I et al 2001 J Biol Chem 276:24661; Alagramam KN et al 2001 Hum Mol Genet 10:1709; Ino Y et al 2002 Proc Natl Acad Sci USA 99:365; cadherins in development: Halbleib JM, Nelson WEJ 2006 Genes Dev 20:3199.

cADP-ribose: ▶cyclic ADP-ribose

***Caenorhabditis briggsae*:** A close relative of *Caenorhabditis elegans* and living in the same ecological

niche. It appears to have 19,500 protein-coding genes and 12,200 of them clearly orthologous to those of *C. elegans*. Only about 800 of its genes do not show matches in *elegans*. In 96% of the genes, collinearity is preserved. The repetitive sequence is 22.4% in *C.b.* but only 16.5% in *C.e.* (See Fig. C2; Stein LD et al 2003 PLOS Biol 1:166).

***Caenorhabditis elegans*:** A small nematode, which feeds on bacteria. It completes its life cycle in about $3\frac{1}{2}$ days. Approximately 99.8% of the animals have the following chromosomal constitution: 5 pairs of autosomes and two X chromosomes and are hermaphrodites; 0.2% of the populations are XO males generated by nondisjunction. Its genome is about ~97 million bp and has been sequenced. It includes a little more than 19,000 genes and 40% of them appears homologous to that of other organisms. The nervous system includes only about 302 cells. The neurons represent 118 structural classes and the number of positions of identifiable chemical synapses appears to be 7,600. More than 250 genes were identified by mutational analysis to be involved in behavior. All of its genes have been cloned and sequenced. It is one of the best organisms for molecular developmental studies. The simplest developmental pathway of animals is seen in this nematode, with approximately 958 somatic cells, including its nervous system, in a thin 1.2 mm long body of the adult. The egg usually develops hermaphroditically or by fertilization by the rare males, into a 550-cell embryo in the eggshell. Further divisions take place after hatching and passing, by moltings, through four larval stages. The entire

Figure C2. *Caenorhabditis elegans* adult hermaphrodites larval developmental stages

process may be completed in about three days. Through the transparent body, the migration of the embryonal cells and formation of organs can be traced under the microscope using Nomarski differential interference contrast optics. The pattern of differentiation and development displays very little variation. The somatic tissues generally have multicellular origin whereas the intestinal cells and the germline cells, each, are monoclonal. For differentiated functions, cytokinesis is not absolutely required. Differentiation is generally not controlled by the cellular milieu but by the identity of the particular cell (demonstrated by ablation experiments). Nevertheless, signal transduction among cells may also be required for the formation of the egg-discharging mechanisms. Through the involvement of a single anchor cell, the vulva is formed and the uterus passes the egg through the anchor and vulva on the culture medium contained in a Petri plate where development is completed. A somatic “distal tip cell” controls the mitotic activity of the “germ cells” which undergo meiosis and produce the gametes. The hermaphroditic XX females are self-fertilized, but by nondisjunction they also produce male gametes at a frequency of 0.1%. The XO males, when mated with an XX female, produce males and females in equal proportion (see Fig. C2). More than 40% of its estimated 19,000 genes have some homology to genes of other organisms. Of 44 human disease genes analyzed, 32 had significant similarities to its genes. ►unc-86, ►apoptosis, ►RNAi, ►Nomarski differential interference contrast microscopy, ►cell lineages, ►operons, ►dauer larva, ►*Photorhabdus*, ►*Xenorhabdus*, ►*Pristionchus*, egg laying controls: Schafer RS 2006 Annu Rev Genet 40:487; Hodgkin J, Herman RK 1998 Trends Genet 14:352; sequence biology; 1998 Science 282:2011; *Caenorhabditis* resources: Antoshechkin I, Sternberg PW 2007 Nature Rev Genet 8:518; www.wormatlas.org; <http://www.wormbase.org>, ►*elegans.swmed.edu*, <http://www.wormbook.org>; expressed sequence tags of 30 nematode species; <http://www.nematode.net/index.php>; Textpresso, *C. elegans* and *C. ramenei*: <http://wormbase.org>.

CAF (chromatin assembly factor): Facilitates the structural organization of the chromosomal elements in association with acetylated histones. Its three subunits are Cac1, Cac2, and Cac3. The small CAF-1 subunit p48 is identical to the retinoblastoma-associated protein 48 (RbAp48). The p48 homolog of *Arabidopsis* (AtMSI1) may regulate processes of tissue differentiation in a quantitative manner (Hennig L et al 2003 Development 130:2555). Deletion of any one single Cac increases UV sensitivity. CAF defect in *Arabidopsis* results in fasciation. ►chromatin,

►CAC, ►RCAF, ►retinoblastoma, ►ACF, ►chromatin remodeling, ►nucleosomes, ►fasciation, ►PCNA; Tyler JK et al 2001 Mol Cell Biol 21:6574.

CAF (CD8 antiviral factor): α -defensins or β -chemokines secreted by CD8 T cells appear to be the active elements. CAF1 and CCR4 are required for deadenylation. ►defensin, ►chemokine, ►T cells, ►acquired immunodeficiency; Zhang L et al 2002 Science 298:995.

Café-au-Lait Spot: A light brown skin macule. These spots can be diagnostic signs of neurofibromatosis (see Fig. C3). ►neurofibromatosis

Figure C3. Café-au-lait spot

Caffeic Acid (3,4-dihydroxycinnamic acid phenethyl ester, CAPE): Caffeic acid is related to flavonoids present in honeybees' glue. It has antiviral, antiinflammatory, immunomodulatory effects and it inhibits tumor growth, lipid peroxidation, lipoxygenase, ornithine decarboxylase, protein tyrosine kinase and the activation of NF- κ B. (See named entries separately, ►antimutagen)

Caffeine: A modified purine molecule, present in coffee, tea, cola nuts and other plants. It is biosynthesized from adenosine monophosphate and guanosine monophosphate through several steps first yielding xanthosine, which is methylated to 7-methylxanthosine that is converted into 7-methylxanthine then into 3,7-dimethylxanthine (theobromine) and then into 1,3,7-trimethylxanthine/caffeine (see Fig. C4) (Ogawa M et al 2001 J Biol Chem 276:8213).

Figure C4. Caffeine

It is a stimulant and a diuretic. Caffeine itself is not a clastogen but it interferes with the repair of spontaneously or otherwise caused chromosomal damage, and thus may enhance the mutagenic potential of irradiation and chemicals by overriding

checkpoint controls in the cell cycle. A ubiquitin conjugating protein (encoded by fission yeast gene *rhp6*), required for entry into mitosis, may be affected by caffeine. Interference with Cdc25 phosphatase and Cdc2 opens the path to mitosis and does not leave enough time for DNA damage. Oral LDLo is 192 mg/kg for humans (see Fig. C5).

Figure C5. Chromosome breakage on caffeine. Human leukocyte culture in the presence of caffeine with multiple chromosome breakage. (From Ostertag W, Greif BJ 1967 Human Genet 3:282)

LD₅₀ orally for male mice is 127 mg/kg, for females 137 mg/kg. Caffeine action on the stimulation of the nervous system is controlled through DARPP32. Consumption of coffee with high diterpene content (kahweol, cafestol) may enhance detoxification of O⁶-alkylguanine and other mutagenic/carcinogenic compounds (Huber WW et al 2003 Fundamental Mol Mech Mutagen 522:57). By RNAi technology, theobromine synthase activity can be reduced in transgenic coffeea plants thereby reducing the caffeine content by genetic means (Ogita S et al 2003 Nature [Lond] 423:823). ▶**purine**, ▶**theobromine**, ▶**LDLo**, ▶**LD₅₀**, ▶**checkpoint**, ▶**Cdc25**, ▶**Cdc2**, ▶**alkaloids**, ▶**DARPP**, ▶**coffee**; Schlegel R, Pardee AB 1986 Science 232:1264; Linskog M et al 2002 Nature [Lond] 418:774.

CAGE (cap-analysis gene expression, CAGE tag): Used for the identification of transcription start sites and the associated promoters. The capped gene is subjected to reverse transcription. The biotin-labeled full-length cDNA is released and MmeI restriction endonuclease-recognition site (TCCRAC, 20-18 nt away) is introduced at the 5'-end. After PCR amplification the cloned fragments are sequenced (Kodzius R et al 2006 Nature Methods 3:211). ▶**cap**, ▶**biotin**, ▶**reverse transcription**, ▶**PCR**

Caged Compound: A caged compound is rendered inactive by combining it with a photosensitive molecule and then introducing it into the cell by microinjection, electroporesis or protoplast fusion

and subsequently irradiating it by UV light of a specific wavelength or by laser beam leading to liberation of the molecules (e.g., Ca⁺⁺, cAMP, GTP) from the sensitizer (e.g., nitrobenzyl side chain). This procedure permits the study of localized effects within the cytoplasm. Fluorochromes can also be caged for monitoring the behavior of subcellular structures, e.g., the function of tubulins. ▶**microinjection**, ▶**electroporation**, ▶**protoplast fusion**, ▶**fluorochromes**, ▶**UV**, ▶**laser**, ▶**tubulin**; Shigeri Y et al 2001 Pharmacol Ther 91:85.

CAHMR: A very rare autosomal recessive cataract, hypertrichosis and mental retardation syndrome. ▶**cataract**, ▶**hypertrichosis**, ▶**mental retardation**, ▶**cerebro-oculo-facio-skeletal syndrome**; Temtamy SA, Sinbawy AHH 1991 Am J Med Genet 41:432.

Cairns Structure: A DNA molecule undergoing bidirectional θ replication. ▶**θ replication**; ▶**bidirectional replication**; Cairns J 1963 Cold Spring Harb Symp Quant Biol 28:43.

Cajal Body (coiled body): Nuclear organelles, usually at the nucleolar periphery. They contain p80 coilin, fibrillarin, snRNP, etc., and are involved in processing mRNA, rRNA, snRNA; they interact with histones and neuronal functions, etc. A Cajal body-like (yet distinct from it) structure occurs in plants too and it is involved in processing miRNA (Song L et al 2007 Proc Natl Acad Sci USA 104:5437). ▶**coilin**, ▶**coiled body**, ▶**snurposome**, ▶**RNAi**, ▶**microRNA**; Gall JG 2000 Annu Rev Cell Dev Biol 16:273; sno and Cajal RNA: <http://gene.fudan.sh.cn/snoRNAbase.nsf>.

CAK (cyclin-dependent-activating kinase): CAK is, generally, a component of the TFIIF transcription factor, but in *Saccharomyces* it is not part of TFIIF. It activates CDC28. ▶**transcription factors**, ▶**Cdk**, ▶**MO15**, ▶**cyclin**, ▶**CDC28**; Chen J et al 2003 Nature [Lond] 424:228; Gall JG 2003 Nature Rev Mol Cell Biol 4:975.

CAK_β: ▶**CAM**

Calcineurin (serine/threonine protein phosphatase-IIB, PP2B): Its action is dependent on calcium and calmodulin. Calcineurin is the target of cyclosporin and FK506. Calcineurin, by binding to NF-AT, incites the immune system and activates neuronal and muscle development but not muscle growth. If this binding could be selectively blocked—without affecting other functions—immuno-suppression could be controlled to the great benefit of various therapeutic transplantations (Venkatesh N et al 2004 Proc Natl Acad Sci 101:8969). Calcineurin and Mpk1 (Map kinase) and Zds1 (regulator also of Cdc42) proteins regulate the action of gene *SWE1* (a member

of the *WEE1* family) at transcription and post-transcription and the calcium-induced delay in G2 phase of the cell cycle. The product of the DSCR1 (Down syndrome candidate region) gene is an inhibitor of calcineurin and increases senile Alzheimer plaques and neurofibrillary tangles two-three times (Chan B et al 2005 Proc Natl Acad Sci USA 102:13075). ▶calmodulin, ▶immunosuppressant, ▶cyclosporin, ▶FK506, ▶serine/threonine phosphoprotein phosphatases, ▶T cells, ▶NF-AT, ▶MAP, ▶Cdc42, ▶Wee, ▶cardiomyopathy hypertrophic familial, ▶BAD, ▶Bcl, ▶Alzheimer disease; Crabtree GR 2001 J Biol Chem 276:2313; Ermak G et al 2001 J Biol Chem 276:38787; Luan S et al 2002 Plant Cell 14:S389.

Calcinosis, Tumoral, Familial: The symptoms involve subcutaneous calcium deposits, mainly at the joints, caused by recessive mutation of the GALNT3 gene at 2q24-q34, encoding a glycosyltransferase-causing mucin type O-glycosylation. The patients also display hyperphosphatemia (increased blood phosphate level). GALNT2 and GALNT1 mutations are also known. Dominant form of the disease is due to mutation in the FGF23 (fibroblast growth factor) gene at 12p13.3 (Benet-Pagès A et al 2005 Hum Mol Genet 14:385). (See Topaz O et al 2004 Nature Genet 36:579).

Calcitonin (CT, 11p15.2-p15.1): An oligopeptide hormone of the thyroid gland, controlling calcium and phosphate levels, and an antagonist of parathyroid hormone. The calcitonin gene-related peptide and substance P induce inflammation by dilation of the blood vessels. Calcitonin receptors are encoded at 2q31-q32 and 7q21.3. ▶animal hormones, ▶immune privilege, ▶adrenomedullin

Calcium Ion Channels: These voltage-regulated channels are made up of several subunits, each encoded at different human chromosomal sites: CACNL1A2 (neuroendocrine/brain) at 3p14.3; the CACNL1A4 isoform is at 19p13; CACNA1S (skeletal muscle) at 1q32; CACNA1C (cardiac muscle) at 12p13.3; CACNA2D1 in several tissues modulate the activity of the channel at 7q21-q22; the β -subunit, CACB1, is at the same location; the γ -subunit, CACNG1, is encoded nearby at 17q24. Ca^{2+} -ATPase is one of the most important pumps for calcium uptake through cell membranes. ▶ion channels, ▶calmodulin, ▶second messengers, ▶dihydropyridine receptor, ▶ ω -agatoxin, ▶ ω -conotoxin, ▶neurotransmitters; Catterall WA 2000 Annu Rev Cell Dev Biol 16:521; Toyoshima C, Nomura H 2002 Nature [Lond] 418:605; muscle and nervous disorders: Rizzuto R, Pozzan T 2003 Nature Genet 34:135.

Calcium Signaling: Calcium plays the role of a second messenger and activates many enzymes in the cell. It regulates synaptic activity of the neurons, cell adhesions, motility, proliferation, etc. When phospholipase C (PLC) is activated, the cells release intracellular Ca^{2+} through the calcium-release activated calcium channels (CRACs), receptor-operated calcium channels (ROCs), and store-operated calcium channels (SOCs). The incoming calcium then replenishes the Ca^{2+} store in the cell; it is also called CCE (capacitative Ca^{2+} entry). Hormones may activate the CCE, by immune reactions or by neural receptors. Light signal transduction in *Drosophila* requires PLC activation, synthesis of IP3 and the release of Ca^{2+} . For normal vision the flies must be able to maintain Ca^{2+} homeostasis. Mutants are known (and cloned) that represent gene loci involved in calcium regulation. Nuclear gene expression may be regulated through the CRE element whereas the cytoplasmic signaling may be mediated by SRE. A large and transient rise of Ca^{2+} activates transcriptional regulators such as NF- κ B, JNK; NFAT is activated by low Ca^{2+} levels. Intracellular Ca^{2+} triggers the activation of T lymphocytes by antigen. ▶calmodulin, ▶calcium ion channels, ▶calcineurin, ▶calcitonin, ▶PLC, ▶IP3, ▶CRE, ▶SRE, ▶homeostasis, ▶NF- κ B, ▶JNK, ▶NFAT, ▶SKID, ▶Darier-White disease; Wallingford JB et al 2001 Curr Biol 11:652; Lewis RS 2001 Annu Rev Immunol 19:497; Carafoli E 2002 Proc Natl Acad Sci USA 99:1115; Sanders D et al 2002 Plant Cell 14:S401.

Calciumphosphate Precipitation: May significantly enhance the chances of DNA uptake by (*E. coli* or mammalian) cells to be transformed (transfected). ▶bacterial transformation, ▶cotransfection

Calcofluor White (Tinopal): A fluorescent brightener that can be used to monitor cell wall formation in protoplast suspensions. ▶fluorochromes

Caldesmon: An 83 kDa actin- and calmodulin-binding protein. During mitosis it dissociates from the microfilaments as a consequence of mitosis-specific phosphorylation of actomyosin ATPase. ▶calmodulin, ▶myosin, ▶ATPase; Krauze K et al 1998 Biochem Biophys Res Commun 247:576.

Calico Cat: Heterozygous *female* animals with black-yellow-white fur patches (see Fig. C6). The alternation of black and yellow fur is due to inactivation of the genes residing in one or the other of the two X chromosomes. In males, this pattern occurs only in connection with the Klinefelter (XXY) constitution. The white fur is an autosomal trait controlled by the S (spotted) gene. ▶X-chromosome inactivation, ▶tortoiseshell fur, ▶lyonization

Figure C6. Calico cat

Call: ►base-calling

Callicebus: ►Cebidae

Callithricidae: Callithricidae are new world monkeys (marmosets and tamarins). *Callithrix argentata* 2n = 44; *Callithrix humeralifer* 2n = 44; *Callithrix jaccus* 2n = 46; *Callimico goldi* 2n = 48, some males 47; *Cebuella pygmaea* 2n = 44; *Leontocebus rosalia* 2n = 46; *Sanguinis fuscicollis illigeri* 2n = 46; *Sanguinus oedipus* 2n = 46; *Tamarinus mystax* 2n = 46; *Tamarinus nigricollis* 2n = 46. ►primates

Callose: A carbohydrate (glucan) formed on injured plant tissue.

Callus: A solid mass of plant cells (generally) on synthetic media; thickening of animal skin; unorganized bone growth (see Fig. C7).

Figure C7. Plant callus

Calmette-Guérin: ►*Bacillus Calmette-Guérin*

Calmeglin: A Ca^{2+} protein with 54% homology to calnexin but its expression is limited to the stage of pachytene to spermatid development. It is a chaperone. ►calnexin, ►chaperone

Calmodulin (CaM): A 17,000 M_r acidic protein (of 108 amino acids) with 4 Ca^{2+} binding sites affecting (among others) membrane transport, chromosome

movement, and processes in fertilization; it functions as a regulatory unit of several enzymes although calmodulin itself is not an enzyme (see Fig. C8). The CaM superfamily includes ~600 proteins. Calmodulin binding results in conformational changes of the target proteins (~300). CaM binds calcium between the C and D helix and also at the E and F helices (loop) and CaM is also called a EF hand protein. The EF hand is rather well preserved in a variety of calcium-sensing proteins of diverse functions. The presence of Ca^{2+} /CaM is required for phosphorylation of several proteins (myosin light chain kinase, phosphorylase kinase). CaM-kinase II mediates the secretion of neurotransmitters. It activates tyrosine hydroxylase required in catecholamine biosynthesis. It is involved in the control of such brain functions as memory and learning. CaM-kinase II is capable of autophosphorylation even in the absence of Ca^{++} . CaM regulates adenylate cyclase (cAMP), and cAMP regulates CaM. A-kinase, regulated by CaM, phosphorylates the IP_3 receptor, and cAMP and CaM-kinases control CREB. The delta subunit of phosphorylase kinase is CaM. CaM activates cyclic nucleotide phosphodiesterase, an enzyme degrading cAMP. CaM is ubiquitous among eukaryotes and it is one of the most conserved proteins. In vitro proteome assay is available for calmodulin binding proteins (Shen X et al 2005 Proc Natl Acad Sci USA 102:5969). ►cAMP, ►phosphorylases, ►autophosphorylation, ►signal transduction, ►calcium signaling, ►cAMP, ► IP_3 , ►CREB, ►neurotransmitters, ►aequorin, ►CDC31; Fujisawa H 2001 J Biochem 129:193; Soderling TR et al 2001 J Biol Chem 276:3719; Corcoran EE, Means AR 2001 J Biol Chem 276:2975; Cyert MS 2001 Annu Rev Genet 35:647; Hoeflich KP, Ikura M 2002 Cell 108:739;

C

Calnexin: A membrane-bound chaperone with preference for glycoproteins (Molinari M et al 2003 *Science* 299:1397); it may also associate with an antigen before entering the endoplasmic reticulum. Its soluble homolog is calreticulin. ▶chaperones, ▶calreticulin, ▶endoplasmic reticulum, ▶Cne, ▶BiP; Danilczyk UG, Williams DB 2001 *J Biol Chem* 276:25532; Schrag JD et al 2001 *Mol Cell* 8:633.

Calorie: The amount of heat required to elevate the temperature of 1 gram of water from 14.5 °C to 15.5 °C (4.186 international joules). ▶joule

Calpains: Calcium-dependent neutral cysteine proteases of the papain family. Calpains may cleave neural growth activator protein 35 (p35) resulting in p25. Accumulation of p25 causes the mislocalization of CDK5 then CDK5 and p25 hyperphosphorylate tau, a microtubule-associated protein; consequently, the cytoskeleton disruption leads to death of neurons and to the apoptosis seen in Alzheimer's disease. CALPAIN10 (2q37.3) seems to be linked to diabetes (NIDDM1) and may be identical to it. Two other proteases, carboxypeptidase E/H in human chromosome 4 and pro-hormone convertase-1 (5q15-q21), also seem to be associated with diabetes. ▶protease, ▶papain, ▶tau, ▶Alzheimer's disease, ▶CDK, ▶cytoskeleton, ▶microtubule, ▶diabetes; McGrath ME 1999 *Annu Rev Biophys Biomol Struct* 28:181; Horikawa Y et al 2000 *Nature Genet* 26:163; Sorimachi H, Suzuki K 2001 *Biochem J* 129:653; Perrin BJ, Huttenlocher A 2002 *Int J Biochem & Cell Biol* 34:722.

Calphostin C: An inhibitor of diacylglycerol and Ca^{2+} -dependent phosphokinase CD (PKC). ▶T cells, ▶PKC, ▶diacylglycerol

Calreticulin: A calcium storage protein within the endoplasmic reticulum and also present in the nucleus. It may prevent the glucocorticoid receptor binding to its response element and it is thus a transcription factor and a chaperone. Calreticulin is also required for calcium signaling and cell adhesion by integrins. Calreticulin and heat-shock protein Hsp90 control expression of the human insulin receptor at its earliest maturation stages and modulate its movement within the endoplasmic reticulum before either degradation or cell surface expression (Ramos RR et al 2007 *Proc Natl Acad Sci USA* 104:10470). ▶hormone response element, ▶glucocorticoid, ▶tapasin, ▶integrin, ▶calnexin, ▶endoplasmic reticulum; Nakamura K et al 2001 *J Clin Invest* 107:1245; Fadel MP et al 2001 *J Biol*

Calsenilin: A Ca^{2+} -binding protein which mediates apoptosis and Alzheimer's disease plaque protein, Aβ. ▶presenilin, ▶Alzheimer's disease, ▶apoptosis

Calvin Cycle: The pathway of fixation of CO_2 (1C) into 3-phosphoglycerate (3C), 1,3-bis-phosphoglycerate (3C) and glyceraldehyde-3-phosphate (3C). In this reaction, 3 molecules of ATP and 2 molecules of NADPH are used for each CO_2 converted into carbohydrate. ▶photosynthesis, ▶Krebs-Szentgyörgyi cycle

Calypso: *Drosophila* transposable element (7.2-kb) generally present in 10 to 20 copies per cell. ▶transposable elements, ▶hybrid dysgenesis

Calyx: The collective name of sepals, the basal whorl of the flowers. ▶flower, ▶differentiation

CaM: ▶calmodulin

CAM (cell adhesion molecule): Regulates monolayer formation in cultured mammalian cells and mediates neuronal connections with the aid of the fibroblast growth factor (FGF). Cell-to-cell adhesion is mediated by cadherins, immunoglobulins, selectins, and integrins (see Fig. C9). Integrins and transmembrane proteoglycan mediate cell-matrix adhesion. Focal cell adhesion, integrin-mediated contact between cells and the extracellular matrix is linked to the activation of pp125^{FAK} protein kinase. This enzyme is a member of the family of FakB, PYK2/CAKβ and RAFTK protein tyrosine kinases. PYK2 regulates calcium ion channels and the MAPK signaling pathway. The carboxy terminal of pp125^{FAK} is expressed as a nonkinase pp41/43^{FRNK}. This latter protein is an inhibitor of pp125^{FAK} and the phosphorylation of tensin and paxillin adhesion proteins. PYK2 activity is also coupled with the JNK signaling pathway. NCAM is the neural cell adhesion molecule. Cotranslational translocation of vascular cell adhesion molecule is inhibited by CAM741, a fungus-derived cyclopeptolide involving Sec61β, and subsequently degraded by proteases of the cell. Thus the peptide may have use in the control of some diseases (Besemer J et al 2005 *Nature [Lond]* 436:290). ▶cadherins, ▶ICAM, ▶immunoglobulins, ▶L1, ▶protein zero, ▶fibronectin, ▶selectins, ▶integrins, ▶RGD, ▶tenascin, ▶proteoglycan, ▶JNK, ▶ion channels, ▶extracellular matrix, ▶MAPK, ▶protein kinases, ▶Sec61 complex, ▶Usher syndrome, ▶ADAM, ▶MASA syndrome; Chen L et al 2001 *J Cell Biol* 154:841; Voura EB et al 2001 *Mol Biol Cell* 12:2699; Li R et al 2003 *Science* 300:795.

Figure C9. CAM 741

CAM: ► *Crassulacean acid metabolism*

cam (chloramphenicol transacetylase): Conveys resistance to chloramphenicol, which would block peptidyl transferase on the 70S ribosomes in prokaryotes and in eukaryotic organelles. ► *chloramphenicol*, ► *antibiotics*, ► *protein synthesis*

Camalexin: A phytoalexin that may be a player in the defense of plants against fungal diseases. ► *phytoalexins*, ► *host-pathogen relationships*; Pedras MS, Khan AQ 2000 *Phytochemistry* 53:59.

Cambium: A meristemic tissue layer around the stem of plants providing for growth in diameter. ► *meristem*

Cambrian: A geological era 500–600 million years ago. The fossil plant relics of this era are poorly preserved. All major animal groups, except the vertebrates, were already present. ► *evolution*, ► *geological time periods*

Camel: The two-humped camel (*Camelus bactrianus*): $2n = 74$ and its American relative, the vicuña (*Vicugna vicugna*), and all other camelids also have the same $2n = 74$. The large one-humped dromedary camel (*Camelus dromedarius*) is the “workhorse” of Arabia, North Africa, and India. Although the South American llamas were separated from camels about 3 million years ago, they can form hybrids. Their antibodies lack light chains and are highly soluble. A camelid heavy chain antibody fragment (VSA2) is specific for caffeine and provides a relatively simple and sensitive means for the detection of caffeine in cold or hot beverages even after exposure up to 90 °C (Ladenson RC et al 2006 *Anal Chem* 78:4501). (► *antibody*; Hamers-Casterman et al 1993 *Nature* 363:446; De Genst E et al 2006 *Proc Natl Acad Sci USA* 103:4586).

CAMFAK Syndrome: An apparently autosomal dominant cataract, microcephaly, failure to thrive, kyphoscoliosis (curved spinal column), arthrogryposis (flexure and/or contracture of the joints), and mental retardation. It has been termed also as CAMAK. It bears similarities to the Cockayne syndrome and to

cerebro-oculo-facio-skeletal syndrome and to other developmental anomalies. ► *scoliosis*, ► *cerebro-oculo-facio-skeletal syndrome*

CaMK (calcium-calmodulin-dependent protein kinase): CaMKII is necessary for several physiological processes including learning and memory. NMDA receptors control its translocation. Camk4 serine/threonine kinase is important for mice spermiogenesis. ► *calmodulin*, ► *kinases*, ► *titin*, ► *NMDA*; Yang Y et al 2001 *J Biol Chem* 276:41064.

CaM-KK: A CaMK kinase which activates PKB (protein kinase B), which phosphorylates the apoptotic protein BAD. BAD then interacts with protein 14-3-3 and cell survival is facilitated. ► *apoptosis*, ► *BAD*, ► *protein 14-3-3*, ► *protein kinases*; Tokomitsu H et al 2000 *J Biol Chem* 275:20090.

CaMO: ► *cauliflower mosaic virus*

cAMP: Adenosine 3':5' monophosphate (cyclic AMP, second messenger); has a crucial role in signal transduction and general gene regulation in bacteria and animals (see Fig. C10). For many years there was no convincing evidence for cAMP in plants. More recently though several facts have indicated the role of cAMP in plant development. In 1997, adenylyl cyclase was identified in tobacco tissues. Some molecules can increase the level of cAMP (adenylate cyclase) by binding to certain transmembrane receptors whereas other cellular signal molecules are inhibitory. The stimulatory G_s protein activates adenylyl cyclase. Actually the α_s subunit dissociates from the two other chains and binds to, and hydrolyzes, GTP; it then binds to adenylyl cyclase and boosts the production of cAMP. Upon binding to adenylyl cyclase GTPase activity will increase and an inactive G_s is formed again by recombining α_s with $\beta\gamma$.

Cholera toxin (produced upon infection by the bacterium *Vibrio cholera*) mediates the transfer of adenylyl to α_s and this fact prevents the hydrolysis of its GTP. Therefore, the adenylyl cyclase function stays on, resulting in increased levels of cAMP. This condition then opens a very active sodium and water efflux through the intestinal walls, causing debilitating diarrhea and dehydration of the entire body.

The inhibitory trimeric G_i has a special α_i subunit and it is activated by other types of cellular signals. In G_i the $\beta\gamma$ subunits are dissociated from the α_i subunit and these subunits then directly and indirectly interfere with adenylyl cyclase. More importantly, G_i opens K^+ ion channels in the plasma membrane. The pertussis toxin (due to *Bordetella* bacterial, whooping cough)—in contrast to the cholera toxin—mediates the adenylation of α_i subunit that interferes with responding to the receptors and GDP remains

bound to the G-protein; the adenylate cyclase activity is not blocked and potassium channels are not opened.

One of the most important functions of cAMP is the activation of the four-subunit *protein kinase A*. This phosphorylase enzyme then adds phosphate groups from ATP to serine and threonine residues in certain proteins. Protein kinase A is activated by cAMP through forming a complex with two of its regulatory subunits while the two other separated catalytic subunits are turned on. The enzyme exists in two forms; one is cytosolic whereas the other is bound to membranes and microtubules.

cAMP controls the transcription, in a positive or negative manner, of several other genes. The CREB (cAMP response elements)—located in the upstream region of genes—promote transcription upon phosphorylation of a specific serine residue in the binding proteins whereas the CREM α and β are repressors. cAMP also controls the secretion of cortisol by the kidney cortex, the thyroid hormone, the secretion of the luteinizing hormone (progesterone), adrenaline and glucagon production and glycogen and triacylglyceride breakdown, heart muscle and other muscle functions, etc. ►adenosine-3', ►5' ►monophosphate, ►adenylate cyclase, ►G-protein, ►epinephrine, ►cAMP-dependent protein kinase, ►signal transduction, ►CREB, ►CBP, ►progesterone, ►forskolin, ►cyclic ADP-ribose; Montminy M 1997 Annu Rev Biochem 66:807.

cAMP Receptor Protein (CRP): Assists in the binding of *E. coli* RNA polymerase to the operator of carbohydrate operons (positive regulation), but it may also act as an activator of the negative regulator CytR and as such becomes a corepressor. The DNA binding site is 22 bp arranged in a rotational symmetry. The binding results in DNA bending. ►Lac operon, ►positive control, ►negative control, ►repressor, ►corepressor, ►promoter, ►RNA polymerase, ►DNA bending

Campbell Model: The Campbell model of recombination suggested, first, the mechanism of integration of the (pro)phage into bacteria by reciprocal recombination between the circular bacterial and temperate phage DNA molecules (see Fig. C11) (only a part of the circular bacterial chromosome is shown; in lighter color). ►bacteriophages, ►*E. coli*; Campbell AM 1962 Advances Genet 11:101.

cAMP-Dependent Protein Kinase: ►protein kinase A, ►phosphorylase B kinase

Campomelic Dysplasia (CD, CMD1): A most likely recessive/haploinsufficiency (rather than dominant) bone-formation and gonad-development defect due to mutation in the SOX9 gene in human chromosome 17q24.1-q25.1. The congenital bowing of the skeletal bones and malformation of the head bones usually causes death in early infancy; however, some

individuals survive to early adulthood. This defect is often associated with chromosomal rearrangements and sex reversal. ▶SRY, ▶SOX, ▶sex reversal, ▶gonad; Preiss S et al 2001 J Biol Chem 276:27864; Hill-Harfe KL et al 2005 Am J Hum Genet 76:663.

CAMPTODACTYLY →

Figure C12. Camptodactyly

Camptothecin ($C_{20}H_{16}N_2O_4$): A plant alkaloid, which is an antibiotic and anticancer agent targeting DNA topoisomerase I-DNA complexes. It breaks single-stranded DNA. ▶topoisomerases, ▶etoposide, ▶Werner syndrome; Arimondo PB et al 2002 J Biol Chem 277:3132.

Campylobacter jejuni: A gram-negative, spiral, flagellate bacterium, pathogenic to the stomach and an inducer of the Guillain-Barré syndrome. Its circular DNA chromosome contains 1,641,481 bp encoding 1,654 proteins and 54 stable RNAs. Its genome is virtually free of insertion or phage-associated sequences and has rare repeats but contains short hypervariable sequences. ▶Guillain-Barré syndrome; Parkhill J et al 2000 Nature [Lond] 403:665.

Camurati-Engelmann Disease (CED, diaphyseal dysplasia, 19q13.1-q13.3): Progressive bone formation on the shaft of the long bones and the skull. Muscular weakness and pain, facial paralysis, hearing and vision problems, etc., may be caused by defect in the transforming growth factor-β1 subunit. ▶TGF

CaMV: | cauliflower mosaic virus

Canalization: A genetic buffering mechanism that reduces the visible variations beyond what is expected on the basis of genetic diversity. It is the developmental path modulated by environmental inputs, the epigenetic landscape. It permits the maintenance of hidden genetic variations and thus facilitates the conservation of a “normal” phenotype. Also, it eliminates from the populations those genotypes that cannot adjust to environmental fluctuations. Mutants generally have reduced buffering capacity compared to the wild type (which is best canalized for survival), and can be readily eliminated. ▶genetic homeostasis, ▶genetic assimilation, ▶homeostasis, ▶epigenesis, ▶reaction norm, ▶robustness; Waddington CH 1940 J Genet 41:75; Newman SA, Muller GB 2000 J Exp Zool 288:304.

Canale-Smith Syndrome (ALPS): An autoproliferative disease caused by deficiency of the Fas protein and

defect in apoptosis. ▶Fas, ▶lymphoproliferative diseases, ▶apoptosis

Canary: ▶pathogen identification

Canavan disease: ▶aspartoacylase deficiency

Canavanine: A competitive inhibitor of arginine (natural plant product). ▶competitive inhibitor

Cancer: Cells which continue to divide when cell divisions are not expected; it is an uncontrolled growth, a malignant growth. The cancer cells proliferate irrespective of the normal growth signals or growth regulatory mechanisms, tend to evade apoptosis or immunosurveillance commandeer angiogenesis and all means leading to replication, and invade other cells and tissues by metastasis. Some of the cancers may originate from a small fraction of the cells in a tissue, the *cancer stem cells* (Beachy PA et al 2004 Nature [Lond] 432:324). Some so-called transit-amplifying cells divide a few times than differentiate and lose their proliferating abilities. Loss of polarity during stem cell divisions may lead to cancer. Cells may spread through the blood stream to other locations in the body and initiate secondary foci of malignant growth (metastasis). Cancer may occur in a variety of forms such as leukemia, adenoma, lymphoma, sarcoma, but it is not exactly known how these different types are specified. It appears that there are more than 200 types of cancers. More than 1% of the human genes (291) are involved with cancer; 90% display somatic mutations and 20% show germline mutations, and 10% both (Futreal PA et al 2004 Nature Rev Cancer 4:177). In each cancer several (3–6) different mutations may be found (Hahn WC, Weinberg RA 2002 Nature Rev Cancer 2:331). Among 1,007 somatic mutations in cancer cells, 921 were single base substitutions, 78 were small chromosomal aberrations, and 8 were complex alterations. The number of somatic mutations varied substantially among different types of cancer and was dependent also on recurrent gliomas, which have been treated earlier by alkylating anticancer drugs (temozolomide) or in melanomas ([18.54/Mb] apparently caused by UV light) or in lung cancer ([4.21/Mb] in smokers). Deficiency of DNA repair [32.29/Mb] was also a significant factor although high numbers of mutations could be ascertained that were due to unknown factors. Generally, high frequency of somatic mutations was observed in tissues with rapid turnover and easy exposure to environmental effects (lung cancer [4.21/Mb], gastric cancer [2.10/Mb], colorectal cancer [1.21/Mb]) but some apparently protected tissues (e.g., ovary had also high rates [1.85/Mb]). Generally, nonsynonymous mutations had higher incidence yet it appeared that some synonymous mutations were more frequent than

C

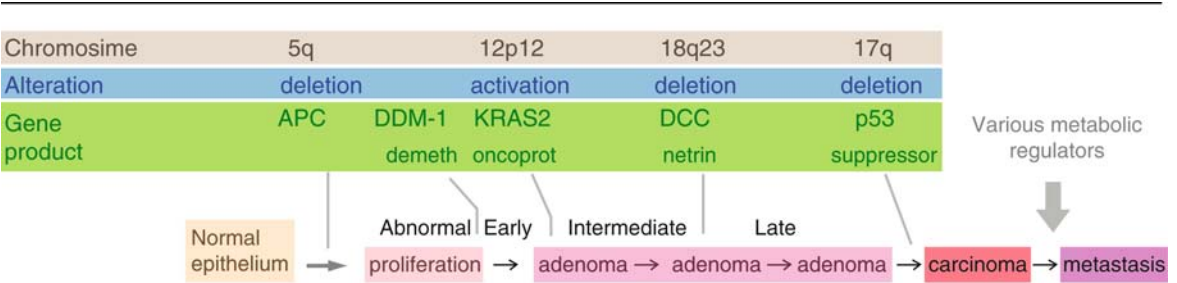

expected by chance indicating that some had conveyed selective advantage in proliferation (“driver mutations”). A somewhat smaller portion of the mutations did not appear selectively advantageous for proliferation (“passenger mutations”). Some, but not all, the *driver mutations* involved one or another protein kinase domains (Greenman C et al 2007 Nature [Lond]: 446:153). Cancer ESTs (expressed-sequence tags) have greater variations than normal ESTs for > 70% of the tested genes. Cancer EST variations were not random, but were determined by the composition of the substituted base (b) as well as that of the bases located upstream (up to base –4) and downstream (up to b + 3) of the substitution event. The replacement base was also not randomly selected but corresponded in most cases (73%) to a repetition of b – 1 or of b + 1. Base substitutions follow a specific pattern of affected bases: A and T substitutions were preferentially observed in cancer ESTs. In contrast, cancer somatic mutations and SNPs identified in the genes occurred preferentially with C and G. On the basis of these observations, a working hypothesis suggested that cancer EST heterogeneity results primarily from increased transcription infidelity (Brulliard M et al 2007 Proc Natl Acad Sci USA 104:7522).

The anomaly in malignant growth is that cells do not remain in a quiescent stage (G₀). They proceed either through terminal differentiation or death (apoptosis), but from G1 phase, and independently from normal cellular regulation, continuing indefinitely to S phase, mitosis and cell division. Normal cells pause at the G1 *restriction point* and respond to the instructions coming through the cyclins. The cyclins (CLNs) coupled with the labile cyclin dependent kinases (CDK4, CDK6) are receptive to mitogens but they are kept in check by several INK (inhibitors of kinase) proteins. When, normally, tumor suppressors such as the retinoblastoma (RB) and other proteins (E2F family) become phosphorylated, the cells exit from G1 and embark on DNA

synthesis. The phosphorylated tumor suppressors transactivate CDKs, and unless cell divisions are blocked at various checkpoints, divisions will continue and proceed in an accelerated and uncontrolled manner. The G1-phase-specific cyclin E-CDK2 complex stimulates more phosphorylation of the tumor suppressors RB and E2F and the dependence on mitogens is diminished. CLN-A–CLN-B dependent kinase (CDK2) reinforces the phosphorylation process and dephosphorylation does not set in until the completion of mitosis. CLN-E and CLN-A associated CDK2 assist the DNA replication machinery. CLN-dependent kinases are also suppressed by CDK inhibitors, p21^{CIP1}, p27^{KIP1}, and p57^{KIP2}, but if the latter ones are deleted or mutated both cell numbers and size increase. Methylation of the promoter of tumor suppressor genes may lead to their silencing and neoplasia. Hypomethylation of oncogenes or retroelements or latent viral sequences in the genome may increase cancerous transformation. The patterns of hyper- and hypomethylation may be quite variable at different restriction enzyme recognition sites. Hypomethylation of some DNA sites may facilitate chromosomal instability, a common cause of neoplasia. Comparative genomic data are summarized in Struski S et al 2002 Cancer Genet Cytogenet 135:63. Cytosine methylation, histone modification and chromatin remodeling are major factors in cancerous transformation (see Table C1) (Jones PA, Baylin SB 2007 Cell 128:683).

Germline mutations are responsible only for about 1% of all cancer cases, and about 10–15% of all cancer has substantial hereditary components. Many cancer genes (oncogenes) have now been cloned but several genes acting in the same biochemical pathway may be responsible for one type of cancer. Also, single genes may be involved in different types of cancer. It has been observed that the range of expression of germline mutations of the same cancer gene is different from those of somatic mutational events. Allelic differences within a gene may cause

Table C1. Some protooncogenes and their role is carcinogenesis

demeth: demethylation, oncoprot: oncoproteins, netrin: guidance protein (Modified after Fearon ER & Vogestein B 1990 Cell 61:757)

different cancers. The majority of cancer cases are the result of somatic mutations arising during the lifetime of the individuals and some are due to unknown environmental factors and thus represents phenocopies. Cancerous growths may be initiated by mutations in structural genes, suppressor genes, methylation of tumor suppressors, transmembrane receptors, transcription factors, regulator genes, cell cycle genes, aneuploidy (hypo- and hyperploidy) repair functions, chromosomal rearrangements (translocations, inversions, transpositions, duplications, deletions), and viral insertions in the chromosomes. Although a single mutation may suffice for uncontrolled cellular proliferation, several additional factors may be involved for full-scale development. The initial mutation may take place in proto-oncogenes. Mutations or loss of the CLN-D1 locus (human chromosome 11q13) and the CDK4 gene (human chromosome 12q13), INK4a (CDK^{INK4a}, chromosome 9p21), p16, p53 are common in many types of cancers. p53 also regulates p21, p27 and p57 proteins. The gene encoding p53 is in human chromosome 17p 13.15-p12 and it is altered in a large number of different cancers. The normal function of p53 is required for the development of the centrosome and proper segregation of the chromosomes (see Fig. C13).

Figure C13. Culture cancer cells lose contact inhibition and grow in overlapping fashion. (After Dulbecco R 1967 Sci. Amer. 216[4]:28)

Hundreds of proto-oncogenes have now been discovered and their possible malfunction due to mutation, chromosomal rearrangement or loss is many fold (see diagram). Some estimates indicate that 1% of the genes may affect cancer (Futreal PA et al 2004 Nature Rev Cancer 4:177). These mutations, similar to other mutations, are generally (not always) recessive and not expressed in diploid cells. When, through another event(s), they become homozygous or hemizygous, a cancerous growth may follow.

This may be the reason why, for the development of cancer, a long period is required after the initial genetic lesion. These genes have normal cellular functions (some of the proto-oncogenes, e.g., *Ras*, encode

G-proteins and play an important role in healthy signal transduction) but mutation may alter their normal role and they may become (cellular) c-oncogenes. The v-oncogenes are viral counterparts of the c-oncogenes. When c-oncogenes are inserted into chromosomes of animals they may provide efficient promoters for cellular genes involved in growth.

In the development of cancer, the products of more than a dozen tumor suppressor genes (e.g., p53, p16) play a major role. Because of mutation, they no longer are capable of controlling genes of the cell cycle. Normal mammalian cells grow in the cultures in an anchorage-dependent fashion, in monolayer. Cancerous cells differ in their growth habit by growing in disarray, in layers (see Fig. C14). Gene expression profiles of tumor-derived cell lines may differ from that of in vivo cancer cells (Sandberg R, Ernberg I 2005 Proc Natl Acad Sci USA 102:2052). Since the human body contains about a billion cells per gram solid tissue, an average adult human body may have about 10^{14} to 10^{15} diploid cells according to the various estimates. Average mutation rates are within the range of 10^{-5} to 10^{-8} per genome, per generation, therefore all human individuals must have suffered numerous mutations with neoplastic potentials yet only a fraction of the human population is afflicted by this group of diseases. The causes of this discrepancy are diploidy, that masks recessive mutations, and the immunological surveillance system recognizes mutant surface antigens, developed on cancer cells, and destroys them before they get out of control. When the immune system weakens by advancing age, by certain diseases (e.g., AIDS) or by taking immunosuppressive drugs, the incidence of cancer increases. The cancerous growth itself is not necessarily lethal but it generally deprives the body from its normal metabolism and the patients succumb to secondary, opportunistic diseases.

Figure C14. Benzo(a) pyrene induced cancer in the laboratory by painting the carcinogen on the skin of a rodent. (Courtesy of Drs Nesnow S and Slaga T)

The general assumption is that cancer develops monoclonally, i.e., in the tumor each cell has a single common ancestor.

This assumption does not preclude, however, that in the same cell lineage additional mutations occurred during the process of multiplication although experimental evidence does not show appreciable frequency of mutation during the progression of cancer. In very rare cases, it has been shown, however, that a particular cancer in an individual may not be monoclonal but that more than a single founder cell contributed to its formation. Also, in some cancer cells, multiple and different genetic mutations, primarily chromosomal alterations, were observed. Some of these multiple alterations may be due to the rearrangement of mini- or microsatellite sequences, some of which are just the consequences of defects in the genetic repair system.

With the technique of inter-simple sequence repeat PCR (INTER-SS PCR), a very large number of chromosomal alterations (insertions, deletions, translocations) are detectable (see Fig. C15). The aberrant karyotypic state of cells is correlated with their response to anticancer drugs and this feature may be used to screen for potential drugs (Roschke AV et al 2005 Proc Natl Acad Sci USA 102:2964).

The PCR product is produced by using a single primer homologous to dinucleotide repeats and attached at 3' by two nonrepetitive sequences as diagrammed below (R = purine, Y = pyrimidine):

The numbers of alterations (genetic instability) are determined by the formula:

$$N = \frac{(\text{No. of altered bands/PCR}) \times (\text{Total genome size}) \times (\text{No. uniquely altered bands})}{[\Sigma \text{ size of PCR fragments}]}$$

(after Boland CR, Ricciardiello L 1999 Proc Natl Acad Sci USA 96:1465. In colorectal cancer cells and premalignant polyps (Stoler DL et al 1997 Proc Natl Acad Sci USA 96:15121) they found extremely high frequency, approximately 11,000 alterations, per cell. They concluded: "...genomic instability being a cause rather than an effect of malignancy....")

The point-mutational origin of cancer has been questioned because (i) there are carcinogens that do not induce gene mutation or are very ineffective mutagens, e.g., asbestos, nickel (Ni^{2+}), butter yellow, urethan, etc., [should be noted that authors list arsenic as a nonmutagenic carcinogen but in barley plants arsenates are strong mutagens]; (ii) the majority mutations in the various types of cancers are not present in all types of cancers; (iii) no genes isolated

from cancers induce mutations in animal or human cells and the loss of the oncogenes, e.g., RAS does not revert cancer cells to normal cells; (iv) the long period of latency does not seem to be consistent with the mutational origin; (v) the cancer cells are unstable whereas mutations are most commonly stable; and (vi) virtually all solid tumors are aneuploid. Wang et al (2002 Proc Natl Acad Sci USA 99:3076) do not find experimental evidence for the presence of mutator activity in colorectal cancer. Loeb et al (2003 Proc Natl Acad Sci USA 100:776) argue in favor of mutator mechanisms because of the extensive genetic heterogeneity in various tumors. Peter Duesberg and coworkers assume that aneuploidy is the basic cause of cancerous transformation (Li R et al 2000 Proc Natl Acad Sci USA 97:3236). The aneuploid cells grow slowly and are less competitive than normal cells and that would explain the delay of the onset of cancer. Furthermore, aneuploids are unstable and with time may affect the expression of many genes.

Genetic tests for cancer risk have serious technical limitations, as it is obvious from the discussions above. In a few instances such as intestinal polyposis, the detection of the presence of the cancer gene may warrant earlier and continued surveillance by colonoscopy. In the presence of defects (MEN2) in RET alleles, prophylactic thyroidectomy may be considered. Identification of individuals with the BRC1 or BRC2 breast cancer genes may warn of the increased possibilities of breast or ovarian cancer, however, preventive surgery may be too high of a price for the uncertain manifestation of the neoplasia. Metastatic conditions may be detected by blood DNA analysis for specific oncogenic markers. RT-PCR and PSA levels may indicate (not just prostate cancer) micro-metastatic conditions. For these types of analyses molecular methods are available. These may detect LOH, microsatellite heterogeneity, telomerase deficiency, or eventually, SAGE and DNA chip analyses may become practical. In cancer, many proteins are altered in expression to various extents. By high-throughput immunoblotting, 64 protein alterations were detected in prostate cancer and in the metastatic stage, an additional 156 alterations occurred (Varambally S et al 2005 Cancer Cell 8:393). When high-throughput genotyping by mass spectrometry queried 238 known oncogene mutations across 1,000 human tumor samples, of 17 oncogenes analyzed,

Figure C15. Cancer PCR product

it was found that 14 mutated at least once, and 298 (30%) samples carried at least one mutation. This type of analysis of mutations permits the study of multiple cancer genes simultaneously and in “real time” to guide cancer classification and rational therapeutic intervention (Thomas RK et al 2007 Nature Genet 39:347).

After two decades of epidemiological research no convincing evidence has been found for the putative leukemogenic effect of low-frequency electromagnetic fields for children. About 85% of human cancers involve solid tumors which are most commonly associated with loss of several genes regulating the cell cycle, growth hormones, cell surface receptors, cell adhesion molecules, etc. Mitotic crossing over may also generate homozygosity for oncogenes. Aneuploidy is common in solid tumors. In tumors of the hematopoietic or lymphatic system, chromosome translocations are frequent. Some of the multiple chromosomal rearrangements in cancer follow a preferred path. In human cells, chemical and physical agents (carcinogens) can induce cancerous growth in culture. The transformation of the coding sequence for the large catalytic subunit of the telomerase (hTERT), the T oncogene of Simian virus 40 and the RAS oncogene into epithelial and fibroblast cell cultures leads to cancerous proliferation and maintenance of this state. Cytokines regulate tumor development at several levels. *Drosophila* has many genes that are homologous to mammalian oncogenes, tumor suppressors, and other genes responsible for abnormal cellular proliferation. Cancer is initiated and maintained by many different mechanisms, yet all of them share the properties of independence of external growth signals, limitations to respond to growth inhibitory and apoptotic signals, and steady proliferative potentials supported by steady angiogenesis and metastasis. The incidence of cancer increases dramatically after age 40 in humans but a plateau is reached after 80. Epithelial carcinomas (breast, prostate, lung, colon, etc.) represent about 9% of cancer in children but by adulthood the share grows to above 80%. ▶genetic tumors, ▶oncogenes, ▶protein tyrosine kinases, ▶cellular transmission of tumor, ▶epigenesis, ▶EC, ▶leukemias, ▶melanoma, ▶carcinogens, ▶ROS, ▶immunological surveillance, ▶environmental mutagens, ▶chromosome breakage, ▶aneuploidy, ▶mosaic variegated aneuploidy, ▶imprinting, ▶Knudson's two mutation theory, ▶Wilms tumor, ▶retinoblastoma, ▶Bloom syndrome, ▶xeroderma pigmentosum, ▶neurofibromatosis, ▶tuberous sclerosis, ▶von Hippel-Lindau syndrome, ▶nevoid basal cell carcinoma, ▶multiple hamartomas, ▶MEN, ▶lentigin, ▶leiomyoma, ▶lipomatosis, ▶tumorigenesis, ▶Beckwith-Wiedemann syndrome, ▶Werner syndrome,

Cancer Chromosomes: Includes information on spectral karyotyping, Multiplex-FISH, Comparative Genomic Hybridization, Mittelman database, etc. (See <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=CancerChromosomes>).

Cancer Classification: Many human genetic diseases involve syndromes, and the symptoms of different syndromes frequently overlap. Therefore, clear separation of a disease may not be straightforward. Similar and even worse is the situation in various types of cancers. Cancers with similar phenotypes may respond differently to therapies. Also, early

the chances of successful treatment. The expression of cancer may depend on a good number of genes. Thus, identifying the expression patterns of the genes may help classification of cancers of similar phenotypes. The cancer investigator faces two main problems: (i) discovery of the main type and possible subtypes of the neoplasia; (ii) predict which class(es) the cancer investigator/therapist deals with. Using microarray hybridization of thousands of genes expressed in the tumors, some smaller groups of genes can be selected for detailed analysis and can be specifically targeted for therapy (Bild AH et al 2006 *Nature [Lond]* 439:353). Recurrent amplification of a liver cancer DNA sequence in mouse chromosome 9qA1 and the corresponding to human chromosome 11q22 revealed the coamplification of the apoptosis inhibitor cIAP1 and the YAP transcription factor. Both of these genes contribute to carcinogenesis. Thus these experiments seem promising to the annotation of human cancer genes (Zender L 2006 *Cell* 125:1253). Comparative genomic hybridization revealed that Nedd9/Hef1 (6p25-p24) was highly expressed in vitro and in vivo in metastasis of melanoma in mice and humans (Kim M et al 2006 *Cell* 125:1269). In yeast, hairpin-capped double strand breaks occur near Alu-like palindromic sequences and can lead to the formation of intra-chromosomal amplicons with large inverted repeats or extra-chromosomal palindromes similar in function to mammalian double-minute chromosomes.

These amplicons can lead to tumor formation in mammals (Narayanan V et al 2006 *Cell* 125:1283). ▶microarray hybridization, ▶cluster analysis, ▶recursive partitioning, ▶cancer, ▶predictor gene, ▶RLGS, ▶cancer signature, ▶aptamer, ▶DiGE, ▶IAP, ▶YAP, ▶comparative genomic hybridization, ▶amplicon, ▶DM (double-minute) chromosome, ▶palindrome; Golub TR et al 1999 *Science* 286:531; Wooster R 2000 *Trends Genet* 16:327; Zhang H et al 2001 *Proc Natl Acad Sci USA* 98:6730.

Cancer Death Rate: Usually initiated by several somatic mutations and only about 5% of the cases are attributable to germline mutations. In the USA, annually, 1.6–2.5 million new cancer cases occur and the death rate is about 560,000/year. The worldwide cancer death rate is about 6.6 million/year. In men, the most common types of cancer is that of the prostate (43%), and lung and bronchus cancer (13%). In women, breast cancer is most common (30%), lung/bronchus (13%) and colon/rectum cancer (11%) follow. Lung cancer claims more deaths (32% and 25%) in both sexes than any other types. Although the rates of cancer deaths are somewhat declining, the incidence of cancer is not. About 70% of the cancer victims may show some remission, 50% of them relapse and become unresponsive to currently available treatments. ▶cancer, ▶cancer therapy, ▶cancer gene therapy

Cancer Gene Therapy: Transforming by (1) cytokine genes; (2) introducing genes encoding foreign antigens; (3) using antisense RNA or DNA constructs; (4) functional tumor suppressor alleles; (5) introducing the wild type dominant oncogenes; (6) ribozyme technology; (7) transferring the *Herpes simplex* virus thymidine kinase (HSVTK) gene, making the tumor sensitive to ganciclovir (GCV); (8) using artificial transcription factors for remodeling gene expression may be exploited; (9) RNAi technology. Sensitive cancer targets (such as growth signals or apoptosis evasion) can be identified by the use of short, interfering RNAs (Ngo VN et al 2006 *Nature [Lond]* 441:106). Using the aptamer-siRNA chimeric RNA construct facilitated the targeting of siRNA to specific cancer cells. The aptamer part of the PSMA cell surface receptor, overexpressed in prostate cancer cells and in tumor vascular epithelium, recognized the target, the construct was taken up and the siRNA specifically inhibited tumor growth (McNamara JO II et al 2006 *Nature Biotechnol* 24:1005). Phosphorylation of GCV (GCV-TP)

inhibits DNA polymerase that stops cancer cell proliferation, (10) using the multiple drug resistance gene, MDR; (11) magic bullets have been attempted; (12) and some approaches of tumor vaccinations are now in clinical trials. Cancer vaccines are based on whole cells, cell extracts and specific antigens, including carbohydrate-protein conjugates, GM2, GD3, and fucosyl GM1 gangliosides, globo H, Lewis blood group antigens and mucin core structures. The difficulty facing immunological defense is that cancer cells are of self-origin and the immunological response to them is not good. Rejection of the malignant cells is very effective if tumor vaccines, e.g., after viral infection or transfection, elicit the expression of a foreign gene by a viral gene. Some individuals are immunosuppressed probably because some suppressor T cells down-regulate the effector T cells. In some cases, the signaling to the T cell receptors seem to be disabled or diminished. Some studies indicated an activation of the immune system by introduction of cytokine genes into the tumors. This might be the result either of better signaling or the recruitment of granulocyte-macrophage-colony-stimulating factor (GM-CSF). The tumor cells may display unusual epitopes (mutated β -catenin, caspase) on their MHC molecules and thus be recognized by the immune system, causing the rejection of the parent-type tumor cells. These epitopes may actually occur as differentiation antigens, present in reduced amounts in normal cells too, and the treatment must avoid hurting the normal cells. There may be substantial variations among the different tumors, thus the immunotherapy faces complications. Some of the human cancers are of viral origin, and in these cases proteins essential for the maintenance of the cancerous state can be targeted. The therapeutic strategy must also consider whether cell-mediated (T cell) or antibody-mediated defense (Th1 helper cells) may be the most effective route to go. In case the patients were exposed to radiation or chemotherapy, they may be immunosuppressed or tolerant and the immunotherapy reduces chances for success. Some instances of “generic”

immunotherapy may help, but “custom” therapies using the mutated self-antigens of the patients may have higher probability for success. Tumor cell-based vaccines, immunization with tumor peptides, DNA- or RNA-based vaccination, stimulation of the lymphocytes, or reintroduction into the patients of their own in vitro stimulated lymphocytes or antigens are within some of the therapeutic repertoires. When mice experimental tumors were rendered transgenic for TNF (tumor necrosis factor, IL-2, IL-12 IL-4 [interleukin]), IFN- γ (interferon), GM-CSF (granulocyte-macrophage colony stimulating factor), the tumors went into remission or rejection. Actually, IL-2 itself is not directly curbing the proliferation of cancer cells; rather it stimulates the expansion of lymphocytes, which have antitumor activity. CD8⁺ T lymphocytes recognize 8–10-amino acid peptides generated from, and selected for by, in vitro sensitization of T cells and then cytoplasmic proteins by proteasomes, and displayed on the cancer cell surface by class I HLA molecules. CD4⁺ T cells—in contrast—recognize extracellular proteins, engulfed and digested in the endosomes, and displayed on the cell surface by class II HLA molecules. Based on these properties, cancer antigens can be purified and characterized. Cancer antigens can be tested on intact cancer cells by this *reverse immunology*. Another newer technology is represented by SEREX. In cancer cells, thousands of genomic instabilities may occur generating a great variety of new types of cancer antigens.

Some success was achieved in the rejection of melanoma and lymphoproliferative cancers by immunization *via* the sensitized lymphocytes (adoptive therapy). Autologous T lymphocytes, transgenic for the T cell receptor, when introduced into melanoma caused regression of the cancer in some patients (Morgan RA et al 2006 Science 314:126). Administration of IL-2 cytokines substantially enhances the effectiveness of some immunotherapies (Rosenberg SA 2001 Nature [Lond] 411:380). The use of IL-12 in humans is avoided because of liver toxicity.

Figure C16. Cancer gene therapy. The toxin gene is transactivated and turned on, killing the cancer cell after it has been exposed to the transactivator by connecting the circuit through the oncoprotein to the upstream activator sequence (UAS). (Diagram modified after Da Costa, LT et al 1996 Proc Natl Acad Sci USA 93:4192).

C

New technologies are continuously developed. One of such cancer therapy design would convert the cancer genes (oncoprotein) into cancer killer genes by activating a toxin gene according to a construct outlined (see Fig. C16). The oncoprotein has a DNA-binding domain (DBD), transactivator domain (TAD) and the killer-binding domain (KBD). Another possibility is to fuse the *Pseudomonas* exotoxin (PEA) to the extracellular domain of the HER2 transmembrane receptor protein. Transformed lymphocytes can then introduce, into the cancer cells, the toxin that inactivates elongation factor-2 (EF-2). Transfection of antisense RNA-producing constructs has been proven successful in animal models. Human tissue factor (TF), an important receptor of the blood coagulation cascade, can be targeted to endothelial blood vessels of the tumor by an appropriate antibody. TF complexed with antihemophilic factor VII activates the serine protease zymogen factors IX and X resulting in the formation of thrombin and blood clotting. Blocking specifically and locally the blood supply (antiangiogenesis) to the tumor may cause its substantial regression.

Small peptides—identified by the technique of phage display—that have a special affinity for the tumor blood vessels, can be linked to potent antibiotics (such as doxorubicin) and appear to be a promising alternative to chemotherapy. Unlike the dangers of drug resistance in chemotherapy, antiangiogenesis in endothelial cells does not lead to resistance. The cancer gene therapy vectors must be so designed that they would recognize and destroy the cancer cells without inflicting damage to the normal cells even if they are interspersed with tumor cells. By employing cancer cell-specific promoters (such as the melanocyte-specific tyrosinase promoter or the α -fetoprotein promoter specific for liver carcinomas or the c-erb-B2 specific for breast, ovarian cancer and neuroblastoma) the expression of the genes controlling cytotoxic substances can be localized. The *progression-elevated gene-3* (PEG-3) is an originally rodent gene, which is selectively expressed in a variety of cancer cells but not in normal cells. The transcription factors AP-1 and PEA-3 are the main factors in determining the cancer cell specificity of the promoter of PEG-3. Placing an apoptosis inducing gene (e.g., p53, mda-7/IL24) under the control of the PEG-promoter completely inhibited a prostate cancer xenograft in nude mice, indicating the potential and highly selective value of such a construct in cancer gene therapy (Su Z-Z et al 2005 Proc Natl Acad Sci USA 102:1059; Sarkar D et al 2005 Proc Natl Acad Sci USA 102:14034). Radiation responsive and hormonal receptor regulatory systems may permit the combination of radiation treatment and hormone therapy along with the cytotoxicity

transgene. Cancer cells may become resistant to treatment during the expansion of the tumor. The probability of resistance is proportional to the detectable cell number multiplied with the mutation rate ($M \times \mu$). If ($M \times \mu$) is much smaller than 1, then the expected number of resistant cells is independent of μ and increases with M (Iwasa Y et al 2006 Genetics 172:2557).

Cancer gene therapy is an innovative, new research area and more work is required before it could become a general clinical practice (Varmus H 2006 Science 312:1162).

Some anaerobic (*Clostridium beijerinckii*, *Bifidobacterium longum*) or facultative (*Salmonella typhimurium*) anaerobic bacteria preferentially accumulate in some tumor tissues. A *Salmonella* strain transgenic for cytosine deaminase converts the nontoxic 5-fluorocytosine to the active antitumor 5-fluorouracil. Administration of this bacterium, followed by treatment of fluorocytosine, effectively regressed tumors in mice (Paglia P et al 1998 Blood 92:3172). Unfortunately, the first attempts to apply this technique to human melanoma were not effective. *Salmonella typhimurium* A1 strain auxotrophic for Leu/Arg amino acids and labeled with green fluorescent protein (or other fluorochrome) grew continuously in prostate tumor tissue and caused regression of the tumor without obvious harm to the host nude mice (Zhao M et al 2005 Proc Natl Acad Sci USA 102:755). ►gene therapy, ►cytokines, ►antisense technologies, ►RNAi, ►nanoparticles, ►tumor suppressor genes, ►tumor vaccination, ►multidrug resistance, ►magic bullet, ►epitope, ►MHC, ►MDR, ►transfection, ►ERBB2, ►biomarkers, ►exotoxin, ►EF-2, ►ganciclovir, ►plasmovirus, ►antihemophilic factors, ►tissue factor, ►cancer prevention, ►phage display, ►topoisomerases, ►camptothecin, ►cell therapy, ►MoMuLV, ►retroviral vectors, ►tTA, ►oncolytic viruses, ►OL (1)p53, ►p21, ►p16^{INK}, ►mda-7, ►AP-1, ►retinoblastoma, ►immunotherapy, ►immunotherapy adoptive, ►gangliosides, ►Lewis blood group, ►globo H, ►T cell, ►immune system, ►lymphokines, ►ribozymes, ►angiostatin, ►endostatin, ►adenovirus, ►adeno-associated virus, ►vaccinia virus, ►HIV, ►SEREX, ►mini-organ therapy, ►suicide vectors, ►oncogene antagonism, ►tumor infiltrating lymphocytes, ►tumor vaccination, ►dendritic cell vaccine, ►liposome, ►bystander effect, ►cancer death, ►cytosine deaminase, ►transcriptional targeting, ►Philadelphia chromosome, ►cancer therapy, ►informed consent, ►anti-4-1BB monoclonal antibody, ►immune surveillance, ►immunostimulatory DNA, ►Onyx-015, ►GFP, ►fluorochromes, ►auxotroph, ►nude mouse; Nettelback DM et al 2000 Trends Genet 16:174; Kudryashov V et al 2001 Proc

Cancer Prevention: Prevention of cancer is different from cancer chemotherapy in as much as it is not expected to kill fully cancerous cells; rather, it is aimed at blocking either the primary or the secondary malignancy routes. The chemical treatment may reverse neoplastic development or block preneoplastic conditions without substantial toxicity. Chemicals that stop metabolic activation of procarcinogens were also sought. The cyclooxygenase (COX-2) enzyme appears to increase during the development of intestinal tumors. Blocking the activity of this enzyme by MF-tricyclic without side effects is one approach. Breast cancer may be blocked by tissue-specific estrogen inhibitors (raloxifen, LY353381). Prostate cancer prevention is feasible by interference with estrogen receptors (flutamide). Lung cancer development may be arrested by restoration of the expression of a retinoic acid receptor- β by 13-cis-retinoic acid. Approaches to vaccination against cancer are being worked on. Glycopeptides resembling cell surface tumor antigens may be produced by laboratory techniques. These may then trigger immune responses. Early detection of a cancerous condition may facilitate more effective medication. Various such tests are available, e.g., breast cancer mammography, Pap smear for cervical cancer, the PSA test for prostate

cancer, and fecal occult blood test or colonoscopy for colon polyps. It is highly desirable to find noninvasive and accurate markers for other neoplasias. One approach is to examine blood samples for mutant DNA molecules. In the plasma, 47,800 molecules of the adenomatous polyposis (APC) gene occurred/mL and in a test, 8% of them were found to be mutants in affected individuals. In comparable healthy samples a level of only 0.01 to 1.7% mutant molecules appeared (Diehl F et al 2005 Proc Natl Acad Sci USA 102:16368). ►cyclooxygenase, ►RAR, ►tamoxifen, ►raloxifen, ►retinoic acid, ►immunological surveillance, ►peptide vaccination, ►cancer, ►breast cancer, ►Gardner syndrome, ►Pap test, ►prostate cancer; Levi MS et al 2001 Curr Med Chem 8:1439.

Cancer Prognosis: ►cancer signature

Cancer Promoter: ►phorbol esters

Cancer Signature: Cancer is an abnormal development and it is important to know why and how normal cells embark on such a trajectory(s) of disease. On the basis of microarray hybridization data available in databases it appears that the E2F transcription factor regulates many types of cancers, whereas Myc-Max, Rel and ATF were disproportionately expressed in specific types of cancer cells. In breast cancer, coordinated amplification of MYC and CSN5 genes provides a prognosis for the progression (Adler AS et al 2006 Nature Genet 38:421). Unfortunately, most of the lists of predictor genes display small overlaps and do not permit the making of reliable trajectories for individual cases. Efforts are still underway to make prognosis and spare patients from hard radiation or chemotherapies unless there is a high probability for success (Ein-Dor L et al 2006 Proc Natl Acad Sci USA 103:5923). Dynamic imaging traits in noninvasive computed tomography (CT) systematically correlate with the global gene expression programs of primary human liver cancer. Combinations of twenty-eight imaging traits can reconstruct 78% of the global gene expression profiles, revealing cell proliferation, liver synthetic function, and patient prognosis. Thus, genomic activity of human liver cancers can be decoded by noninvasive imaging, thereby enabling noninvasive, serial and frequent molecular profiling for personalized medicine (Segal E et al 2007 Nature Biotechnol 25:675). ►E2F, ►Myc, ►ATF, ►Polycomb, ►Oncomine, ►tomography, ►cancer classification; Rhodes DR et al 2005 Nature Genet 37:579.

Cancer Stem Cell: Cancer stem cells can be found in small numbers in tumors. They can recapitulate the original type of tumor. They have been found in human leukemia and breast cancer. In the brain cells of a mouse, neoplastic activity is maintained only in

C

the presence of CD133. Some of the stem cells are actually *transit amplifying cells*, which, after some self-renewal, produce differentiated rather than cancer cells. The stem cell niche, which provides the factors necessary for self-renewal, determines the capacity of the transit amplifying cell to be proliferative or assume terminal differentiation. Self-renewal is regulated by suppression of differentiation. Leukemia stem cells can maintain the identity of the progenitor from which they arose but a limited number of them can express genes of normal hematopoietic stem cells if initiated by MLL–AF9 fusion (Krivtsov AV et al 2006 Nature [Lond] 442:818). In a mouse gene, *Bmi1* suppresses differentiation of hematopoietic stem cells. *Bmi1* regulates oncoproteins and (Tp53, p16^{Ink4a}, p19^{Arf}) determines whether they promote proliferation or stay tumor suppressors (Kim WY et al 2006 Cell 127:265). The first step in cancer development is a mutation, which inactivates expansion of normal stem cells. The transit amplifying cell continues to proliferate without differentiation and subsequently additional mutations generate self-renewing cancer stem cells (Clarke MF, Fuller M 2006 Cell 124:1111). The relatively small number of stem cells in cancer can mutate and acquire resistance to drug therapy (Dean M et al 2005 Nature Rev Cancer 5:275). ▶**stem cells**, ▶**progenitor**, ▶**EC**, ▶**p16^{Ink4a}**, ▶**p53**, ▶**CD133**, ▶**MLL**; AF, Singh SK et al 2004 Nature [Lond] 432:396; Dalerba P et al 2007 Annu Rev Med 58:267.

Cancer Susceptibility: Susceptibility to cancer may be affected by environmental factors and genotypic differences. The most effective environmental carcinogens are polycyclic aromatic hydrocarbons and aromatic amines. The genetic predisposition depends on the individual differences in the activation and detoxification systems. The major risk factors are mutation(s) in tumor suppressor genes. Somewhat less important are the mutations in activating enzymes that may, however, become important under conditions of longer or repeated exposure to carcinogens. The detoxification process itself may also involve activation of the procarcinogens into carcinogens. The metabolic factors include the P450 cytochrome system, glutathione-S-transferase (GST), epoxide hydrolase and *N*-acetyltransferase (NAT), and defects in apoptosis, cell cycle, genetic repair, etc. Individuals with mutations in the enzymes' modulating responses to carcinogens may be at increased risk. Generally, the contributing factors include interactions among several of the modulatory enzymes. Therefore, the risk on the basis of analyzing a single enzyme may not be sufficient. Ethnic, sex, and age differences exist in susceptibility. Some of

the differences may be caused by cultural and environmental factors (diet, smoking, etc.). So far no general method is available for cancer screening. Binding antibodies isolated from whole serum can screen random peptide libraries generated by phage display. This procedure then identifies potential targets for drug therapy as well the metastatic stage of prostate cancer (Mintz PJ et al 2003 Nature Biotechnol 21:57). ▶**cancer**, ▶**carcinogens**, ▶**environmental mutagens**, ▶**activation of mutagens**, ▶**P450**, ▶**glutathione-S-transferase**, ▶**epoxide**, ▶**cancer signature**; Taningher M et al 1999 Mutation Res 436:227; QTL analysis; Demant P 2003 Nature Rev Genet 4:721.

Cancer-Testis Antigens: These antigens are coded in several human chromosomes and are expressed in different types of cancer, including the testis. ▶**MAGE**

Cancer Therapy: On the basis of progress in annotation of the sequenced genes, specific targets can now be identified. Among them the oncogenes-activating kinases can be neutralized. Small molecules may target oncogenic signals. Specific monoclonal antibodies can be joined with cytotoxic agents and delivered to selected cancer sites. One newer approach for finding anticancer molecules is to mix two isogenic cell lines; in one of them the cancer suppressor K-Ras allele has been deleted by homologous recombination. The two lines are marked differently by fluorescent tags (YFP and BFP, respectively). The cell mixture is exposed to a library of ~30,000 chemicals. The growth differential of the two cell lines (determined by the intensity of the label) can be assessed on a large scale and selectively, and it was revealed that a novel cytidine analog (sulfinyl cytidine, SC-D) is selectively toxic to the cancer but does not interfere with the healthy cells. In addition, the chemical inhibited xenografts of the mutant Ras (Torrence CJ et al 2001 Nature Biotechnol 19:940). Bacterial infection may reduce the proliferation of cancer cells. *Salmonella typhimurium* leu-arg auxotrophs grow in viable as well as necrotic areas of tumors; the nutritional auxotrophy severely restricts growth in normal tissue. The antitumor efficacy of the *S. typhimurium* auxotrophic leu-arg has increased antitumor virulence in prostate cancer (Zhao M et al 2007 Proc Natl Acad Sci USA 104:10170). The immune effector cell population of cytokine-induced killer cells along with oncolytic virus (thymidine kinase deleted Vaccinia) effectively targeted the tumors and synergistically attacked mouse mammary cancer cells without harming normal cells (Thorne SH et al 2006 Science 311:1780).

Liposomase (liposome-lysing enzyme) of *Clostridium novyi-NT* bacterium can enhance the release of cancer drugs with increased efficiency when delivered by liposomes. Mouse tumors treated with this bacterium and liposomal doxorubicin (an antineoplastic agent) eradicated tumors (Cheong I et al 2006 Science 314:1308). Boron Neutron Capture Therapy (BNCT), based on selective capture of thermal neutrons, is capable of neutralizing malignant melanoma—when successfully targeted to tumor cells—in case other treatments fail (Hawthorne MF 1993 Angewandte Chem Int Ed English 32:950). In the majority of cancer cells, reactive oxygen species (ROS) accumulate and aid further proliferation of and increase in genetic instability. The cancer cells try to cope with this problem with the production of antioxidants such as glutathione. β -phenylethyl isothiocyanate, a natural product in cruciferous vegetables, is known to disable antioxidants in the cells. Thus, when provided to cancer cells, it further boosts ROS effects and thus selectively kills cancer cells and improves the survival of nude mice. ROS molecules are particularly deleterious to mitochondrial membranes. Normal cells are not much affected, probably because their antioxidant level is usually low (Trachootham D et al 2006 Cancer Cell 10:241).

Cancer Vaccines: ▶cancer gene therapy, ▶vaccines

Candela: A unit of luminous intensity. A standard radiator produces 60 candela/cm² at the freezing temperature of platinum (−2,046K); 1/60 candela = 1 candle (new unit). 1 foot candle = 10.76 lux; 1 lux = 1 lumen/m²; 1 lumen = is the total visible energy emitted from one candle point luminous intensity.

Candida albicans: A human diploid (n = 8) fungal opportunistic pathogen in hospitals with ~200 species. The mating type is determined by a mechanism similar to that in *Saccharomyces cerevisiae*. There is a difference, however, in the regulation of the

system. In *C. albicans* the **a** mating type dependent genes require activation by a high mobility group of protein **a2**, encoded by the *MATa* locus, whereas in basically the same system in *S. cerevisiae*, the **a**-dependent genes are normally until repressed by the **α 2** protein encoded by the *MATa* locus (Tsong AE et al 2006 Nature [Lond] 443:415). The chromosomes frequently display polymorphism because of rearrangements. The largest chromosome is frequently designated as R because it contains the ribosomal DNA cluster. Conjugating laminarin (β -glucan) with diphtheria toxoid CRM197 (inactivated exotoxin) provided a highly effective vaccine against vaginal candidiasis and also *Aspergillus fumigatus* in rodents (Torosantucci A et al 2005 J Exp Med 202:597). Isochromosome of two left arms of chromosome 5 is associated with resistance to azole drugs (Selmecki A et al 2006 Science 313:367). Azole drugs are used as systemic antifungal agents; they block 14 α -lanosterol demethylase, essential for ergosterol biosynthesis.
 ▶candidiasis, ▶*Aspergillus*, ▶ergosterol, ▶mating type determination in yeast; Janbon G et al 1998 Genetics 95:5150; genome databases; <http://genolist.pasteur.fr/CandidaDB>; <http://www.candidagenome.org/>.

Candidate Gene: A candidate gene is already mapped in a chromosomal region and possibly included in the DNA fragment to be mapped, but it is not known (although hoped) that it is involved in a particular function or phenotype associated with a mutation. The functional identity of the isolated DNA requires rigorous biochemical proof. In case multiple alleles of the gene are available, the verification of the identity is greatly facilitated. In case the wild type allele of the isolated gene is returned by transformation in a mutant stock and the normal phenotype is restored, there can be no doubt about identity. ▶gene isolation, ▶transformation genetic; Ernst JF 2000 Microbiol 146:1763; candidate gene prediction for hereditary disease: <http://www-micrel.deis.unibo.it/~tom/>; in *Arabidopsis* and rice: <http://www.scbio.org/qtl2gene/new/>.

Candidiasis, Familial, Chronic Mucocutaneous (FCMC):

An apparently autosomal recessive (2p) immunodeficiency involving T lymphocytes, resulting in infections of the mucous membranes, skin and nails by *Candida* fungi. The diploid *C. albicans* (n = 7, 16 × 10⁶ bp) is the most prevalent pathogen in this type of disease and it is responsible for the very common and frequently lethal nosocomial infections. During infection of the murine urinary tract by *Candida glabrata* (a nicotinic acid auxotroph), nicotinic acid supply becomes limited and this results in silencing of NAD⁺-dependent histone deacetylase. As a consequence, the normally silent adhesin genes are

expressed and candidiasis ensues (Domergue R et al 2005 Science 308:866). ▶[immunodeficiency](#), ▶[nosocomial](#), ▶[rosacea](#); De Backer MD et al 2000 Annu Rev Microbiol 54:463; Chibana H et al 2000 Genome Res 10:1865.

C

Candle: ▶[candela](#)

Canine Transmissible Venereal Tumor (CTVT, Sticker sarcoma): CTVT is transmitted as an allograft from existing tumors by sexual intercourse of dogs, biting and other contact of affected areas, but not by dead cells or cell filtrates. A LINE1 element is found in all transmissible venereal tumors near a c-myc oncogene. Current extensive evidence indicates that cancer cells can evolve into a transmissible parasite (Dingli D, Nowak MA 2006 Nature [Lond] 443:35). The CTVT of dogs seems to have originated from a wolf or East Asian breed of dog between 200 and 25,000 years ago, and it has been somatically propagated in diverse modern breeds. The dog leukocyte antigen gene of the tumors differed from that of normal dogs and seems to be clonally transmitted. The control region of the mtDNA also supported the clonal origin of the tumors despite some mutations. The original clone diverged into two subclades during early evolution and is maintained as such today. The tumor is highly aneuploid yet its current karyotype is remarkably constant (Murgia C et al 2006 Cell 126:477). ▶[aneuploidy](#), ▶[HLA](#), ▶[oncogene](#), ▶[LINE1](#), ▶[clade](#), ▶[Tasmanian devil](#)

Cannabinoids: About 60 related compounds synthesized by the hemp plants (*Cannabis*) and present in the psychoactive drug marijuana (see Fig. C17). Besides the psychoactive effects, they have various immunosuppressive properties and may control pain initiation and transmission through modulation of the rostral ventromedial medulla of the brain and tremor in multiple sclerosis. Some “endocannabinoids” are present in cocoa, milk and other human food, but do not appear to be responsible for cravings after chocolate or have other psychoactive effects. Δ^9 -Tetrahydrocannabinoid may reduce sexual activity and fertility by affecting steroid metabolism. THC (1 mg kg^{-1}) orally administered (thus below the psychotropic effect) reduces atherosclerosis in mice (Steffens S et al 2005 Nature [Lond] 434:782).

Figure C17. Cannabinoid (THC)

Endocannabinoids, in cooperation with leptin, also regulate food intake and body weight; leptin restricts food craving whereas endocannabinoids increase appetite. Anandamide also protect the central nervous system against inflammation (Eljaschewitsch E et al 2006 Neuron 49:67). The endocannabinoid anandamide, in low concentration, promotes receptivity of the mouse uterus to embryo transplantation, whereas at higher levels the receptivity is reduced. So far there is no evidence for the normal control of fertility although obese mice may be sterile until leptin is supplied. Endocannabinoids also activate the pleasure sensations, e.g., in eating tasty food, and this may explain addiction to cannabinoids. They may adversely affect/facilitate long-term potentiation of memory. An endocannabinoid transporter can increase cannabinoid level in the brain by 5-fold and points to the potential use of endocannabinoid transporter antagonists (Moore SA et al 2005 Proc Natl Acad Sci USA 102:17852). ▶[immunosuppressants](#), ▶[leptin](#), ▶[excitotoxicity](#), ▶[Cannabis sativa](#), ▶[horseradish](#), ▶[osteoporosis](#), ▶[analgesic](#); Iversen LL 2000 The Science of Marijuana Oxford Univ Press, New York; Di Marzo V et al 2001 Nature [Lond] 410:822; Carlson G et al 2002 Nature Neurosci 5:723; Mereu G et al 2003 Proc Natl Acad Sci USA 100:4915.

Cannabis sativa (hemp): A generally dioecious species (*Moraceae*) with a diploid chromosome number of 20, including either XX female or XY male flowers (see Fig. C18). The XXXY tetrasomics are also gynoeceous. Hermaphroditic forms are also known that produce more seed and only somewhat reduced amount of fiber. Low-cannabinoid genetic stocks are known. ▶[cannabinoids](#), ▶[hop](#); Onaivi ES (ed) 2002 Biology of Marijuana, Taylor & Francis, New York; de Meijer EPM et al 2003 Genetics 163:335.

Figure C18. *Cannabis*

Cannibalism: Animals eating members of their own species. In heterocannibalism the eaten individuals are not the offspring of the cannibal. Filial cannibals devour their own offspring. The latter class is generally less frequent because it is usually counterproductive

for fitness. Filial cannibals apparently lack the ability to identify their own offspring. Males are more likely to commit filial cannibalism than females because they have much less investment in the progeny. ►fitness; DeWoody JA et al 2001 Proc Natl Acad Sci USA 98:5090.

Canola: An erucic acid-free rapeseed oil crop, *Brassica napus* (2n = 38, AACC genomes). ►erucic acid

Canonical Sequence: A typical set of nucleotides in several genes (e.g., in a Pribnow box or Hogness box or other conserved elements).

Canyons: Deep structural sites on the viral surface where receptors bind.

CAP (catabolite activator protein): A homodimer with two subunits of M_r 22,000. It has a binding site for cAMP and DNA with a helix-turn-helix motif. As long as glucose is available in the nutrient medium the *Lac* operon of *E. coli* is inactive because glucose, a catabolite of lactose, represses the operon (catabolite repression). In order to turn on the operon the CAP protein must be attached to the CAP site, in a process mediated by cAMP. The adenyl cyclase enzyme forms the latter from ATP and this process is inhibited by glucose. When glucose is used up, cAMP is formed and the latter binds to CAP; the complex binds to its palindromic site in the DNA (GTGAGTTAGCTCAC) near the promoter of the operon and transcription by the RNA polymerase is activated. Without CAP the promoter is very weak. In order to pursue normal transcription the grip of the repressor protein must also be lifted and this is mediated by lactose (allolactose). The cAMP-CAP complex also regulates the arabinose and galactose operons. ►negative control, ►positive control, ►transcriptional activation, ►regulation of gene activity, ►lac operon, ►arabinose operon, ►galactose operon, ►cAMP, ►palindrome; Johnson CM, Schleif RF 2000 J Bacteriol 182:1995; Benoff B et al 2002 Science 297:1562.

CAP (ceramide-activated protein): CAP kinase mediates tumor necrosis factor and interleukin-1 β functions. It also phosphorylates Raf1 on Thr 269 and increases Raf affinity for ERK kinases. ►RAF, ►ceramides, ►ERK, ►TNF, ►interleukin; Chalfant CE et al 2000 Methods Enzymol 312:420.

Cap: A methylated guanylic residue linked at transcription to the 5' end of the eukaryotic mRNA (7MEG_{5'}ppp-mRNA) or 2,2,7-trimethyl guanosine in U RNA. The prokaryotic mRNA has only three phosphates at the 5' nucleotide end. The cap of the (long-life) eukaryotic mRNA stabilizes it (makes it less sensitive to nucleases), assures the transport of

the mRNA to the cytosol, and facilitates its binding to the ribosome and initiation of transcription by lending itself as an anchor to eIF4F eukaryotic initiation factors. The eIF factors and various binding proteins determine which mRNAs are transcribed at a certain stage of the development. The eI-4E binding protein 4E-BP may also act as a tumor suppressor. Upon phosphorylation, 4E-BP dissociates from the eIF4F complex resulting in increase of translation. This and other inhibitory proteins regulate nerve function and the consolidation of memory (Richter JD, Sonnenberg N 2005 Nature [Lond] 433:477). The cap also regulates splicing of the first intron. A capping complex (CBC), composed of cap-binding nuclear proteins, CBP80 and CBP20 mediates the effect of cap on pre-mRNA splicing. CBC then mediates the export of RNA. The U3 snRNA also has a trimethylated cap that is added in the nucleus and the RNA remains in the nucleus. Binding between the cap and the poly(A) tail promotes translation. Picornavirus mRNAs lack the 5' caps and thus translation initiation is cap-independent and it begins at an IRES site. ►capping enzymes, ►eIF4, ►regulation of gene activity, ►ribosome scanning, ►FLAG, ►poly[A], ►IRES; Rottman F et al 1974 Cell 3:197; Efimov VA et al 2001 Nucleic Acids Res 29:4751.

Cap3: The N-terminal domain of FLICE. ►FLICE

CAP'n'Collar Genes (CNC): CNC genes are basic leucine zipper transcription factor regulating homeotic genes. ►DNA binding protein domains, ►homeotic genes

Cap Snatching: Viral RNA replication secures primers for its initiation by cleaving off about a dozen nucleotide long pieces from the 5'-end of nuclear RNA polymerase II transcripts. The cleavage is mediated by a virus-encoded endonuclease. The priming does not involve hydrogen bonding between the primers and the 3'-end of the viral RNA template. ►primer; Duijsings D et al 2001 EMBO J 20:2545.

Capacitation of Sperm: ►fertilization

Cap-Binding Protein Complex (CBC): Binds to the 5'-end of the mature mRNA and facilitates U snRNA export. ►protein synthesis, ►U RNA, ►export adaptors, ►nuclear pore, ►eIF, ►translation initiation

Capillary: A structure resembling hair; usually bearing a small bore through which liquids can move, such as in the capillary veins or capillary tubes, or soil capillary spaces.

Capillary Electrophoresis: Capillary electrophoresis uses gel-filled glass/quartz tubes of 50–100 μ m

diameter and 20–50 cm length to facilitate fast separation of substances in the electric field by applying high voltage (10–30 kV) without excessive heating up of the system because of better dissipation of the heat. UV or fluorescence detects labeling.

►electrophoresis, ►ultrathin-layer chromatography, ►DNA sequencing; Guttman A, Ulfelder KJ 1998 *Adv Chromatogr* 38:301.

Capillary Transfer: Capillary transfer is used to draw a buffer by wicks from a reservoir to an electrophoretic gel containing separated DNA fragments. The gel is in contact with the absorbent papers. The moving stream elutes the DNA from the gel and deposits it onto a nitrocellulose or nylon filter in immediate contact with the gel, in between the gel and the stack of papers topped by a glass plate and weighted down. ►Southern blotting

Capping Enzymes: Generate the mRNA cap by using GTP and the diphosphate splits off from the first nucleotide triphosphate of the first residue in the pre-mRNA (see Fig. C19). The 5' terminal triphosphate is replaced by the guanyl group of GTP and it loses the γ and βPO_4 groups.

No capping takes place if, at the terminal position, there is a monophosphate. The capped G indicates the beginning of the transcript. The G is methylated by guanosine-7-methyl transferase at the 7 position. The 2'-OH is subsequently methylated by 2'-O-methyl transferase using SAM as a methyl donor. The capping reaction is associated with Pol II and the triphosphate termini of U6 RNA, 5S RNA and the pre-tRNAs, transcribed by Pol III, are not capped. The caps stabilize the mRNA and facilitate the ribosomal attachment. Initiation factor eIF-4E recognizes the cap and mediates its binding to the 40S ribosomal subunit. Picornaviruses do not need the cap and they inactivate the cap-binding proteins of the host and thus turn off the synthesis of host proteins. ►class II genes, ►cap, ►picornaviruses, ►Pol II eukaryotic, ►transcription factors, ►eIF, ►FLAG; Cho EJ et al

1997 *Genes Dev* 11:3319; Shuman S 2000 *Progr Nucleic Acid Res Mol Biol* 66:1; Changela A et al 2001 *EMBO J* 20:2575; Pei Y et al 2001 *J Biol Chem* 276:28075.

CAPS (cleaved amplified polymorphic sequences): CAPS are produced by digesting PCR products by restriction enzymes to find polymorphism in the DNA. ►PCR, ►restriction enzyme, ►AFLP

Capsaicin: The pungent substance of *Capsicum* peppers. It may be anticarcinogenic due to its antioxidant function. The capsaicin (vanilloid) receptor is a cation channel required for heat and pain perception. Bradykinin and nerve growth factors activate a G-protein-coupled and tyrosine kinase receptors and phospholipase C signals to the primary afferent neurons. The potentiation also requires the VR1 heat-sensitized ion channel on sensory neurons. PIP₂ controls its receptor's sensitivity (Prescott ED, Julius D 2003 *Science* 300:1284). The alkaloid galanthamine present in some *Amaryllidaceae* plants is also supposed to have beneficial effects on some nervous diseases, particularly on Alzheimer disease (see Fig. C20).

Capsaicin-containing fruits are generally avoided by wild mammals but not by birds (Jordt S-E, Julius D 2002 *Cell* 108:421). It is apparently a self-defense substance in the plants because birds are efficient dispensers of the seed but mammals are not because the seed passing through their alimentary channel loses germination in contrast to a bird's. Some spider toxins also invoke inflammatory pain by activating capsaicin receptors (Siemens J et al 2006 *Nature [Lond]* 444:208). ►phenolics, ►nociceptor, ►kininogen, ►nerve growth factor, ►signal transduction, ►phospholipase, ►alkaloids, ►horseradish, ►PIP₂; Chuang H-h et al 2001 *Nature [Lond]* 411:957; capsaicin synthase and biosynthetic pathway: Prasad BCN et al 2006 *Proc Natl Acad Sci USA* 103: 13315.

Figure C19. Cap of the eukaryotic mRNA

Figure C20. a. Capsaicin, b. Galanthamine

Capsid: The protein shell of the viral genetic material. In complex viruses, a lipid bilayer may be acquired from the host during budding (exit) of the virus. In some viruses, nucleic acids may also be found in the shell. For completion of the infection the capsid is shed and the genetic material is uncoated. ►virus, ►viral capsid; <http://viperdb.scripps.edu/>.

Cap-Snatching: Some RNA viruses (tomato spotted wilt, influenza virus) cleave by an endonuclease 10–20 nucleotides from the 5' end of a host messenger RNA and use the capped leader for priming their transcription or viral RNA synthesis (van Knippenberg I et al 2005 Virology 335:122; Rao P et al 2003 EMBO J 22:1188).

Capsomer: The protein subunits of the viral capsids.

Capsule: A polysaccharide coat of bacterial cells or in general structure with polysaccharide content or a fungal sporangium, or a seed capsule of plants formed by fusion of two or more carpels. In *E. coli* about 80 capsular serotypes have been recognized. The serotype-specific structures are lipopolysaccharides or capsular polysaccharides and have an important role in bacterial virulence (Whitfield C 2006 Annu Rev Biochem 75:39). ►LPS, ►serotype, ►carpel

Capture PCR: Facilitates the isolation of DNA sequences of next to known nucleotide segments. To restriction enzyme-digested DNA ends, linkers of two base-paired oligonucleotides are ligated. By using a biotinylated primer of known sequence the construct is extended. This permits the capture of the extended products on a streptavidin-coated medium. These products are further amplified by PCR with the aid of another specific oligonucleotide hybridized to the 3'-end of the biotinylated sequence. The simultaneous isolation of a large number of fragments, if greatly facilitated by the use of a manifold, connected

to each individual, well of a microtiter plate. ►PCR, ►restriction enzyme, ►biotinylation, ►streptavidin, ►microarray hybridization; Lagerstrom M et al 1991 PCR Methods Appl 1:111.

CAR: Cyclic AMP receptor. ►cAMP

CAR1 (coxsackie and adenovirus receptor): A 368 amino acid receptor that recognizes the avian leukosis-sarcoma virus envelope and induces apoptosis upon infection. It is homologous to the TNF/NGF mammalian family (TRAIL) receptors. CAR is also a cellular attachment receptor for adenovirus, a useful vector in gene therapy. CAR-transgenic mice are promising models for human gene therapy. ►TRAIL, ►TNF, ►NGF, ►apoptosis, ►coxackie viruses, ►adenovirus; Tallone T et al 2001 Proc Natl Acad Sci USA 98:7910.

CaR: An extracellular calcium receptor and thus regulator of diverse metabolic functions.

CAR-β (constitutive androstane receptor): CAR-β is negatively regulated by androstanes. ►androstane

C3a-R: Receptor of C3a complement component. Its mass varies (83–104 kDa). ►complement

C5a-R: Receptor of the C5a complement component. The size of this protein encoded in human chromosome 19q13.3 varies greatly (8–52 kDa) depending on the cells it is found on. ►complement

Carbachol (carbamylcholine chloride): A cholinergic agonist, resistant to cholinesterase; carbachol may increase phosphorylation of RAS. ►cholinesterase, ►RAS

Carbamoylphosphate Synthetase Deficiency (CPSI, 2q35): Hyperamonemia is caused by defects in several enzymes in the mitochondria; others are encoded by several autosomes and are cytosolic. Carbamoylphosphate synthetase/aspartate transcarbamoylase/dehydroorotase (2p21) is a three-enzyme locus involved in pyrimidine synthesis. Ornithine transcarbamylase deficiency (OTC) is encoded at Xp2.11. ►urea cycle, ►CAD, ►channeling

Carbenicillin: A semi-synthetic antibiotic of the penicillin family; effective against gram-negative and some gram-positive bacteria (see Fig. C21). ►antibiotics

Figure C21. Carbenicillin

Carbocation: ►carbonium ion

Carbohydrate: Sugars and their polymers. See <http://www.dkfz.de/spec2/sweetdb>; carbohydrate-protein interactions; <http://www.functionalglycomics.org/static/consortium/>.

C

Carbohydrate Arrays: Detect the specific binding of various oligosaccharides to different proteins. Oligosaccharide decorated proteins have numerous functions in healthy and diseased cells. See <http://www.glycosciences.de/tools/>.

Carbon Dating: ►radiocarbon dating

Carbon Fixation: Photosynthetic organisms form sugars from atmospheric CO₂. ►C3, ►C4 plants

Carbonic Anhydrase (CA): Catalyzes the reactions $\text{H}_2\text{CO}_3 \rightleftharpoons \text{H}_2\text{O} + \text{CO}_2$, i.e., it provides an equilibrium between carbonic acid and carbon dioxide, and the addition reaction of $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}^+$ plus, i.e., the formation of carbonium ion from carbon dioxide. This is a Zn enzyme of about M_r 30,000 and is common in various eukaryotic tissue (1–2 g per L of mammalian blood). It is an extremely active enzyme but a much lower rate also catalyzes the hydration of acetaldehyde. In humans, seven isozymic forms have been identified. CA 1, 2 and 3 were located to chromosome 8q13-q22. CA2 is about 20 kb apart from CA3 and it is transcribed in the same direction while CA1 and CA3 are separated by about 80 kb and their direction of transcription is opposite. CA1, 2, and 3 are common in the muscles. CA2 (8q22) deficiency is involved in osteopetrosis with renal tubular acidosis. CA4 (17q23) and CA9 (17q21.2) are closely linked. CA5 (16q24.3), an apparently mitochondrial protein, does not appear to be of specific significance; it may participate in gluconeogenesis. The CA6 gene is present in chromosome 1p37.33-p36.22 and the gene is expressed in saliva. The CA7 gene is in another chromosome (16q21-q23) and is specific for the kidney, lung and liver mitochondria. The CA10 (chromosome 7) codes for α -carbonic anhydrase. CA11 (19q13.2-q13.3) is primarily a brain enzyme but it is also expressed in the spinal cord and other tissues. CA12 (15q22) shows slightly elevated expression in some tumors. CA14 is expressed primarily in the adult brain and several visceral organs but only in the fetal heart (1q21). ►osteopetrosis, ►mitochondrial genetics, ►mtDNA, ►gluconeogenesis

Carbonium Ion: A group of atoms containing only 6 electrons (rather than the normal octet); it is considered highly reactive and is supposed to be involved in the reactions following alkylative processes in chemical mutagenesis and carcinogenesis (see Fig. C22). ►mutagen specificity, ►alkylating agents, ►carcinogen

Figure C22. Methyl carbonium ion

Carbonyl group: Such as occurs in aldehydes and ketones (see Fig. C23).

Figure C23. Carbonyl group

Carboxyl group: (see Fig. C24).

Figure C24. Carboxyl group

Carboxyl Terminus: ►C-terminus

Carboxypeptidase: A zinc-containing proteolytic enzyme cleaving the polypeptide chain at the carboxyl end after substrate binding caused an “induced fit”, i. e., a conformational change in the enzyme protein. The “electronic strain” due to the presence of Zn accelerates catalysis. ►latexin, ►mast cells, ►aspar-toacylase deficiency

Carcinoembryonic Antigen (CEA): CEA may be expressed in the normal epithelium of the colon but it is frequently found in colorectal, gastric, pancreatic and in some breast and non-small-cell lung carcinomas. It may be targeted by genetic immunization. ►immunization genetic; Jacobsen GK et al 1981 Oncodev Biol Med 2:399.

Carcinogen: An agent that is capable of causing cancerous transformation of cells. Carcinogens include chemical, physical, and viral agents. *De novo* carcinogenicity may have several steps: initiation (DNA adduct formation, mutation), promotion (DNA methylation, clonal expansion of the altered cell(s), progression (increased methyltransferase activity, additional mutational events and/or other chemicals modulating the process), and invasive events (metastasis). Some of the carcinogens do not act by mutation though. The chemical compounds may be genotoxic; they act directly on the DNA (e.g., ethyleneimine, various epoxides, lactones, sulfate esters, mustard gas, 2-naphthylamine, nitroamides and nitrosoureas, etc.). They can be procarcinogens that require enzymatic activation (e.g., polycyclic or heterocyclic hydrocarbons such as benzo[a]pyrene, benzanthracene, etc.) or can be inorganic compounds or

elements that interfere with the fidelity of DNA replication. Some carcinogens act by some sort of physical means (e.g., various polymers, asbestos). Some hormones may also promote carcinogenesis in an indirect manner. Phorbol esters, n-dodecane, etc., may not be the primary cause of cancer but are considered to be promoters of cancerous growths. The latter group of chemicals, not acting directly on DNA, is frequently called *epigenetic carcinogens*. Carcinogens include most of the mutagens, many industrial and laboratory chemicals, pesticides, insecticides, fungicides, drugs, cigarette smoke, benzo(a)pyrene, medicines (cyclosporin, estrogens, tamoxifen, etc.), diethylstilboestrol, cadmium and nickel compounds, cosmetics, food preservatives, food additives, flame retardants, cross-linking agents, plastics, solvents, paints, adhesives, exhaust fumes, other products of combustion, tar, soot, benzenes, naphthalenes, carbamates, cyanates, metals, nitroso compounds, alkylating agents, terpenes, some fibers (asbestos), arsenics, etc. Several natural plant products are potential carcinogens, e.g., pyrrolizidine alkaloids, safrole, mycotoxins such as aflatoxins, antibiotics such as streptozotocin, viruses such as the Epstein-Barr virus, Simian virus 40, HIV, hepatitis B and C virus, some papilloma viruses, adenoviruses, etc. Many food products such as oxidized fats, overcooked meats, etc., are also potential carcinogens because of the carcinogens formed in them during their exposure to certain conditions. The direct assays of carcinogens involve testing the induction of skin or lung tumors in rodents, breast tumors in young female Wistar or Sprague-Dawley strains of rats, examination of rodent livers for carcinogenic response, etc. The determination of carcinogenicity at relatively low potency is extremely difficult by direct animal assays because tumorigenesis may occur only after a long delay (months or years) following exposure. Furthermore the required population size may be practically prohibitive. Also, all experiments must include an equal size concurrent control to obtain reliable information. The application of the carcinogen to the test animals may be by painting the skin, through subcutaneous or intravenous injection, through the diet or drinking water, through inhalation, etc. Since many of the carcinogens are also mutagens the preliminary tests are generally conducted by mutagenic assays that permit the evaluation in large populations, within a short time and at low cost. The mutagenic assays (Ames test) usually try to substitute for the animal activation system by human or animal liver (microsomal) fractions. In human and animal populations, the high caloric diet may be an important factor in tumor formation. The response of humans to carcinogens is not entirely identical to that of animals; e.g., the prostate, pancreas, colon, cervix/uterus cancers are low in lab rodents but high in humans.

In contrast, liver, kidney, forestomach, and thyroid gland cancers are frequent in animals but relatively rare in humans. Arsenics are human carcinogens but not for laboratory rodents. Humans cannot be subjected to direct cancer tests and most reliable cancer information could come from epidemiological studies. Humans defective in epoxide hydrolase and glutathione *S*-transferase M1 have increased susceptibility to carcinogens. Unfortunately, complex factors and low frequencies frequently bias data. The carcinogenesis process itself may be due to increased energy production by glycolysis and by the expression of oncogenes [defects in tumor suppressors] (Ramanathan A et al 2005 Proc Natl Acad Sci USA 102: 5992). ▶genetic tumors, ▶neoplasia, ▶cancer, ▶oncogenes, ▶hepatitis B virus, ▶hepatitis C virus, ▶Epstein-Barr virus, ▶SV40, ▶mutagen assays, ▶ionizing radiation, ▶radiation effects, ▶radiation hazard assessment, ▶adduct, ▶activation of mutagens, ▶cocarcinogens, ▶cigarette smoke, ▶bioassays in genetic toxicology, ▶MTD, ▶peroxisome, ▶ k_e test, ▶IARC Monographs; Kitchin KT ed 1999 Carcinogenicity, Marcel Dekker, New York; <http://www.iarc.fr/monoeval/allmonos.htm>; 1485 potential carcinogens: <http://potency.berkeley.edu/cpdb.html>.

Carcinogenesis: Carcinogenesis is the process of cancer induction and progression. Human cells require more genetic changes than mouse cells for neoplasia; there is also tissue specificity in carcinogenesis (Rangarajan A et al 2004 Cancer Cell 6:171). Mutator mutations decrease genome stability and accelerate the accumulation of random mutations, including those in oncogenes and tumor suppressor genes, especially when they occur early during development. However, if the mutator mutation is not in itself oncogenic, acquiring that mutation would add an extra, potentially time-consuming step in carcinogenesis (Beckmann RA, Loeb LA 2006 Proc Natl Acad Sci USA 103:14140) ▶cancer, ▶tumorigenesis, ▶carcinogen, ▶angiogenesis, ▶checkpoint, ▶Knudson's two-mutation theory; Ponder BAJ 2001 Nature [Lond] 411:336.

Carcinoma: A malignant cancer tissue of epithelial origin.

Carcinostasis: Tumor growth inhibition.

CARD (caspase recruitment domain, genes at several chromosomal locations): CARD is required for the recruitment and activation of caspase-9 by Apaf-1 in apoptosis. CARD15 also contains a nucleotide-binding domain and 10 COOH-terminal leucine-rich domain. Mutations in CARD 15 are involved in inflammatory bowel diseases such as Crohn's disease and ulcerative colitis. CARD domains exist in double-strand RNA detecting helicases in response

to virals such as hepatitis C infection. Consequently, interferon regulatory factor (IRF3) and NF- κ B are activated as a protective measure (Meylan E et al 2005 Nature [Lond] 437:1197). ▶caspase, ▶Apaf, ▶apoptosis, ▶Crohn's disease, ▶colorectal cancer, ▶interferon, ▶NF- κ B; Bouchier-Hayes L et al 2001 J Biol Chem 276:44069; Lesage S et al 2002 Am J Hum Genet 70:845.

Cardiac Arrhythmia: ▶LQT, ▶cardiomyopathy arrhythmogenic ventricular. (See Glass L. 2005 Proc Natl Acad Sci USA 102:10409).

Cardiac Conduction Defect (PCCD, Lenegre disease, Lev disease): A common degenerative heart disease frequently requiring the application of a pacemaker. The defects are associated with sodium or potassium ion channels and are encoded in different chromosomes (19q13.3, 3p21).

Cardio-Auditory Syndrome: ▶Lange-Nielssen syndrome

Cardiochips: Microarray procedures using heart DNA or protein arrays for the in vitro study of the bases of heart diseases (Barrans JD, Liew CC 2006 Methods of Mol Med 126:157). (▶microarray hybridization; ▶protein chips)

Cardio-Facio-Cutaneous Syndrome (CFC, 7q34): Many of the symptoms are shared with the Noonan syndrome and the Costello syndrome: head and face defects, heart and lung anomalies, frequently keratotic skin, sparse friable hair and other malformations. 78% of the individuals displaying the clinical symptoms had mutations in the BRAF gene (7q34). Five individuals who did not have mutations in BRAF had missense mutations in the MEK1 (15q31) and Mek2 (19p13.3) effectors of B-Raf (Rodriguez-Viciano P et al Science 2006 311:1287). ▶Noonan syndrome, ▶Costello syndrome, ▶BRAF, ▶MEK, ▶RAF

Cardiolipin: A diphosphatidylglycerol most common in the mitochondria and bacterial membranes (see Fig. C25). Its deficiency is involved in Barth syndrome (endocardial fibroelastosis). HIV-1 gp41 envelope protein autoantibodies, mAbs 2F5 and 4E10 react with cardiolipin. Current HIV-1 vaccines may not induce these types of antibodies because autoantigen mimicry of the conserved membrane proximal epitopes of the virus (Haynes BF et al 2005 Science

3008:1906). ▶endocardial fibroelastosis, ▶acquired immunodeficiency, ▶autoantibody, ▶monoclonal antibody, ▶epitope, ▶mimicry macromolecular

Cardiomyopathies: A group of noninflammatory heart diseases affecting about 25,000 persons annually in USA. (see for details, ▶heart disease, ▶cardiomyopathy hypertrophic, ▶cardiomyopathy arrhythmogenic ventricular, ▶arrhythmogenic right ventricular cardiomyopathy, ▶Duchenne, muscular dystrophy, ▶Becker muscular dystrophy, ▶Barth syndrome [endocardial fibroelastosis], ▶Costello syndrome, ▶Acyl-CoA dehydrogenase deficiencies, ▶cardiomyopathy dilated, ▶superoxide dismutase, ▶cardiac arrhythmia, ▶cardiovascular diseases, ▶myopathy, ▶mitochondrial diseases in humans, ▶histiocytoid cardiomyopathy, ▶cathepsins; Seidman JG, Seidman C 2001 Cell 104:557).

Cardiomyopathy, Arrhythmogenic Ventricular (ARVD): The autosomal dominant (14q24.3, 14q12-q22, 1q32, 10p12-p14) and possibly recessive condition involves fibrous/fatty replacement of heart muscles particularly in the right ventricle. It causes unusual palpitation, faintings (syncope), heart failure and possibly sudden death. ▶cardiomyopathies, ▶arrhythmogenic right ventricular cardiomyopathy, ▶phospholamban

Cardiomyopathy, Dilated (CMD): CMD involves thinner than normal ventricular heart walls, reduced contractility, and heart failure. Prevalence in USA is about 4×10^{-4} and about 1/4 of them is hereditary and may benefit from heart transplantation. Defects may involve recessive β oxidation of fatty acids, including acyl-CoA dehydrogenase, carnitin palmitoyl transferase II, and impaired mitochondrial oxidative phosphorylation. Missense mutation in cardiac actin gene (ACTC, human chromosome 15q11-qter) seems to be involved. Also several genes for idiopathic dilated cardiac myopathy (IDC) have been located in human chromosomes Xp21, Xq28, 1p1-1q21, 1q32, 2q31, 2q14-q22, 3p22-25, 5q33-q34, 6p24, 6q12-q16, 9q13-q12, 10q21-q23, 14q11, 15q14, 15q22 and 17q21. Defects in dystrophin and myosin may also be involved. Cardiomyopathy CMD1A involves a defect in lamins (1q21.2-q21.3). Missense mutation in the transmembrane phosphoprotein, phospholamban (6q22.1), inhibits Ca^{2+} -adenosinetriphosphatase pump and causes myocell dysregulation (Schmitt JP et al 2003 Science 299:1410). Autoimmune dilated cardiomyopathy may be due to deficiency of the PD-1 receptor. Homoplasmic point mutations in mitochondrial tRNA^{His} may predispose for CMD. ▶cardiovascular diseases, ▶acetyl coenzyme A, ▶carnitin, ▶fatty acids, ▶mitochondrial diseases in humans, ▶actin, ▶dystrophin, ▶cardiomyopathies, ▶lamins, ▶PD-1; Chien KR 1999 Cell 98:555;

Figure C25. Cardiolipin

Schönberger J, Seidman CE 2001 *Am J Hum Genet* 69:249; Caforio AL et al 2007 *Circulation* 115:76.

Cardiomyopathy, Hypertrophic, Familial (FHC): FHC has heterogeneous autosomal dominant symptoms (thickening of the heart's ventricular walls, shortness of breath, arrhythmia and sudden death). Four genes are known to be involved controlling contractile heart proteins such as β myosin heavy chain (human chromosome 14q11-12), α tropomyosin (15q2), troponin T (1q3) and cardiac myosin binding protein C (11p11.2). Additional gene loci have been implicated in human chromosome 7q3, 18 and 16. Cardiac hypertrophy may be blocked by inhibitors of ADAM12 protein, which sheds heparin-binding epidermal growth factor (HB-EGF), responsible for hypertrophy. Calmodulin-binding transcription activators (CAMTA2) stimulate cardiac growth (hypertrophy) by opposing histone deacetylases (Song K et al 2006 *Cell* 125:453). [►cardiomyopathy dilated](#), [►cardiovascular diseases](#), [►myosin](#), [►troponin](#), [►cardiomyopathies](#), [►ADAM](#); Asakura M et al 2002 *Nature Med* 8:35.

Cardiomyopathy, Restrictive: Restrictive cardiomyopathy affects the expansion (diastole) of the heart without much effect on the contraction (systole). Only about 10% of the cases are clearly hereditary and X chromosomal or autosomal dominant. [►cardiomyopathies](#)

Cardiotrophin (CT-1, ~22 kDa, encoded at 16p11.1-p11.2): Cytokine regulating cardiac muscle cells. It shares a receptor with LIF and other cytokines. [►LIF](#), [►cytokine](#)

Cardiovascular Diseases: Affect the heart and the vein system. Generally premenopausal women show lower risk than men, but after menopause female susceptibility increases substantially (Mendelsohn ME, Karas RH 2005 *Science* 308:1583). [►coronary heart disease](#), [►mucopolysaccharidosis](#), [►lipidoses](#), [►lipoproteins](#), [►Tangier disease](#), [►lysosomal storage disease](#), [►hypertension](#), [►coarctation of the aorta](#), [►sickle cell disease](#), [►Ehlers-Danlos syndrome](#), [►Marfan syndrome](#), [►Norum disease](#), [►hyperthyroidism](#), [►LQT](#), [►cardiomyopathies](#), [►familial hypercholesterolemia](#), [►hypo-betalipoproteinemia](#), [►hypo- \$\alpha\$ -lipoproteinemia](#), [►homocystinuria](#), [►telangiectasia hereditary hemorrhagic](#), [►Williams syndrome](#), [►supravalvular stenosis](#), [►idiopathic ventricular fibrillation](#)

CaRE: A cis-acting element responsible for induction of the c-fos protooncogene by calcium. [►FOS](#), [►cis-acting element](#)

Caretaker Gene: The caretaker genes repair genetic defects that might lead to instability or cancer. [►gatekeeper](#), [►tumor suppressor genes](#); Kai M et al 2006 *Methods Enzymol* 409:183.

CaRG: A conserved promoter element [CC(A/T)₆GG] closely related to SRF. [►promoter](#), [►SRF](#)

CaRG Box: [►SRE](#)

Cargo Receptors: Special molecules in or on the plasma membrane that are recognized by adaptins associated with clathrin-coated vesicles and thus trap various molecules in the process of endocytosis. clathrin, endocytosis, receptors, adaptins; Moroianu J 1999 *J Cell Biochem Suppl* 32–33:76.

CARL: [►comparative anchor reference loci](#)

CARM1: Co-activator associated with arginine methyltransferase-1, related to AdoMet. It may mediate transcription when recruited to the steroid receptor co-activator (SRC-1) and cofactors p300 and PCAF. [►AdoMet](#), [►SRC-1](#), [►p300](#), [►PCAF](#), [►histones](#), [►pluripotency](#); Chen SL et al 2002 *J Biol Chem* 277:4324.

Carney Complex: Multiple and usually pigmented neoplasias of soft tissues and the heart (myxoma). One form is CNC2, located at 2p16, the other CNC1 is at 17q23-q24. The latter is presumably a dominant mutation in a tumor suppressor regulatory alpha unit of a cAMP dependent protein kinase (PRKAR1A). (Groussin L et al 2002 *Am J Hum Genet* 71:1433).

Carnitine (γ -trimethylamino- β -hydroxybutyrate): Facilitates the entry of fatty acids into mitochondria. It occurs in all organisms and it is most abundant in the muscles (0.1% of dry matter). Systemic carnitine deficiency involves progressive cardiomyopathy, skeletal myopathy, hypoglycemia, hyperammonemia and Sudden Infant Death Syndrome. The basic defect is in a gene encoding sodium-dependent carnitine transporter. Carnitine defects may be coded in human chromosomes 5q33.1, 3p21, 1p32, 11q13, 9q34. [►TAP](#)

Carnitine Palmitoyl Transferase Deficiency (CPT I, 11q13): CPT I regulates the carnitine transfer through mitochondrial membranes and its deficiency may be lethal, but it can be effectively treated by medium-chain triglycerides.

Carnosinemia: Carnosine is a neurotransmitter dipeptide of β -alanine and histidine. Enzymatically it may be split by carnosinase into two components, or by the action of a methyltransferase it may be converted into anserine. An autosomal recessive defect in carnosinase may lead to the excretion of carnosine, anserine and homocarnosine, and neurological disorders. [►neuromuscular diseases](#), [►anserine](#)

Caroli Disease: A recessive polycystic kidney disease (6p21.1-p12) due to fibrocystin defect. [►polycystic kidney disease](#)

C

Carotene, β : Widely considered as an anticarcinogen but recent studies indicate that it enhances the activity of several cytochrome (CYP) activating enzymes. Large-scale epidemiological studies indicate increase in cancer caused by a variety of carcinogens. (See Paolini M et al 1999 *Nature* 398:760; ►carotenoids, ►cytochromes, ►activation of mutagens).

Carotenoids: Accessory light absorbing pigments of yellow, red or purple color, including carotene, lutein and xanthophylls. (See Park H et al 2002 *Plant Cell* 14:321; Isaacson T et al 2002 *Plant Cell* 14:333; Grossman AR et al 2004 *Annu Rev Genet* 38:119; Kim J DellaPenna D 2006 *Proc Natl Acad Sci USA* 103:3474).

Carp (*Cyprinus carpio*): $2n = 98$, genome size bp/n = 1.7×10^9 .

Carpel: The floral leaf forming the (enclosure) site for the ovules (see Fig. C26). ►ovule, ►flower differentiation, ►gynoecium

Figure C26. Carpel

Carrier: A human heterozygote for a recessive gene that is not expressed in that individual but may be transmitted to the progeny. *Obligate carrier* is identified on the basis of family history; the natural parents of a homozygous recessive individual must be carriers unless a rare mutational event happened in the heterozygous embryo after fertilization or the natural father is not identical with the legal one.

$$R = \frac{P(Ma|A = D)}{P(Ma|A \neq D)} \times \frac{P(Mb|B = D)}{P(Mb|B \neq D)}$$

The posterior probability that chromosome A is the carrier of the mutation in question is $R/(R + 1)$ (see R at left); and Ma and Mb represent the marker information for chromosomes A and B, respectively. D stands for the mutation-bearing chromosome so $P(Ma|A = D)$ would indicate the probability that chromosome A would be carrying the mutation and $P(Mb|B = D)$ would be the same for chromosome B. Identification of carriers of human diseases using molecular, enzymological, cytological or other

techniques may be highly desirable for early treatment of various human diseases. Genetic counseling may take advantage of the information of the carrier status of the prospective parent(s). The knowledge of carrier frequencies may allow predictions about the occurrence of genetic diseases and may affect governmental health care as well as insurance policies. ►heterozygote, ►Bayes theorem, ►counseling genetic; microarray analysis: Watts JA et al 2002 *Am J Hum Genet* 71:791.

Carrier DNA: A nonspecific DNA that may be mixed with the specific DNA to facilitate transformation or other manipulations. ►transformation

Carrier Protein: Transports solutes through membranes while its conformation is altered. Some transport a single type of molecule (uniporter); others carry more in the same (symporter) or opposite directions (antiporter).

Carrot (*Daucus carota*): All cultivated forms are $2n = 2x = 18$.

Carrying Capacity: A term of ecological genetics. It means that in a particular environment only a certain number of species or individuals of a species can survive and their survival depends on their genetic adaptation. The carrying capacity of a vector is the size of the DNA that it can accommodate. ►ecogenetics, ►vectors

CART (cocaine- and amphetamine-regulated transcript): A leptin-dependent molecule that suppresses craving for food and antagonizes the feeding stimulatory neuropeptide Y. ►leptin, ►neuropeptide Y

Carter-Falconer Mapping Function: The Carter-Falconer mapping function is based on the assumption that there is substantial positive interference along the length of the chromosome: map distance = $0.25 \{0.5[\ln(1 + 2r) - \ln(1 - 2r)] + \tan^{-1}(2r)\}$ where r = the observed recombination fraction, \ln = natural logarithm, \tan = tangent. ►Haldane's mapping function, ►Kosambi's mapping function, ►mapping function; Carter TC, Falconer DS 1950 *J Genet* 50:307.

Cartilage: A fibrous connective tissue; it may also be converted into bone tissues during postembryonic development. It is rich in collagen and chondroitin sulfate. The Ror2 receptor-like tyrosine kinase deficiency leads to skeletal abnormalities and brachydactyly. ►collagen, ►chondrocyte, ►brachydactyly, ►arthritis, ►aggrecanase, ►shark cartilage; Mariani FV, Martin GR 2003 *Nature [Lond]* 423:319.

Cartilage-Hair Dysplasia: ►chondrodysplasia McKusick type

Cartilage-Hair Hypoplasia (CHH): Dwarfism, short fingernails, cartilage deficiency, and weak immune system due to a chromosome 9 defect. The condition is common among the Lancaster county Amish and some Finnish populations. ► [Amish](#)

Caruncle: A small outgrowth on animal and plant tissues.

Caryonide: A clonal derivative of a cell, which, after conjugation, retains the original macronucleus in ciliates and all macronuclei in the subclones are derived from a single macronucleus. ► [Paramecium](#)

Caryopsis: The “seed” (kernel) of some monocots containing the single embryo and endosperm and also tissues derived from the fruit (pericarp) (see Fig. C27).

Figure C27. Caryopsis

CAS: Chemical Abstract Service Registry that identifies chemicals by specific numbers.

It is a most comprehensive database of chemistry, including information related to life sciences: <http://www.cas.org/>.

CAS (Crcas): A ≈ 130 kDA human microtubule-associated protein involved in the control of chromosome segregation, cell adhesion, cell migration, growth factor stimulation, cytokine receptor engagement, bacterial infection, actin stress fiber formation and Src oncogene-induced transformation. ► [microtubule](#), ► [spindle fibers](#)

CAS (Cse 1p): A transport factor, a nuclear export receptor of α importin. ► [nuclear pore](#), ► [importin](#), ► [karyopherin](#)

Casamino Acids: Hydrochloric acid hydrolysate of casein, containing amino acids (except tryptophan that is destroyed by the process). Total nitrogen content 8 to 10%, NaCl 14 to 38%.

Cascade: (In genetics) is a sequence of events depending on specific consecutive steps such as feedback control, signal transduction and differentiation. Cascades direct temporal programs of successive gene expression during development. Feed-forward, feedback and checkpoints can be elementary motifs of a larger cascade of events of a network and noise may affect the output. Longer cascades require larger number of motifs (Hooshangi S et al 2005 Proc Natl Acad Sci USA 102:3581). ► [network](#), ► [genetic network](#), ► [feed-forward](#), ► [feedback](#), ► [checkpoint](#)

Cascade Hybridization: The procedure for enriching a certain fraction of the DNA transcribed at a particular developmental stage (see Fig. C28). Total cDNA is hybridized in a cascade of events with 20, 50 and 100 in excess amounts of mRNAs synthesized at stage 2. The hybrid is then adsorbed into a hydroxyapatite column. Unbound molecules are passed through. The unbound emanate is then hybridized

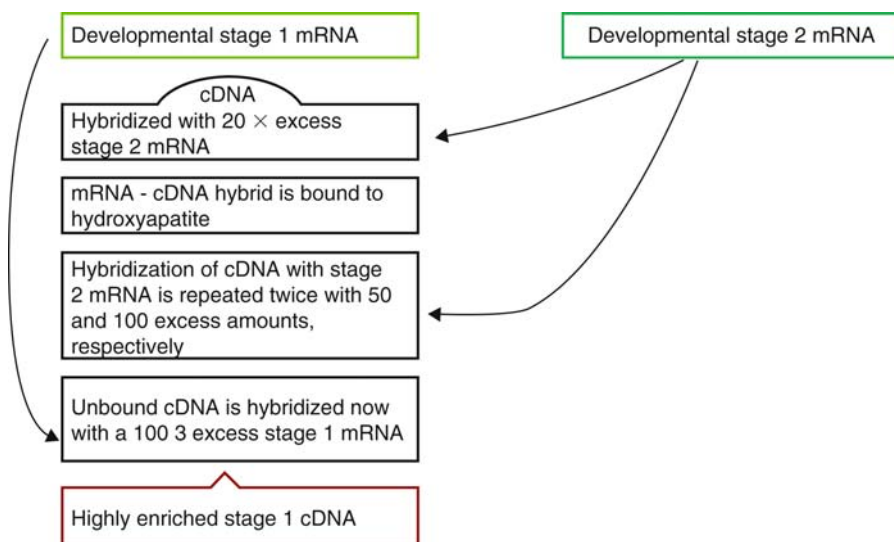

Figure C28. Cascade hybridization

with 100 excess of stage 1 mRNAs. Thus, the cDNA transcribed only in stage 1 is much enriched. (See diagram, ►mRNA, ►cDNA, ►hydroxyapatite, ►subtractive cloning; Timberlake WE 1980 Dev Biol 78:497).

C

Cascade Testing: Cascade testing is basically a genetic screen for carriers in a population beginning with the natural parents of a proband and then extended to relatives. Such a test has a much higher chance to locate carriers than a random one and it is more economical. ►proband, ►carrier, ►genetic screening; Krawczak M et al 2001 Am J Hum Genet 69:361.

CASE (computer automated structure evaluation): CASE relates the correlation between chemical structure and biological activity of chemicals. ►SAR, ►MULTICASE, ►biophore

Casse-Case Design: The deviation from the theoretical expectation that a certain disease phenotype, independent from environmental exposure, can be used to assess the environmental component of prevalence. Also, some health liabilities increase the sensitivity to another, e.g., the APOE E allele increase the chances and the degree of expression of Alzheimer disease and hypertension aggravates the disease (Kang JH et al 2005 Neurobiol Aging 26:475). Reduced efficiency alleles of melanocortin-1 receptor gene reduces skin pigmentation and increases the susceptibility to UV light-induced skin cancer (Rees JL 2004 Am J Hum Genet 75:739). ►prevalence, ►phenylketonuria, ►melanocortin, ►xeroderma pigmentosum, ►environmental effects, ►epidemiology

Case Control Design: Case control design is often used in human genetics when the genetic determination of a polygenic disease condition is compared to unaffected "controls." Such studies on gene frequencies are frequently loaded by errors because of differences in ethnicity. Inferences based on sibs provide better information. The prospective cohort studies employ the presence of risk markers for the potential expression of the disease. ►sib, ►genomic control, ►incidence; Wilson JF, Goldstein DB 2000 Am J Hum Genet 67:926; Manolio TA et al 2006 Nature Rev Genet.7:812.

Cash: ►apoptosis

Cask: A nuclear-binding protein indirectly facilitating nucleosome assembly. ►nucleosome; Wang GS et al 2004 Neuron 42:113.

Caspase: A class of 14 cysteine-dependent aspartate-directed heterotetramer proteases that regulate apoptosis and oogenesis. Caspases are activated by

different mechanisms (Shi Y 2004 Cell 117:855). When a virus infects an organism the natural killer cells (NK) secrete to the surface of the infected cell perforin that allows (among other proteins) the entrance of granzymes into the infected cells. Granzyme B then processes pro-caspases into active caspases and these mediate the suicidal process of apoptosis. The binding of the Fas ligand (FASL) to FAS receptors and the recruitment of pro-caspases can activate caspases and subsequently lead to apoptotic suicide. Caspase-8/Mach (2q33) initiates apoptotic death signals downstream of the death receptors located on the plasma membrane through effector caspases 6 (4q25), 3 (11q22) and 7 (10q25). Caspase-8 is required for the activation of NF- κ B, which is a factor of lymphocyte activation. Thus, caspase-8 deficiency involves defective apoptosis and immunodeficiency because of impairment of T, B and killer lymphocyte functions (Su H et al 2005 Science 3007:1465). Caspase-8 expression suppresses metastasis in neuroblastoma (Stupack DG et al 2006 Nature [Lond] 439:95). Six-nucleotide insertions and deletions in the promoter of CASP-8 increase cancer susceptibility (Sun T et al 2007 Nature Genet 39:605). Caspase 3 and 7 are essential for apoptotic function (Lakhani SA et al 2006 Science 311:847). Caspase activity is required also for nonapoptotic functions such as sperm development, neural stem cell differentiation, erythrocyte, keratinocyte and lens differentiation and lymphocyte proliferation. In *Drosophila*, IKK-related kinase regulates NF- κ B activation or interferon regulatory factor in mammals and determines inhibitor of apoptosis, IAP1 (Kuranaga E et al 2006 Cell 126:583).

Cellular/mitochondrial damage may also lead to the release of cytochrome c into the cytosol resulting in the activation of the pro-caspase-9 (1p34) and thereby eventually apoptosis. The effector caspases then target the CAD-Inhibitor-CAD (I^{CAD}) complex and release CAD (a DNase) from the cytoplasm into the nucleus. Mutation in caspase-10/Flice (2q33) may lead to the autoimmune lymphoproliferative syndrome, ALPS. Caspase-12 is activated by stress of the endoplasmic reticulum and may contribute to neurotoxicity by amyloid- β . Caspase-2 (12q21.33-q23.1) has homology to ICH1. Caspase-2 is a pro-inflammatory molecule and Bcl-2 and Bcl-X_L antiapoptotic molecules regulate it. The Bcl family proteins interact with the NLR family of proteins (such as NALP1), which involve caspase and NF- κ B activation in vertebrates, but are absent from *Caenorhabditis* and *Drosophila* (Bruey J-M et al 2007 Cell 129:45).

Activation of caspase may have a therapeutic effect by slowing down or preventing the accumulation of the huntingtin protein, and it is conceivable that the

production of A β in Alzheimer's disease is proportional to the cleavage activity of caspase(s). There is no agreement among research workers on whether the mitochondria would have the leading role in the initiation of apoptosis or if the mitochondrial events are only part of the apoptosis process already underway. Caspase-mediated cleavage of inhibitor proteins may lead to gain in function. Cysteine proteases may be required for infection of plants by potyviruses and their inhibitors may confer resistance to tobacco etch virus and potato virus Y. ►apoptosis, ►oogenesis, ►lymphocytes, ►NF- κ B, ►killer cells, ►granzyme, ►perforin, ►FAS, ►Apaf, ►CAD, ►ICAD, ►CARD, ►Smac, ►cytochromes, ►IAP, ►DIABLO, ►BIR, ►AKT, ►RGD, ►ALPS, ►NALP, ►Huntington's chorea, ►Alzheimer disease, ►Egl, ►Bcl/apopain, ►ICE, ►ICH, ►scaffold-mediated activation; Earnshaw WC et al 1999 Annu Rev Biochem 68:383; Goodsell DS 2000 Stem Cells 18:457; Goyal L 2001 Cell 104:805; Tinel A, Tschopp J 2004 Science 304:843, caspase regulation review: Riedl SJ, Shi Y 2004 Nature Rev Mol Cell Biol 5:897.

Casper (Flip): ►apoptosis, ►FLIP

Cassava (*Manihot esculenta*): Belongs to the Euphorbiaceae; originally an American perennial shrub and an important source of carbohydrate. The 98 species all have $2n = 36$ chromosomes.

Cassette: ►vector cassette

Cassette Mutagenesis: A synthetic DNA fragment is used to replace a short sequence of DNA and thus alters the genetic information at a site. ►mutation induction, ►localized mutagenesis, ►TAB mutagenesis, ►targeting genes; Cho SW et al 2001 Eur J Biochem 268:3205.

Cassettes Model of Sex Expression: The cassette model explains switches of the mating type in homothallic (*HO*) yeast by the transposition of either one or the other (*a* or α) silent, distant elements (cassettes) to the sex locus *MAT* where they can be expressed as shown in the diagram (see Fig. C29). ►mating type determination in yeast

Figure C29. Cassette model of sex expression

Caste: A specialized group within an insect society, e.g., workers among bees. The social and ethnic complexities of the castes of the Indian subcontinent are very difficult to define. Although intermarriage among the

castes was limited, some ethnic mixing diluted the cultural isolation. During the 1500–1200 BC period, several Aryan groups have invaded the subcontinent and some of the descendants of the invaders, the Brahmins, retained their elite, priestly status. The Brahmins were less bound by the strict rules of marriage than the rest of the castes, i.e., they could take wives from outside their caste. Their existence is mainly legal and legendary evidence of their origin and evolution. Recent DNA studies based on mitochondrial and Y chromosomal evidence indicate that the only egg-transmitted DNA displays the same variations as the average of the populations. The Y chromosome DNA is apparently more similar to the European human races. These data confirm the earlier anthropological views about their origin and also prove that women had chances for upward mobility while the male lineages were more strictly controlled. ►Eve foremother of mitochondrial DNA, ►Y chromosome; Majumder PP 2001 Genome Res 11:931; Bamshad M et al 2001 Genome Res 11:994.

Castor Bean (*Ricinus communis*): An oil crop and ornamental plant adapted to a wide range of climates (see Fig. C30). The viscosity of its oil is rather constant at various temperatures and it is thus a good lubricant for high-speed engines. Also, it is a very potent irritant and laxative and used for medical purposes. The plant also contains the lectin ricin that is one of the most toxic compounds known; 2–5 mg/kg is lethal for humans and in mice the intraperitoneal minimal lethal dose is 0.001 μ g ricin nitrogen/g body weight. All species are $2n = 20$.

Figure C30. Castor bean

Castration: The surgical removal of the gonads or the chemical prevention of testosterone production to prevent reproduction and reduce sex drive. A male deprived of testes is also called a eunuch. The surgical removal of the female gonads is spaying (oophorectomy). ►eunuch, ►ovariectomy, ►estrogen, ►androgen; Kolvenbag GJ et al 2001 Urology 58 (2 Suppl.): 16; Muss HB 2001 Semin Oncol 28:313.

CAT (chloramphenicol acetyltransferase): Conveys resistance to the antibiotic chloramphenicol.

Cat (*Felis catus*): The domesticated cat, $2n = 38$; the majority of wild cats have also $2n = 38$ or 36. The first cat-like carnivores appeared ~35 million years ago and modern species diverged ~11 million years ago (Johnson WE et al 2006 Science 311:73). Cats have been domesticated for about 10,000 years ago. Among the over 30 distinct breeds about 200 genetic diseases are known and many of them are homologous to the hereditary diseases of humans. See Gold L 1996 Cats are not Peas: a Calico History of Genetics Copernicus O'Brien SJ et al 2002 Annu Rev Genet 36:657; ►conservation, ►genetics

Cat Cry Syndrome: ►cri du chat

Cat Eye Syndrome: Autosomal dominant; it involves vertical pupil, nonperforated anus, heart, kidney malformations, etc. The patients display tissue mosaicism and generally there are one or more copies of a modified human chromosome 22q11.2 site (microduplications or microdeletions in a low copy-number repeat). ►coloboma, ►eye diseases, ►DiGeorge syndrome; Ensenuer RE et al 2003 Am J Hum Genet 73:1027.

Cat Scan: ►tomography

CAT Transporters: Transport through membranes the cationic amino acids (arginine, lysine, ornithine, histidine). ►transporters, ►ABC transporters, ►translocon; Vékony N et al 2001 Biochemistry 40:12387.

Catabolic: (An adjective) ►catabolism

Catabolism: Degradative metabolism of chemical substances in the cells, mediated by enzymes, most commonly for energy utilization.

Catabolite Activator Protein (CAP): ►CAP

Catabolite Repression: Carbohydrates (glucose) repress the synthesis of enzymes involved in carbohydrate metabolism or other metabolic steps by decreasing the level of cyclic AMP. In some instances, the glucose repression does not depend on cAMP because cAMP does not relieve its repression (e.g., pyrroline dehydrogenase, putrescine aminotransferase). Some bacteria fail to synthesize sufficient amounts of cAMP (*Bacillus megaterium*), and yet they display an intense glucose effect. Catabolite repression may be strongly modulated by the catabolite modulation protein factor (CMF). The catabolite repressor-cAMP system may also function as an activator of genes. Catabolite repression may switch to activation in case the gene carries overlapping promoters or when divergent dual promoters

exist. Some organisms (e.g., yeast) can discriminate among different nitrogen sources (and turn off the utilization of the less desirable ones) by a mechanism called nitrogen catabolite repression. ►glucose effect, ►feedback controls, ►Lac operon, ►cAMP, ►DNA bending, ►cytosine repressor [CytR], ►FNR, ►promoter; Gancedo JM 1998 Microbiol Mol Biol Rev 62:1092; Stülke J, Hillen W 2000 Annu Rev Microbiol 54:849.

Catalase (CAT): Enzymes that mediate the reaction $2\text{H}_2\text{O}_2$ (hydrogen peroxide) $\rightarrow 2\text{H}_2\text{O} + \text{O}_2$. CAT is encoded in human chromosome 11p13. In plants, the catalase enzymes are essential under conditions of photorespiration and for lipid metabolism. ►peroxide

Catalysis: Mediates chemical reactions without being used up in the process. Enzymes are biocatalysts. ►enzymes

Catalytic Antibody: Catalytic antibodies contain catalytic and selective binding sites in one molecule and perform enzymatic reactions as enzyme mimics. Their catalytic efficiency is generally suboptimal, however, the range of the specificity may be broader than that of the regular enzymes. ►abzyme; Hilvert D 2000 Annu Rev Biochem 69:751; Wentworth P Jr 2002 Science 296:2247.

Catalytic RNA: ►ribozymes

Catalytic Site: ►active site

Catalytic Triad: Three amino acids (Ser-His-Asp or Cys-His-Asp) frequently found in the catalytic domain of enzymes, although they are not necessarily juxtaposed. (See Chen SC, Bahar I 2004 Bioinformatics 20(1):177).

Cataplexy: A muscular defect evoked by emotional effects; it is usually associated with narcolepsy. ►narcolepsy

Cataracts: Diseases of the eyes causing opacity of the lens. Cataracts are under X-chromosomal (Xp), autosomal dominant (connexin, 1q21-q25; crystallin, 2q33-q35; developmental regulator *PITX3*, 10q25, 16q22.1, 17q24, 13q11-q12) and autosomal recessive (galactosemia [17q24], chondrodysplasia punctata, Zellweger syndrome [7q11, 12q11-q13]) control (see Fig. C31). The normal eye displays no opacity whereas the cataract appears in various shapes and

Figure C31. Cataracts

distribution of opacity on the lens. In a juvenile-onset hereditary cataract, a single amino acid substitution (Arg-14→Cys) in the γ -crystallin protein was responsible for progressive opacity. The dominant disorder MIP at 12q14 represents a membrane-bound aquaporin protein. An autosomal dominant cataract has been assigned to 15q21-q22. A recessive locus at 9q13-q22 is responsible for a progressive adult cataract. Recessive homozygosity for chromosome 7p21.3-p15.3 encoding a 521-amino acid protein (hyccin) involves demyelination of the white matter in the brain and the peripheral nervous system is responsible for bilateral cataracts (Zara F et al 2006 Nature Genet 38:1111). A chromosome 20q locus (CHMP4B) has a different subcellular distribution than wild type and an increased capacity to inhibit release of virus-like particles from the cell surface, consistent with deleterious gain-of-function effects. These data provide the first evidence that CHMP4B, which encodes a key component of the endosome sorting complex required for the transport-III (ESCRT-III) system of mammalian cells, plays a vital role in the maintenance of lens transparency (Shiels A et al 2007 Am J Hum Genet 81:596). ▶ Wilms' tumor, ▶ Lowe's disease, ▶ chondrodysplasia, ▶ eye diseases, ▶ microbody, ▶ ASMD, ▶ aquaporin, ▶ connexin; Héon E et al 2001 Amer J Hum Genet 68:772.

Catastroph, Mitotic: Disruption of nuclear division by chemical, physical, or other agents. ▶ error catastrophe

Catatonía, Periodic: A form of schizophrenia with psychomotor disturbances controlled by a major factor at 15q15. ▶ schizophrenia; Stöber G et al 2000 Am J Hum Genet 67:1201.

CATCH: Cardiac defect, abnormal face, thymic hypoplasia, cleft palate, hypocalcemia are symptoms associated with a deletion in human chromosome 22q11.2. ▶ DiGeorge syndrome, ▶ velocardiofacial syndrome, ▶ cleft palate, ▶ hypocalcemia

Catecholamines: Catecholamines are neurotransmitters. ▶ neurotransmitters

Categorical Study: A study conducted by categories, such as all deafness.

Catenanes: Interlocked DNA circles (see Fig. C32).

Figure C32. Catenanes

Catenated: Attached like two links of a chain.

Catenins: Intracellular attachment proteins, connecting the inward-reaching carboxyl end of cadherins to actin filaments within the cell; β -catenin is involved in axial polarity of development, in cell proliferation pathways and the development of adenomatous polyposis of the colon, breast cancer and other tumors; its degradation predisposes it to Alzheimer's disease. β -Catenin activates the transcription of cyclin D1 and the promoters, which display TCF/LEF binding sites. p21^{ras} also activates cyclin D1 at promoters with Ets and CREB sites. In adenomatous polyposis cells, the degradation of β -catenin is reduced. A dominant negative TCF is inhibitory to the expression of cyclin D1. Overproduction of β -catenin increases hair growth in mice. ▶ cadherin, ▶ actin polyposis adenomatous intestinal, ▶ LEF; ▶ Tcf, ▶ p21^{ras}, ▶ CREB, ▶ cyclins, ▶ ETS, ▶ Gardner syndrome, ▶ conductin, ▶ presenilin, ▶ Armadillo, ▶ cyclin D, ▶ wingless; Huber AH, Weis WI 2001 Cell 105:391; cell lineage determination: Olson LE et al 2006 Cell 125:593.

Cat-Eye Syndrome: The pupil appears vertical because of a deformity of the iris; heart anomaly, imperforate anus, and various degrees of mental retardation occur. The anomaly is apparently caused by the presence of an extra copy of a very short metacentric chromosome 22q (partial trisomy or tetrasomy). The symptoms vary depending on the structure of this extra chromosome. ▶ mental retardation, ▶ trisomy, ▶ tetrasomy, ▶ duplication

Catfish (*Ictalurus punctatus*): One of the economically most important freshwater fish species. (See Waldbieser GC et al 2001 Genetics 158:727).

CATH: A hierarchical classification of protein domain structures. ▶ protein structure, ▶ protein domains, ▶ SCOP; http://www.biochem.ucl.ac.uk/bsm/cath_new/index.html; <http://www.cathdb.info>.

Cathecolamine: ▶ neurotransmitter

Cathepsins (CTS): Intracellular cysteine proteases generally relegated to the lysosomes. In humans, CTSK and CTSO are encoded at 1q21; in a mouse, four cathepsins are in as many different chromosomes. In mice, deficiency in cathepsin C may not affect their health, but their cytotoxic lymphocytes (CTL) are inactive because granzymes A and B are not processed. Cathepsins may be involved in processing of keratins. Secreted cathepsin L may generate endostatin from collagen XVIII. Mutation in cathepsin K may underlay osteopetrosis or osteosclerosis. Cathepsins are upregulated in different tumors and may be considered as targets for therapy (Joyce JA et al 2004 Cancer Cell 5:443). CTS is substantially expressed in some breast cancers and suspected to favor metastasis. It can cleave a 16 kDa

part off of prolactin, which seems to be responsible for postpartum cardiomyopathy (Hilfiker-Kleiner D et al 2007 Cell 128:589). ▶antimicrobial peptides, ▶lysosomes, ▶pseudosyndactylism, ▶Toulouse-Lautrec, ▶periodontitis, ▶keratin, ▶endostatin, ▶collagen, ▶granzyme, ▶Ebola Virus, ▶prolactin, ▶cardiomyopathies; McGrawth ME 1999 Annu Rev Biophys Biomol Struct 28:181.

C

Cathode Rays: Electromagnetic radiation emitted by the cathode toward an anode in a vacuum tube. After exposure of a metal target to this radiation, X-rays are generated (see Fig. C33). ▶electromagnetic radiation, ▶X-rays

Figure C33. Cathode tube

Cation: A positively charged atom or radical. ▶ion, ▶electrolyte

Cation Exchange: Replacement of one positive ion by another on a negatively charged surface.

Cationic Amino Acids: ▶CAT transporters

Cationic Lipid: ▶liposome, ▶cytofectin GS2888, ▶lipid cationic, ▶lipofection

Cationic Liposome: ▶liposome

Cation- π Interaction: Plays a role in determining protein structure. It is more likely that a cationic side chain of lysine or arginine, when close to an aromatic amino acid (phenylalanine, tyrosine or tryptophan), would result in an interaction than with a neutral amine. Arg and Trp are most likely to be involved. ▶protein structure

Catkin: Male inflorescence of some plants, e.g., oak (see Fig. C34).

Figure C34. Catkin

CATR1: A genetic element encoding 79 amino acids and a long untranslated region, expressed in malignant tumors. This element does not have homology with other oncogenes or tumor suppressor genes. It has been localized to human chromosome 7q31-q32. ▶cancer, ▶tumor oncogenes, ▶tumor suppressor, ▶AIG; Li D et al 1995 Proc Natl Acad Sci USA 92:6409.

CATS (comparative anchor tagged sequences): ▶comparative maps, ▶anchoring

Cattalo: The hybrid of buffalo ($2n = 60$) and cattle ($2n = 60$) with reduced male fertility.

Cattanach Translocation: Involves the X-chromosome and autosome 7 of mouse. It includes several X-chromosomal fur color genes that may be subject to lyonization. ▶lyonization, ▶translocation; Cattanach BM 1975 Annu Rev Genet 9:1.

Cattell's Paradox: An apparent negative correlation between family size and average IQ of children that would lead to a gradual decline of IQ in the progenies. The observation was due to improper ascertainment, ignoring the childless descendants. ▶IQ, ▶ascertainment test; Higgins JV et al 1962 Eugenics Quart 9:84.

Cattle (*Bos taurus*): $2n = 60$. Genetic evidence indicates that the European breeds originated from Near East herds, rather than the now extinct European wild ox (*Bos primigenius*). The Indian cattle, the zebu (*Bos taurus indicus*) (see Fig. C35), were domesticated independently in the Indus Valley, the present day Pakistan (Beja-Pereira A et al 2006 Proc Natl Acad Sci USA 103:8113). The domesticated African cattle seem different from other domesticated breeds on

Figure C35. Zebu

C

Figure C36. (a) Old Texas longhorn bull; (b) Neolithic cave bull; (c) Modern Jersey dairy cow; (d) Modern shorthorn beef cattle

the basis of mitochondrial DNA (see Fig. C36). (Troy CS et al 2001 Nature [Lond] 410:1088; Hanotte O et al 2002 Science 296:336; microsatellite map: Ihara N et al 2004 Genome Res 14:1987; <http://www.tigr.org/tdb/tgi>; bovine genome database: <http://locus.jouy.inra.fr/cgi-bin/lgbc/mapping/common/intro2.pl?Base=goat>).

Caucasoid (Caucasian): A commonly used misnomer for ethnic groups of European, North African, Near-East and Indian descent. The term has been coined erroneously when anthropologists believed their origin was in the Caucasus area. It is sometimes used as collective term for white-skinned people. In fact, the group includes many brown-skinned populations too.

Caudal: Tail oriented.

Caudates Structure: A tail-like appendage.

Cauliscent: Leaves that are born separated by visible internodes on a stem (see Fig. C37). ▶ [rosette](#)

Figure C37. Caulescent

Cauliflower Mosaic Virus: (CaMV) is a (~8 kbp) double-stranded DNA virus with limited potential use for genetic engineering. It infects cruciferous

plants like turnip, broccoli, *Arabidopsis*, etc. The DNA of the virus shows three discontinuities (“gaps”), 1 in one of the strands and 2 in the other. The promoter of the 35S transcript of the virus drives high-level constitutive expression of genes spliced to it and it is widely used; the promoter of the 19S peptide gene has not been proven nearly as good for biotechnology. ▶ [agroinfection](#), ▶ [retroid virus](#), ▶ [activation tagging](#); Balázs E et al 1985 Gene 40:343; Hirth L 1986 Microbiol Sci 3:260; Hohn T, Fütterer J 1992 Curr Opin Genet Dev 2:90, al-Kaff N, Covey SN 1994 J Gen Virol 75 [Pt 11]:3137.

Caulobacter: A dimorphic Gram-negative group of prokaryotes. The cells may have either a long flagellum or a thicker stalk of about 2/3 of the 2 μm length of the cell. The formation of these appendages has been extensively studied and the hierarchy of genes regulates them. *Caulobacter crescentus* genome of 4,016,942 bp encodes ~3,767 genes. ▶ [Gram-negative/Gram-positive](#); Niernan WC et al 2001 Proc Natl Acad Sci USA 98:4136.

Caulonema: In the gametophyte of some mosses a special type of cells are formed subapically and separated by oblique walls.

Cave Art: ▶ [Lascaux cave](#)

C

Caveolae (plasmalemmal vesicles): Caveolae are ~70 nm diameter flask- or Ω -shape, detergent-insoluble glycolipid vehicles/rafts moved by actin motors on the surface of T cells and other endothelial cells. The caveolae are loaded with kinases, protectin/CD59, decay accelerating factor (DAF), alkaline phosphatase, Thy-1 glycoprotein, and signaling adapter molecules. After DC28 engages the T cell receptor, the rafts are attracted to the area where the antibody contacts the TCR. The caveolae concentrate lipids, proteins, prenylated proteins, glycosylphosphatidyl inositols, various membrane receptors, actin, myosin, ezerin, NSF, signal transducing proteins, etc. Caveolae have a role in the transmission of the Pr^{Sc} prions, transfer into the cells pathogens (SV40, *Campylobacter*) and protein toxins of pathogens (cholera, *Plasmodium*, *Trypanosoma*, *Leishmania* toxins). Caveolae may play a role in cardiovascular diseases because they transport cholesterol, lipoproteins and affect blood clotting. ▶raft, ▶DC28, ▶CD48, ▶TCR, ▶DAF, ▶protectin, ▶flotillin, ▶Thy-1, ▶endocytosis, ▶antigen-presenting cell, ▶signal transduction, ▶potocytosis, and other terms at their alphabetical locations; Shin J-S, Abraham SN 2001 Science 293:1447; Galbiati F et al 2001 Cell 106:403.

Caveolin (CAV): CAV-3 (300–350 kDa), encoded at human chromosome 3p25 as homo-oligomers consisting of 12–14 monomers and are associated with the sarcolemma and co-localized with dystrophin. The same RNA encodes CAV-1 (21–24 kDa) and CAV-2 but processed differently. They are integral membrane proteins and bind G proteins. Caveolin-1 is a negative regulator of caveolae-mediated endocytosis to the endoplasmic reticulum. CAV-1 is essential for regeneration of the liver in mice by coordinating lipid metabolism. In *cav-1*^{-/-} animal glucose also facilitated survival (Fernández MA et al 2006 Science 313:1628). ▶sarcolemma, ▶dystrophin, ▶muscular dystrophy, ▶prostate cancer; Engelman JA et al 1998 Am J Hum Genet 63:1578; Anderson RGW 1998 Annu Rev Biochem 67:199; Pol A et al 2001 J Cell Biol 152:1057; Le PU et al 2002 J Biol Chem 277:3371.

Cavitation: After the formation of the 32-cell stage of the mammalian embryo a fluid secretion occurs during the blastocyte stage, which initially accumulates between the cells, and then it is collected in the blastocoele. ▶blastocyte, ▶blastocoele

CBAVD: ▶congenital bilateral aplasia of the vas deferens

CBC: ▶cap-binding protein complex

CBER: Center for Biological Evaluation and Research: A branch of the United States Food and Drug Administration involved in blood, vaccines, cellular/

gene therapy, tissue and devices relevant to human health. (See <http://www.fda.gov/cber/>).

CBF/NF-Y: A trimeric CCAAT binding (factor) protein, which, with other proteins, facilitates transcription. ▶CAAT; Maity SN, de Crombrughe B 1998 Trends Biochem Sci 23:174.

C57BL: Strains (B6 and B10) of black inbred mouse commonly used for genetic studies (mutation).

CBL2 (oncogene): Three cellular homologs of this viral oncogene are expressed in mammalian hematopoietic (blood cell forming) systems. In humans it was located to chromosome 11q23.3. Its translocations to chromosome 4 are associated with acute leukemia and B cell lymphoma. The oncogene is present in the ecotropic Cas-Br-M virus and the form present in lymphomas is a recombinant between the virus and the cellular oncogene. The 100 kDa transforming fusion protein has sequence homology to the yeast transcription factor GCN4 and to *sli-1* regulator of vulval development in *Caenorhabditis*. Apparently, this family of genes modifies receptor tyrosine-kinase mediated signal transduction. Cbl-b controls the dependence of T cell activation by CD28. ▶oncogenes, ▶signal transduction, ▶Jacobsen syndrome, ▶Src, ▶Syk, ▶CD28, ▶SLAP; Thien CBF, Langdon WY 2001 Nature Rev Mol Cell Biol 2:294.

CBP (CREB binding protein, p300): CBP is associated with CREB and mediates the induction of some promoters by cAMP (see Fig. C38). It interacts with p300 (or may be the same), the nuclear hormone-receptors and the basic transcription machinery. In addition, it interacts with a range of transcriptional activators and coprecipitates with RNA polymerase holoenzyme. CBP has a signal-regulated transcriptional activation domain, regulated by Ca²⁺ and calmodulin-dependent protein kinase and cAMP. CBP with histone acetyltransferase activity may function also as a coactivator of p53. The loss of CBP may be the basis of the Rubinstein-Taybi syndrome. ▶cAMP, ▶CREB, ▶p300, ▶E1A, ▶APC, ▶transcriptional activators, ▶Rubinstein syndrome, ▶p53, ▶cap, ▶histone acetyltransferase, ▶transcription factors, ▶calmodulin; Mayr BM et al 2001 Proc Natl Acad Sci USA 98:10936; Tunell AS et al 2005 Nature [Lond] 438:690.

Figure C38. cAMP regulation of transcription. (Modified after Montminy, M. 1997 Annu. Rev. Biochem. 66:897)

CBP2: A cellular-binding protein required for splicing class I mitochondrial introns. The catalytic RNA domains must be in a folded form before CBP2 binds to them. Subsequently, other proteins are attached to the 5' domain. In this ribozyme, the catalytic component remains the RNA but the protein associated with it increases the splicing rate by three orders of magnitude. ▶intron, ▶ribozyme, ▶spliceosome, ▶mtDNA; Shaw LC, Lewin AS 1997 Nucleic Acids Res 25:1597.

CBP-II: Similar to eIF-4F translation factor. ▶eIF-4F

CbpA: A protein of *E. coli* that is similar in function and structure to the DnaJ co-chaperone, but its transcription is initiated with stationary phase σ^{38} subunit of the RNA polymerase. ▶DnaJ, ▶Hsp70, ▶co-chaperone; Ueguchi C et al 1995 J Bacteriol 177:3894.

CBS (conserved sequence elements): Three short sequences in the mtDNA where the transition from DNA to RNA synthesis takes place. ▶DNA replication mitochondria, ▶mtDNA

CBS (chromosome breakage sequence): A 15 bp nucleotide sequence at 50 to 200 sites in the micronuclear DNA of ciliates near the breakage sites where the genome rearrangement occurs in the macronuclear chromosomes. ▶Tetrahymena; Fan Q, Yao MC 2000 Nucleic Acids Res 28:895.

CC57: A very popular black inbred mouse line. Has low spontaneous mammary tumors but highly prone to lung tumors. A large number of variants exist.

CC CKR5: A chemokine receptor. ▶chemokines, ▶RANTES, ▶CXCR, ▶CCR; Combadiere C et al 1996 J Leukoc Biol 60:147.

CCAAT: ▶CAAT box

CCCH Zinc Finger Proteins: mRNA inhibitors and antiviral agents. They contain CCCH amino acids (3 cysteine, 1 histidine) in the tandem zinc-finger domain. ▶DNA binding protein domains; Lai WS et al 2002 J Biol Chem 277:9606.

CCDS: The Consensus CDS (CCDS) project is a collaborative effort to identify a core set of human and mouse protein coding regions that are consistently annotated and of high quality. The long-term goal is to support convergence toward a standard set of gene annotations. ▶consensus; www.ncbi.nlm.nih.gov/CCDS.

CCE (cell cycle element): CCE has 11 bp that bind the histone nuclear factor (HiNF-M), required for the activation of Histone 4. ▶HiNF, ▶IFN, ▶IRF-2, ▶immune surveillance

CCG-1: CCG-1 is the hamster gene responsible for G1 phase cell cycle arrest.

CCL5: ▶RANTES

CCL39: A hamster lung fibroblast cell line.

CCR: Chemokine receptors; same as CKR. CCR2 is the receptor for MCP-1 and related chemokines MCP-3, MCP-4, MCP-5. CCR7⁺ cells express lymphnode-homing receptors without having immediate effector function. CCR7⁺ possesses effector function and they differentiate from CCR7⁺ cells upon activation by cytokines and antigens. ▶chemokine, ▶CKR5, ▶CXCR, ▶MCP-1, ▶acquired immunodeficiency syndrome, ▶effector, ▶metastasis; Luther SA, Cyster JG 2001 Nature Immunol 2:102.

CCR4-NOT: A deadenylation complex.

CCSB-HI: Center for Cancer Systems Biology Human Interactome. (Rual J-F et al 2005 Nature [Lond] 437:1173).

CCT: Cytosolic chaperonins. ▶chaperonins, ▶Bin3p, ▶Bin2p, ▶TRiC, ▶TCP20

CCW: Counterclockwise (see Fig. C39).

Figure C39. CCW

CD1: Antigen-presenting molecules—distantly related or unrelated to MHC proteins—for the T lymphocytes. CD1 can deliver to T cells endosomal lipoglycan antigens and other non-peptide ligands to the T cells, which are then stimulated to produce γ interferon and interleukin-4. CD1 is encoded in human chromosome 1q22-q23. ▶T cell, ▶killer cell, ▶cytokines, ▶interferon, ▶HLA, ▶antigen presenting cell, ▶major histocompatibility antigen, ▶lipid antigen, ▶saposin, ▶lipid antigen; Park S-H, Bendelac A 2000 Nature [Lond] 407:788; Zhou D et al 2004 Science 303:523, Mattner J et al. 2005 Nature [Lond] 434:525.

CD2: A T cell surface glycoprotein, mediating cell adhesion (to antigen-presenting cells) and the transduction of signals; it is encoded in human chromosome 1q22-q23. Haploinsufficiency for CD2-associated protein increases the susceptibility to kidney glomerular lesions (Kim JM et al 2003 Science 300:1298). Anti-CD2 protein is used for in vivo lymphocyte depletion to prevent immune

intolerance to the foreign antigen in therapeutic application of stem cells. ▶CD48, ▶haploinsufficient, ▶kidney diseases

C

CD3: Immunoglobulins of γ (25 K), δ (20 K), ϵ (20 K) and ζ (16 K) molecular (weight) chains expressed on all T cells; assist in transducing signals when the major histocompatibility-antigen complex binds to the surface. CD3 δ -negative lymphocytes fail to induce the ERK kinase and are unable to undergo positive selection. They are encoded in human chromosome 11q23. ▶immunoglobulin, ▶HLA, ▶signal transduction, ▶T cell receptor, ▶tumor vaccination, ▶ERK, ▶LAT

CD4: Cell surface protein (55 kDa) with domain binding major histocompatibility (MHC II) molecules on helper T cells. CD4⁺ T cells induce clonal proliferation of B cells along two paths. CD4⁺ B cells prime CD8⁺ T cells for clonal proliferation when they repeatedly encounter foreign antigens. Foreign antigens switch on through the B cell antigen receptors. When CD8⁺ T cells are not primed this way, they undergo apoptosis through the TRAIL ligand (Janssen EM et al 2005 Nature [Lond] 434:88). The CD40L (CD40 ligand) and interleukin-4 (IL-4) promote the proliferation of B cells. CD95 (Fas) and Fas ligand (FasL) limit the access of mitogenic signals and mediate apoptosis in response to auto-antigens. T cells are co-stimulated by CD80 (B7.1) or CD86 (B7.2) by binding to CD28 on the antigen-presenting cells (APC). For normal function both CD40 and Fas functions must be maintained. CD4 is encoded in human chromosome 11q13. ▶HLA, ▶MHC, ▶T cells, ▶B cells, ▶CD8, ▶CD40, ▶LCK oncogen, ▶autoantigen, ▶apoptosis, ▶TRAIL, ▶interleukins, ▶FAS, ▶APC, ▶CD80, ▶CD86, ▶CD28; Groux 2001 Microbes Infect 3:883.

CD5: A transmembrane protein on the surface of T cells and some B cells. It may be a negative regulator of the T cell receptor (TCR) mediated signal transduction. Encoded at human chromosome 11q13. ▶T cell receptor; Weston KM et al 2001 J Mol Recognit 14:245.

CD8: Homo- or heterodimer proteins (M_r 70 K) on cytotoxic T cells (CTL), binding class I major histocompatibility molecules. CD8 lymphocytes recognize the endogenously generated antigens, associated with MHC class I molecules, and such as those formed in cancer cells. CD8A and CD8B are encoded in human chromosome 2p12. CD8 is an active player in the T cell recognition complex. Regular activated T lymphocytes are associated with heterodimeric CD8 $\alpha\beta$ ligands, whereas the memory T cells differentiate from the homodimeric CD8 $\alpha\alpha$ (Madakamutil LT et al 2004 Science 304:590).

▶T cell, ▶HLA, ▶MHC, ▶CD4, ▶LCK oncogen, ▶memory immunological; Fujii S et al 2001 Blood 98:2143.

CD9: A transmembrane protein of the tetraspanin family. It is a "molecular facilitator." The eight exons of the murine CD9 extends to 20 kb. Homozygous knockouts are physically normal in both males and females, however, only 50–60% the females produced offspring. Some reduction in fertility was observed also in the homozygous males. The pup mortality was also higher. CD9 associated integrin $\alpha 6\beta 1$ is apparently required for egg-sperm fusion. ▶tetraspanin, ▶CD81, ▶CD 82, ▶integrin, ▶fertilin, ▶fertilization, ▶knock-out; Charrin S et al 2001 J Biol Chem 276:14329.

CD11a/18: Binds CD54 (ICAM) and mediates cell adhesion. CD11 is α integrin (human chromosome 16p12-p11); CD18 is β integrin (human chromosome 21q22.3). CD11b/CD18 are the CR3 complement receptors binding the C3b complement component. Salmonella infection is spread from the gastrointestinal tract to the bloodstream by CD18-expressing phagocytes. ▶integrin, ▶ICAM, ▶complement

CD14: Glycosylphosphatidylinositol-anchored membrane protein sensing lipopolysaccharides of invading microbes as part of the defense mechanism. It enhances B lymphocyte and monocyte differentiation and it is encoded at the human chromosome 5q23-q31 region. ▶innate immunity, ▶Toll; Glück T et al 2001 Eur J Med Res 6:351.

CD15 (α -fucosyltransferase, 11q21): Important for the function of leukocyte adhesion molecule, LAD2. ▶leukocyte adhesion; Nakayama F et al 2001 J Biol Chem 276:16100.

CD16 (Fc γ RIII, immunoglobulin G [IgG] Fc receptor III): A neutrophil-specific antigen encoded at 1q23. It may be involved in cytokine signaling to lymphocytes. ▶antibody; Paolini R et al 2001 Proc Natl Acad USA 98:9611.

CD18: ▶CD11a/CD18

CD19 (16p11.2): Important for the differentiation of B cells; it is a tyrosine kinase receptor. On mature B cells it is associated with CD81 and CD21. CD19 immunotherapy can be used during pre-B lymphocyte malignancies as well as in autoimmune diseases and humoral transplant rejection (Yazawa N et al 2005 Proc Natl Acad Sci USA 102:15178). ▶leukemia, ▶BCP, ▶B cell, ▶genistein; Uckun FM et al 1993 J Biol Chem 268:21172; Otero DC et al 2001 J Biol Chem 276:1474.

CD21: C3dg/C3d complement receptor 2 (CR2), 150 kDa. CD21 provides signals for B lymphocyte survival in the germinal center. ▶complement, ▶TAPA-1, ▶germinal

center, ▶TCL; Cherekuri A et al 2001 J Immunol 167:163.

CD22: Associated with immunoglobulin of B cell membranes. Tyrosine phosphorylated CD22 activates SHP protein tyrosine phosphatase and this down-regulates signaling through the immunoglobulin (Igμ). If CD22 is prevented from binding to μIg, the B cell may become 100-fold more receptive. CD22 is encoded at human chromosome 19q13.1. ▶lymphocytes, ▶B cell, ▶signal transduction; van Rosenberg SM et al 2001 J Biol Chem 276:12967.

CD23: A low-affinity receptor of immunoglobulin E (IgE) playing a role in allergy. ▶allergy; Kilmon MA et al 2001 J Immunol 167:3139.

CD25: The interleukin-2 receptor α chain encoded at human chromosome 10p15-p14. ▶interleukins; Suttmuller RP et al 2001 J Exp Med 194:823.

CD26 (dipeptidyl-peptidase IV, DPP IV): A pluripotent exopeptidase, expressed on the membrane of memory T cells, endothelial and epithelial cells. It interferes with immune reactions. It processes chemokines. ▶chemokines, ▶CXCR; Collebaut C et al 1993 Science 262:2045; Herrera C et al 2001 J Biol Chem 276:19532.

CD27: A TNF receptor glycoprotein encoded at 12p13. It regulates immune reactions; the CD27-ligand, CD70 is encoded at 19p13. ▶TNF, ▶TRAF; Jacquot S et al 2001 Int Immunol 13:871.

CD28: A homodimeric immunoglobulin (M_r 80 K), encoded in human chromosome 2q33-q34, present on the surface of helper T cells. The CD28/B7 and LFA-1 provide co-stimulation to T cell activation. CD28 is also a specific activator of JNK or the NF-κB in the presence of the T cell receptor (TCR). Co-stimulation initiates the active transport of protein and lipid domains to the area of the cell-to-cell contact, depending on myosin. ▶T cell, ▶B cell, ▶TCR, ▶CTLA, ▶ICOS, ▶CD80, ▶CD86, ▶anergy, ▶JNK, ▶NF-κB, ▶caveolae, ▶motor proteins, ▶Cbl; Salomon B, Bluestone JA 2001 Annu Rev Immunol 19:225.

CD30: A member of the tumor necrosis factor/nerve growth factor receptor family, including also TNF-R1, TNF-R2, CD40, CD27, Fas, etc. Their extracellular domain has cysteine-rich repeats. It interacts with TRAFs and indirectly with NF-κB. Deficiency for CD30 disarms CD8 positive T cells very aggressively and destroys pancreatic islets and contributes to the autoimmune reaction leading to diabetes in cooperation with other genes. CD30 is encoded at human chromosome 1p36. (See items

separately, ▶allergy; Hombach A et al 2001 Gene Ther 8:891).

CD31: Inhibitory receptor of myeloid, platelet endothelial and some T cells, encoded at 17q23. (See Balduini CL et al 2001 Br J Haematol 114:951).

CD33 (human chromosome 19q13.3): Inhibitory receptor of myeloid cells with sialic acid ligand. (See Mingari MC et al 2001 Immunol Rev 181:260).

CD34: A sialomucin-like adhesion protein expressed on 1–3% of the (CD34⁺) bone marrow cells and is associated with hematopoietic function; it is encoded in human chromosome 1q32. ▶hematopoiesis, ▶selectin, ▶SDF; Pratt G et al 2001 Br J Haematol 114:937.

CD35: Receptor CR1 (190 kDa) of the C3b complement component encoded at human chromosome 1q32. ▶complement; Klein MA et al 2001 Nature Med 7:488.

CD36 (Fat): The CD36 gene is in rat chromosome 4 and is responsible for the quantitative effects of diabetes type2, obesity, hyperlipidemia, essential hypertension and platelet formation. The human gene was mapped to 7q11.2. The gene encodes fatty acid translocase. CD36 deficiency (common in some African and Asian human populations) may increase susceptibility to malaria. CD36 and CD51 regulate dendritic cells and thereby the immune response. CD36 is also a sensor of microbial diacylglycerides and is a factor in susceptibility (Hoebe K et al 2005 Nature [Lond] 433:523). ▶diabetes, ▶hypertension, ▶hyperlipidemia, ▶malaria, ▶immune response, ▶diacylglycerol; Urban BC et al 2001 Proc Natl Acad Sci USA 98:8750.

CD38 (Okt10/p45): A 45 kDa antigen, encoded in human chromosome 4p15, of acute lymphoblastic leukemia cells with an activity similar to adenylyl-ribosyl cyclase. It is a multifunctional protein regulating cell adhesion, differentiation and proliferation, and it is a marker of the progression of HIV-1 infection. In CD38-deficient mice, oxytocin level of the plasma decreased and the social behavior was affected. Replacement of oxytocin rescued social memory and maternal care in the animals (Jin D et al 2007 Nature [Lond] 446:41). ▶leukemia, ▶cyclic ADP-ribose; Cakir-Kiefer C et al 2001 Biochem J 358 [pt2]:399, crystal structure: Liu Q et al 2005 Structure 13:1331.

CD40 (TNFR/SF5): A 48–50 kDa transmembrane glycoprotein (encoded at 20q12-q13.2) expressed on the surface of B cells; their interaction with CD40 ligands is a requisite for the activation of B cells by helper T cells. This system appears critical for the

C

development of humoral immunity. CD40 signaling may prevent Fas-induced apoptosis of B cells by cross-linking the immunoglobulin M complex. It induces B cell differentiation and Ig isotype switching and the expression of CD80. CD40 cytoplasmic tail interacts with CRAF1, a tumor necrosis receptor associated protein. CD40 is expressed also in dendritic cells, activated macrophages, epithelial cells, and several tumors. In the absence of CD40, immunodeficiency arises and initiation of germinal centers suffers. CD40 is upregulated by IFN, IL-1, TNF and possibly by IL-6. CD40 signaling to lymphocytes is mediated by NF- κ B through upregulation of the antiapoptotic proteins Bcl-x and Bfl-1. ▶immunodeficiency, ▶B lymphocyte, ▶T cells, ▶CD40 ligand, ▶germinal center, ▶apoptosis, ▶Fas, ▶Ig α , ▶CRAF, ▶CD80, ▶B7, ▶immunoglobulins, ▶CRAF, ▶dendritic cell, ▶macrophage, ▶hyper-IgM syndrome, ▶adjuvant immunological, ▶CD154, ▶IFN, ▶IL-1, ▶IL-6, ▶TNF, ▶germinal center, ▶Alzheimer's disease; Tone M et al 2001 Proc Natl Acad Sci USA 98:1751.

CD40 Ligand (gp39/CD40L/TBAM; Xq26-q27.2): A membrane-bound signaling molecule associated with CD40 transmembrane protein found on the lymphoid follicles of CD4⁺ T lymphocytes. It may regulate adhesion and movement. Its defect is responsible for X-linked hyper-IgM immunodeficiency. ▶CD40, ▶T cell, ▶immunodeficiency, ▶hyper-IgM syndrome; Vidalain PO et al 2001 J Immunol 167:3765.

CD43: Cell-surface sialoglycoprotein of blood cells and encoded in human chromosome 16p11.2; it is deficient in the Wiskott-Aldrich immunodeficiency. ▶Wiskott-Aldrich syndrome; Bagriacik EU et al 2001 Immunol Cell Biol 79:303.

CD44: A family of cell surface receptors involved in adhesion and movement. The cytokine osteopontin (Eta-1) is one of its ligands, activating chemotaxis but not cell aggregation. Hyaluronate (a carbohydrate ligand) on the other hand affects growth. Thus, metastasis of cancer cells may be controlled by the state of CD44, encoded in human chromosome 11pter-p13. Sulfated CD44 stimulated by TNF- α results in binding of B leukocytes to inflammatory sites. Cells within the CD44⁺ population of human head and neck squamous cell carcinoma possess the unique properties of cancer stem cells in functional assays for cancer stem cell self-renewal and differentiation, and form unique histological microdomains that may aid in cancer diagnosis (Prince ME et al 2007 Proc Natl Acad Sci USA 104:973). ▶osteopontin, ▶TNF, ▶lymphocytes, ▶diabetes mellitus; Ponta H et al 1998 Int J Biochem Cell Biol 30:299;

Teder P et al 2002 Science 296:155; Ponta H et al 2003 Nature Rev Mol Cell Biol 4:33.

CD45 (leukocyte common antigen): A protein tyrosine phosphatase (JAK phosphatase), a transmembrane glycoprotein, activated by antigens on the surface of red blood cells and regulates T and B lymphocytes. Antibodies that react with this leukocyte antigen may prevent rejection of allografts. It is encoded in human chromosome 1q31. In some families with multiple sclerosis, CD45 is altered. ▶lymphocytes, ▶allograft, ▶antibody, ▶multiple sclerosis, ▶lupus erythematosus, ▶lymphoid protein tyrosine phosphatase receptor-type; Virts EL, Raschke WC 2001 J Biol Chem 276:19913.

CD46: A complement-regulatory protein encoded at human chromosome 1q32. ▶antibody, ▶complement, ▶MCP; Evlashev A et al 2001 J Gen Virol 82 [pt9]:2125; Marie JC et al 2002 Nature Immunol 3:659.

CD47: An integrin-associated protein serving as a marker of self-identity on red blood cells. ▶integrin; Blazar BR et al 2001 J Exp Med 194:541.

CD48: A membrane (glycosylphosphatidylinositol associated) protein (1q21.3-q22) cooperating with CD2 in the interaction of the antigen-presenting cell with the T cell receptor. Uptake of bacteria by mast cells may depend on CD48 caveolae. ▶CD2, ▶antigen presenting cell, ▶T cell receptor, ▶caveolae; Veréb G et al 2000 Proc Natl Acad Sci USA 97:6013.

CD52 (CAMPATH-1 antigen): A very small glycosylphosphatidylinositol protein molecule with special recognition for lysing human lymphocytes. It has been effectively used before in therapeutic stem cell transplantation to prevent antigenic reaction to the foreign cells. ▶stem cells

CD54 (19p13.3-p13.2): ▶ICAM

CD55: ▶decay accelerating factor

CD59: ▶protectin

CD62: Its ligand is not expressed in defective B lymphocyte receptors to guard against autoimmunity. (Hartley SB et al 1993 Cell 72:325).

CD63: A transmembrane protein of the tetraspanin family involved in suppression of metastasis. ▶tetraspanin; Ryu F et al 2000 Cell Struct Func 25:317.

CD64 (Fc γ RI, 1q21.2-q21.3): A receptor 1 of the antibody G Fc domain. ▶antibody; Shen L et al 1987 J Immunol.139:534.

CD66 (19q13.2): Inhibitory receptors on granulocytes and some lymphocytes (T, B, NK, Nair KS, Zingde SM, 2001 *Cell Immunol* 208:96).

CD70: ▶ **CD27**

CD80: A member of the interleukin family of proteins encoded at 3q21, same as B7.1, and BB-1. ▶ **antigen presenting cells**, ▶ **CD4**, ▶ **CD28**, ▶ **CD40**, ▶ **B7**, ▶ **interleukins**, ▶ **anergy**, ▶ **co-stimulator**; Hattori H et al 2001 *Clin Exp Allergy* 31:1242.

CD81 (target of antiproliferative antibody/TAPA): A tetraspanin cooperating with CD9. ▶ **CD9**, ▶ **tetraspanin**, ▶ **TAPA**; Charrin S et al 2001 *J Biol Chem* 276:14329.

CD82: A transmembrane protein of the tetraspanin family involved in suppression of metastasis and viral infection. ▶ **tetraspanin**, ▶ **CD9**; Pique C et al 2000 *Virology* 276:455.

CD85: ▶ **ILT**

CD86 (B7.2): T lymphocyte co-stimulatory molecule (encoded at 3q21), binding to the CD28 receptor of antigen presenting cells. ▶ **antigen presenting cell**, ▶ **CD28**, ▶ **anergy**; Flo J et al 2001 *Cell Immunol* 24:156.

CD89: An immunoglobulin A (IgA) receptor (FcαRI) expressed on monocytes, eosinophils and macrophages. ▶ **antibody**; Herr AB et al 2003 *Nature [Lond]* 423:614.

CD95: ▶ **Fas**, ▶ **FADD**

CD98: A regulator protein of integrin-mediated cell adhesion and transport (encoded at 11q13); it indicates T cell activation. CD98 heavy chain mediates integrin-dependent signals and promotes tumorigenesis (Feral CC et al 2005 *Proc Natl Acad Sci USA* 102:355). ▶ **integrin**, ▶ **lymphocytes**; Suga K et al 2001 *FEBS Lett* 489:249.

CD117: The receptor for stem cell factors in thymic lymphocyte precursors. ▶ **T cells**, ▶ **stem cell factor**, ▶ **steel factor**; Shimizu M et al 2001 *Exp Cell Res* 266:311.

CD120 (12p3): A TNF family ligand recognizing the TWEAK receptors. ▶ **TNF**, ▶ **TWEAK**

CD122: A mediator of immunological memory.

CD133 (prominin): Antigens occurring primarily in stem cells; their formation is apparently deregulated upon differentiation. CD133⁺ colon cancer cells—unlike CD133[−] cells—grew exponentially for more than 1 year in vitro as undifferentiated tumor spheres in a serum-free medium, maintaining the ability to engraft and reproduce the same morphological and antigenic pattern of the original tumor (O'Brien CA

et al 2007 *Nature [Lond]* 445:106; Ricci-Vitani L 2007 *Nature [Lond]* 445:111). For glioma stem cells CD133 conveys protection against therapeutic radiation by activating the DNA repair pathway (Bao S et al 2006 *Nature [Lond]* 444:756). ▶ **stem cell**, ▶ **cancer stem cell**, ▶ **colorectal cancer**, ▶ **glioma**

CD134: A receptor or co-receptor of lymphocytes, frequently with the costimulatory OX40.

CD137: Stimulates the response of CD8⁺ T cells to viruses. ▶ **T cell**; Halstead ES et al 2002 *Nature Immunol* 3:536.

CD146 (S-Endo 1 Ag, Mel-Cam, MUC18): A primarily endothelial integral membrane protein, but also occurring in nonmalignant and malignant (melanoma) cells. (See Anfosso F et al 2001 *J Biol Chem* 276:1564).

CD147: A transmembrane glycoprotein with two immunoglobulin-like domains; it is a regulatory part of the γ-secretase complex. ▶ **secretase**; Zhou S 2005 *Proc Natl Acad Sci USA* 102:7499.

CD150: CD150 is important in the activation of interferon-γ and it thus builds immunity to viruses. Some viruses direct the synthesis of homologous proteins to elude the host defense. ▶ **interferon**; Sidorenko SP, Clark EA 2003 *Nature Immunol* 4:19.

CD151: A tetraspanin-forming stable complex with α3β-integrin, a laminin receptor on the cell surface. ▶ **integrin**, ▶ **laminin**, ▶ **tetraspanin**

CD152: ▶ **CTLA**

CD154 (M_r ~ 39K): A CD40 ligand and an immunological adjuvant. A member of the TNF receptors encoded at 20q12-q13.2. Antibodies blocking CD154 interfere with the rejection of tissue transplants in monkeys. ▶ **CD40**, ▶ **adjuvant immunological**; Pierson RN et al 2001 *Immunol Res* 23:253; McGregor CM et al 2004 *Proc Natl Acad Sci USA* 101:9345.

CD200 (OX2): A membrane glycoprotein negatively regulating macrophages. ▶ **macrophage**; Clark DA et al 2001 *Semin Immunol* 13:255.

CD Antigens (cluster of differentiation antigens): A large number of antigens of the leukocytes that can be classified and identified by monoclonal antibodies. ▶ **CD proteins**; Mason D et al 2001 *J Leukoc Biol* 70:685.

C/D Box: ▶ **snoRNA**

CD Fraction (constant dosage): of the DNA in a chromosome including the functionally known genes. They are expected to be balanced with each other within a chromosome. These genes may, however, be amplified without serious detriment,

but changing the dosage of the syntenic genes (aneuploidy) may have very undesirable consequence. ► [aneuploidy](#)

C

CD proteins (clusters of differentiation): Accessory proteins on the surface of the T cells. ► [T cells](#), ► [integrins](#), ► [LFA](#), ► [ICAM](#)

CDC (cell division cycle): The CDC genes encode cyclin-dependent kinase. More than 100 CDC genes have been discovered, and in 2001, Leland Hartwell, Paul Nurse and Tim Hunt were awarded the Nobel Prize for the original discoveries. ► [cell cycle](#), ► [CDK](#)

CDC1: A regulatory subunit of DNA polymerase δ . CDC1 seems to regulate the cellular Mn^{2+} level. ► [pol \$\delta\$](#) , ► [CDC27](#); Reynolds N, MacNeill SA 1999 Gene 230:15.

CDC2: A protein, which, when associated with mitotic cyclin proteins, becomes the MPF (maturation promoting factor) of the oocytes, a serine/threonine protein kinase. Cdc2 controls the transition from the G_1 to the S phase and prevents the reinitiation of the cell cycle at G_2 . Cdc2 also interacts with ORC. Phosphorylation of Cdc2 on threonine-14 (by *Xenopus* protein Myt1) and tyrosine-15 (by fission yeast protein Wee1) inhibits the activity of the Cdc2. For the activity of Cdc2, CAK (cyclin-dependent kinase) phosphorylates threonine-161. At the $G_2 \rightarrow M$ transition Cdc25 protein dephosphorylates Thr¹⁴ and Tyr¹⁵ and consequently Cdc2 suppresses MPF during interphase. High CDC2 activity inhibits anaphase but not the degradation of securin. ► [MPF](#), ► [cell cycle](#), ► [Cdc5](#), ► [securin](#), ► [separin](#), ► [mitosis](#), ► [ORC](#), ► [Plx1](#), ► [CDK](#), ► [Wee1](#), ► [Mik1](#), ► [Cdc25](#), ► [LATS](#); Vas A et al 2001 Mol Cell Biol 21:5767; Karaïskou A et al 2001 J Biol Chem 276:36028; Stemmann O et al 2001 Cell 107:715.

CDC4 (Fbw7/Ago): A protease required for the transition from the G_1 to the S phase during the cell cycle in cooperation with CDC34, CDC53 (cullin), and SKP1. CDC4 contains an F box, which interacts with SKP1 and 8 WD-40 repeats common for proteins involved in protein-protein interactions. Inactivation of human CDC4 results in chromosomal instability that may precede carcinogenesis (Rajagopalan H et al 2004 Nature [Lond] 428:77). ► [cell cycle](#), ► [CDC34](#), ► [WD-40](#), ► [SKP1](#), ► [APC](#); Desautels M et al 2001 J Biol Chem 276:5943.

CDC5: A fission yeast meiotic checkpoint control gene homologous to polo kinase. The CDC5 proteins are related to Myb and conserved through evolution. CDC5 is required for splicing pre-mRNA. ► [checkpoint](#), ► [Myb oncogene](#), ► [polo kinase](#), ► [splicing](#); Lee SE et al 2001 Curr Biol 11:784; Lee BH, Amon A 2003 Science 300:482.

CDC6: A protein DNA polymerase δ that appears in G_1 and early S phase and late mitosis. Apparently it takes part in the formation of the pre-replicative complexes and ORC. It is encoded at 17q21.3. ► [cell cycle](#), ► [ORC](#), ► [MCM](#), ► [cdt1](#), ► [cdc18](#), ► [DNA polymerases](#), ► [geminin](#); Yanow SK et al 2001 EMBO J 20:4648; Gowen Cook J et al 2002 Proc Natl Acad Sci USA 99:1347.

CDC7: A cell division cycle serine/threonine kinase with histone (H1) specificity. ► [cycle](#), ► [histones](#), ► [DBF4](#); Guo B, Lee H 1999 Somat Cell Mol Genet 25:159.

CDC10: A transcription factor for ribonucleotide reductase (CDC22). CDC10 mediates also budding in yeast. ► [ribonucleotide reductase](#); Jeong JW et al 2001 Mol Cells 12:77.

CDC13: A protein which is a regulator of gene *cdc2* in cooperation with genes *wee1* and *cdc25*; it is required also for the maintenance of telomeres in yeast. To accomplish meiosis in fission yeast the Mes1 protein suppresses the degradation of CDC13. Mes1 protein is specific for meiosis II but it is not required for regular mitosis (Izawa D et al 2005 Nature [Lond] 434:529). ► [wee1](#), ► [cdc25](#), ► [Stn1](#), ► [cell cycle](#), ► [telomere](#); Pennock E et al 2001 Cell 104:387; Chandra A et al 2001 Genes & Dev 15:404.

CDC14: A monocyte differentiation factor (5q31.1); a phosphatase, which inactivates cyclinB/Cdk1 and activates Swi5, which facilitates the transcription of Sic1. Sic1 is normally phosphorylated by cyclinB/Cdk1. CDC14 dephosphorylates also Cdh1 resulting in the activation of APC. CDC14 is initially detectable in the nucleolus where it is sequestered by another protein Cfi1 (CDC14 factor inhibitor) but eventually spreads into the nucleus and even to the cytoplasm. CDC14 regulates mitotic exit in cooperation with other proteins. ► [cyclinB](#), ► [Sic](#), ► [Cdk1](#), ► [Swi](#), ► [Cdh1](#), ► [APC](#), ► [cell cycle](#), ► [E2F](#), ► [mitotic exit](#), ► [FEAR](#), ► [Net1](#), ► [separin](#), ► [microtubules](#); Guertin DA, McCollum D 2001 J Biol Chem 276:28185; Azzam R et al 2004 Science 305:516.

CDC15: An inhibitor in MEN, controlling exit from mitosis along with TEM1. ► [MEN](#), ► [TEM1](#); Mah AS et al 2001 Proc Natl Acad Sci USA 98:7325.

CDC16 (APC6): ► [CDC27](#), ► [APC](#)

CDC17: *Saccharomyces cerevisiae* gene for DNA polymerase α and CDC17⁺ is a DNA ligase I gene of *Schizosaccharomyces pombe*. ► [DNA polymerases](#), ► [DNA replication](#); Adams MA et al 2000 Mol Cell Biol 20:786.

CDC18: A rate-limiting activator (initiator) of replication. It interacts with ORC2. In the human chromosome it is encoded at 17q21.3. In budding yeast it is

- CDC6. ▶ORC2, ▶cell cycle, ▶CDC6, ▶cdt1, ▶geminin; Yanow SK et al 2001 EMBO J 20:4648.
- CDC19** (Nda1): A component of the minichromosome maintenance complex (MCM). The human homolog is encoded at 3q21. ▶MCM; Liang DT et al 1999 J Cell Sci 112 [pt4]:559.
- CDC20**: DNA polymerase ϵ and anaphase spindle checkpoint (repair) protein. It is encoded at human chromosome 9q12-q22. It plays a role in the activation of the anaphase-promoting complex (APC). ▶checkpoint, ▶cell cycle, ▶spindle, ▶anaphase, ▶APC, ▶CDH1; Pflieger CM et al 2001 Genes Dev 15:2396.
- CDC20-50**: Potentiate passing beyond metaphase to anaphase in the absence of spindle formation. ▶cell cycle, ▶CDC20, ▶CDC50; Schott EJ, Hoyt MA 1998 Genetics 148:599.
- CDC21**: A component of the minichromosome maintenance complex (MCM), encoded at human chromosome 8q11.2 ▶MCM; Satoh T et al 1997 Genomics 46:525.
- CDC22**: A ribonucleotide reductase acting on purine and pyrimidine nucleoside di- and triphosphates and catalyzes the formation of DNA precursors. ▶ribonucleotide reductase, ▶cdt1; Fernandez Sarabia MJ et al 1993 Mol Gen Genet 238:241.
- CDC23** (APC8): A member of the APC protein complex, encoded at human chromosome 5q31.1. ▶APC; Goh PY et al 2000 Eur J Biochem 267:434.
- CDC24**: A guanine nucleotide exchange factor (GEF) in signal transduction and a DNA replication factor responsible for chromosome integrity. ▶CDC42, ▶GEF; Bose I et al 2001 J Biol Chem 276:7176.
- CDC25**: The cyclin-dependent CDC25 (A, B and C at 5q31) phosphatases remove inhibitory phosphates from tyrosines and threonines to facilitate the transition from G² to mitosis during the cell cycle. In human and mouse cells they represent a multigene family. In about a third of the breast cancers, CDC25B is overexpressed. In *Saccharomyces cerevisiae*, CDC25 genes regulate RAS/cAMP pathway and their mutation causes defects in G₁ phase of the cell cycle. CDC25 is thus a proto-oncogene and when growth factors are exhausted it can induce apoptosis. CDC25 may be downregulated by p53 binding to the DNA and cell cycle arrest (St Clair S et al 2004 Mol Cell 16:725). The *Drosophila* homolog is *stg* (*string*). ▶cell cycle, ▶cdk, ▶ras, ▶budding yeast, ▶MYC, ▶Plx1, ▶Chk1, ▶protein 14-3-3, ▶parvulins, ▶CDC2, ▶GEF, ▶CDF, ▶checkpoint, ▶p53, ▶SOS recruiting system; Forrest A, Gabrielli B 2001 Oncogene 20:4393; Busino L et al 2003 Nature [Lond] 426:87.
- CDC27** (APC3): A member of the tumor necrosis factor receptor family and restricts DNA replication to one round per cell cycle in cooperation with CDC16. It is also a component of the anaphase-promoting complex encoded at 17q12-q13.2. CDC27/p66 is a component of DNA polymerase δ ; its N-terminal 1–166 amino acids binds to CDC1 and its C-terminal 362–369 amino acids interact with PCNA and thus the processivity is supported. ▶TNF, ▶anaphase promoting complex, ▶PCNA, ▶processivity; Shikata K et al 2001 J Biochem [Tokyo] 129:699; Bermudez VP et al 2002 J Biol Chem 277:36853.
- CDC28**: CDC28 in *Saccharomyces cerevisiae* and CDC2 (in *Schizosaccharomyces pombe*) genes are responsible for the start of mitosis in the cell divisional cycle. CDC28p/Cdk1p protein is a cyclin-dependent kinase (CDK). Binding cyclin-3 activates CDC28. The human homolog encoded at 2q33 is a Ser/Arg-rich protein required for splicing of pre-mRNA. ▶cell cycle, ▶CDC2, ▶CDK, ▶CDC34, ▶CDC45, ▶Sic, ▶mRNA; Russo GL et al 2000 Biochem J 351:[pt 1]: 143; CDC28 regulates initiation of meiotic double breaks; Henderson KA et al 2006 Cell 125:1321.
- CDC30**: A member of the tumor necrosis factor receptor family. It is also involved in the control of sporulation of yeast. ▶TNF; Dickinson JR et al 1988 J Gen Microbiol 134 [pt 9]:2475.
- CDC31** (centrin): A Ca²⁺-binding protein in the microtubule-organizing center. ▶MTOC, ▶centrin, ▶calmodulin; Ivanovska I, Rose MD 2001 Genetics 157:503.
- CDC33**: Encodes the eIF-4E translation initiation protein. ▶eIF-4E; Brenner C et al 1988 Mol Cell Biol 8:3556.
- CDC34**: An ubiquitin-activating enzyme. It is required for the G₁→S transition in the cell cycle. The human homolog is encoded at 19p13.3. It facilitates the destruction of Cyclin 2 (CLN2) and Cyclin 3 (CLN3) and degrades the CDK inhibitor, SIC1. CLN2 and CLN3 are phosphorylated by CDC28 before CDC34-dependent ubiquitination. ▶cyclins, ▶SIC1, ▶ubiquitin, ▶cell cycle, ▶Wee1, ▶glucose induction; Ptak C et al 2001 Mol Cell Biol 21:6537.
- CDC39**: A gene with a glutamine-rich repressor product affecting G₁/S phase transition. ▶cell cycle; Collart MA, Struhl K 1994 Genes Dev 8:525.
- CDC40**: A member of the tumor necrosis factor receptor family. It is a pre-mRNA splicing factor. ▶TNF, ▶splicing; Russel CS et al 2000 RNA 6:1565.
- CDC42**: A RHO (Rac) family GTPase protein (encoded at human chromosome 1p36.1). It is involved in signal transduction pathways (see Fig. C40). In yeast, it affects the mating pheromone, signaling and binding several proteins; CDC42 is an activator of the JNK and

C

ERK pathways, including the one responsible for the Wiskott–Aldrich syndrome. CDC42 activation is sufficient to promote a premature cellular senescence that depends on p53 (Wang L et al 2007 Proc Natl Acad Sci USA 104:1248). It causes depolarization of actin and regulates the exit of proteins from the trans-Golgi network. Its GDP-GTP exchange factor is CDC24. It is a substrate for caspases and cooperates with the Fas apoptotic pathway. Integrin-mediated activation of CDC42 is involved in controlling astrocyte polarity with the cooperation of PKC and dynein. CDC42 regulates, also, the attachment of the spindle fibers to the kinetochore. Activation of CDC42 can be monitored by the application of the S-SO dye, which detects conformational changes in proteins (see Fig. C41) (Nalbant P et al 2004 Science 305:1615). The S-SO family of dyes are described by Touthkine A et al (203 J Am Chem Soc 125:4132). ▶actin, ▶integrin, ▶PKC, ▶dynein, ▶astrocyte, ▶Wiskott–Aldrich syndrome, ▶RHO, ▶Rac, ▶Fas, ▶apoptosis, ▶kinetochore, ▶mating type determination in yeast, ▶GTPase, ▶PAK, ▶Bin, ▶JNK, ▶ERK, ▶signal transduction, ▶cell migration, ▶CDC24, ▶Golgi, ▶faciogenital dysplasia; Tu S, Cerione RA 2001 J Biol Chem 276:19656; Etienne-Manneville S, Hall A 2001 Cell 106:489.

CDC44: A *Saccharomyces cerevisiae* gene, encoding the large subunit of RFC. ▶RFC, ▶Okazaki fragment; McAlear MA et al 1996 Genetics 142:65.

CDC45/CDC46-MCM5: Proteins (receptor-like transmembrane protein tyrosine phosphatases) are required for the initiation of chromosomal replication in association with CDC28 and other cyclin kinases. This complex, in association with GINS (Sld5, Psf1, Psf2, Psf3) proteins that are found at the yeast replication fork, are probably involved in eukaryotic helicase machinery (Moyer SE et al 2006 Proc Natl Acad Sci USA 103:10236). The human homolog of CDC45 is encoded at 22q11.2, the CDC46MCM at 22q13.1. Inactivation of CDC45 leads to lymphoproliferation and autoimmunity. ▶MCM, ▶CDC28, ▶cell cycle, ▶helicase, ▶DiGeorge syndrome, ▶autoimmune disease; Ehrenhofe-Murray AE et al 1999 Genetics 153:1171.

CDC48 (p97): An AAA family protein with roles in: the cell cycle, membrane fusion, endoplasmic reticulum assembly, nuclear fusion, Golgi reassembly, degradation of ubiquitin fusion proteins, transcription factor processing, degradation of endoplasmic reticulum associated proteins, apoptosis and chaperone-like activity. ▶terms at separate entries, ▶endoplasmic reticulum-associated degradation, ▶p97; Thoms S 2002 FEBS Lett 520:107.

CDC50: Controls START in the G1 phase of the cell cycle. ▶CDC20, ▶START; Radji M et al 2001 Yeast 18:195.

CDC53 (cullin, CUL): CUL2 was mapped to human chromosome 10p11.2-p11.1; CUL3 is in human chromosome 2. ▶CDC4, ▶glucose induction, ▶cullin; Botuyan MV et al 2001 J Mol Biol 312:177.

CDC55: Mammalian homolog of the yeast CDC20, a mitotic protein. ▶CDC20, ▶spindle; Wang Y, Burke DJ 1997 Mol Cell Biol 17:620.

CDC68 (Spt16): A transcription elongation factor on active chromatin. ▶FACT, ▶transcription factors, ▶chromatin remodeling; Formosa T et al 2001 EMBO J 20:3506.

CDCV: ▶PAF

CDE Elements: ▶centromere, ▶CDF

CDF: A facultative repressor of the cell division cycle. It regulates the expression of CDC25, cyclin A and

MYB. CDF-1 acts on repressor sites CDE (GGCGG) and CHR (ATTTGAA). In the late S phase, CDF binding to promoters leads to derepression of transcription. Binding E2F1 to the promoter upregulates transcription in late G1 phase. Binding both E2F and CDF results in intermediate kinetics. ►cell cycle, ►CDC25, ►E2F1, ►CDE, ►cyclins, ►MYB, ►CHR; Nettlebeck DM et al 1999 Gene Ther 6:1276.

CDH1 (Hct1): An APC-regulatory WD protein with functions similar to CDC20. During anaphase CDC20 is replaced by CDH1. ►Apc, ►CDC20, ►CDC14, ►WD-40, ►mitotic exit, ►mitotic catastrophe, ►Id proteins; Pfleger CM et al 2001 Genes Dev 15:1759.

CDK: Cyclin-dependent kinases involved in cell division (replication) or apoptosis. These kinases do not operate without cyclin. CyclinD-CDK4, CDK6 are involved in G1 of the cell cycle; cyclinE-CDK2 drive G1-S phase and DNA replication; cyclinA-CDK is active in S phase and cell division requires cyclinA-CDK1 and cyclinB in G2 and M phases. CDK2 is essential for the completion of prophase I of meiosis but its deletion does not affect much mitotic cell proliferation or survival in mice (Ortega S et al 2003 Nature Genet 35:25). Full activity is achieved by phosphorylation by CAK. Some cells (myocytes) may be protected from apoptosis by p21^{CIP1} and p16^{INK4a} inhibitors of CDK. p16^{INK4a} prevents the binding of cyclin D to CDK4/CDK6. Among the CDK inhibitors, p15, p16, and p18 specifically inhibit CDK4 and CDK6, whereas p21, p27, p28 and p57 are inhibitors of a wide range of CDK cyclin complexes. CDK4 is a tyrosine phosphorylated in G1 and dephosphorylation is required for the progression into S phase. UV irradiation may prevent dephosphorylation and cells are arrested in G1. If the CDK4 is not phosphorylated in G1, chromosomal breakage increases and a cell death may result. CDK-activating kinase is a component of the CAK-complex and part of the carboxy-terminal of transcription factor TFIIF. The CDK proteins are similar in size (35–40K) and display >40% identity in the different organisms where the somewhat different enzymes are denoted differently. CDC2 is the typical enzyme for fission yeast; and in budding yeast, the cyclin box comparable protein is CDC28, whereas in human cells it is CDK1/CDK. The 300 amino residue catalytic subunit is inactive as a monomer or in the unphosphorylated form. In the inactive state, the substrate-binding site is blocked and the ATP-binding sites are not readily available for the phosphorylation required for activity. The binding of CDK to the ≈100 amino acid cyclin box is indispensable for function. CDK5/p35 are involved in neural development. When p35 is cleaved

into a p25 fragment, CDK5 excessively phosphorylates tau and Alzheimer neurofibrillar tangles appear in the brain. Human CDK7 is homologous to the yeast Kin28 and has subunits of the general transcription factor TFIIF; it phosphorylates the carboxyterminal domain of RNA polymerase II after the formation of the preinitiation complex. CDK7/K in 28 promote transcription. CDK8 is homologous to the yeast Srb10 and it is a subunit of the Pol II enzyme; it is also capable of phosphorylation of the C-terminal domain of Pol II before the formation of the preinitiation complex. CDK8/Srb10 actually inhibit transcription. The difference between Kin28 and Srb10/11 is in the temporal sequence of action. The effect of Srb10 does not apply generally to all genes, but it affects genes which determine cells types, meiosis and sugar utilization. Srb2, 4, 5, and 6 all are positive regulators of transcription. CDK9 (encoded in human chromosome 12) is a cofactor of lentiviral transcription. CDC2 may associate with a few different cyclins whereas CDC28 may be attached to nine different cyclins during the course of the cell cycle. The level and form of cyclins may vary during the cell cycle and their destruction is mediated by ubiquitins. In yeast, activation of CDC28 by the G1 cyclins stimulates the cyclins CLN1 and CLN2 to degrade mitotic cyclins (CLB), after which the G1 phase CLB levels may be elevated leading to the repression of G1 cyclins. When CDC28 is activated CLB decay begins. The CDK-cyclin complex may be inhibited by phosphorylation near the amino end of CDC2 and CDK2 (at Thr 14 and Tyr 15). Phosphorylation at these two residues is followed by a rise of mitotic cyclins (CLB). At the end of the G2 phase Thr 14 and Tyr 15 are dephosphorylated by CDC25 phosphatase and CDC2 is activated. CDK may also be inactivated by protein CKI (a family of inhibitory proteins to the cyclin CDK complex by attaching to the complex). The inhibitory subunits include p21 and p27 and other proteins. Eventually, the CKIs also decay and the cyclic events continue. Selective inhibitors of these kinases may be potential therapeutics. CDK1 is also called CDC28. Human CDK8 and cyclin C carry out the same function as Srb10 and Srb11, the negative regulators of transcription in yeast. ►cyclin, ►kinase, ►tau, ►Alzheimer's disease, ►CAK, ►KIN28, ►PHO85, ►Srb, ►CDC28, ►cell cycle, ►p16^{INK}, ►p53, ►KIP, ►CIP, ►apoptosis, ►UV, ►ubiquitin, ►CLB, ►p21, ►p27, ►p16, ►p57, ►CKI, ►preinitiation complex, ►lentiviruses, ►cyclin T, ►centrosome, ►PITALRE, ►polycystic kidney disease, see also Andrews B, Measday V 1998 Trends Genet 14 (2):68, for CDK inhibitors: Knockaert M et al 2002 J Biol Chem 277:25493; cell cycle: Pagano M, Jackson PK 2004 Cell 118:535.

C

CDKN2A (CDKN2/TP16/p16^{INK4}, 9p21): A cyclin-dependent kinase inhibitor and general tumor suppressor. The gene encodes two proteins p16^{INK4A} regulating retinoblastoma gene (RB) and p19^{ARF}, which regulates p53. ▶**CDK**, ▶**p16**, ▶**ecclampsia**; Palmieri G et al 2000 Br J Cancer 83:1707.

cDNA: DNA complementary to mRNA (made through reverse transcription) and which does not normally contain introns. ▶**reverse transcriptases**, ▶**transcription**, ▶**mRNA**, ▶**Okayama & Berg procedure** (see Fig. C42), <http://www.kazusa.or.jp/huge>, mammalian: <http://mgc.nci.nih.gov>; human database free clones: <http://fldb.hri.co.jp/cgi-bin/cDNA3/public/publication/index.cgi>, Ota T et al 2004 Nature Genet 36:40; Gustincich S et al 2006 J Physiol 575(2):321.

cDNA Library: A collection of DNA sequences complementary to mRNA. ▶**mRNA**, ▶**processed genes**

cDNA Library Screening: Can be carried out by probing the DNA sequences, either with special binding proteins for the purpose of high degree purification or with any DNA or RNA in order to identify genes or gene products isolated from different organisms. ▶**gel retardation assay**, ▶**cloning**, ▶**probe**

CCDP: A mammalian displacement protein at the CCAAT sequence of DNA and competes for binding of CP1, a CCAAT box-binding protein. It is a transcriptional repressor. ▶**CP1**, ▶**CAAT box**; Ellis T et al 2001 Genes Dev 15:2307.

CDP (cytidine diphosphate): A nucleotide involved in the biosynthesis of phospholipid synthesis.

CDPK: Ca²⁺-dependent protein kinases regulate signaling pathways. ▶**signal transduction**; Allwood EG et al 2001 FEBS Lett 499:97; Zhang XS, Choi JH 2001 J Mol Evol 53:214.

CDR: CDR is the complementarity determining region of the antibody's hypervariable region that binds the antigen; it is the antigen-binding site (idiotype). ▶**antibody**, ▶**paratope**, ▶**idiotype**, ▶**look-through mutagenesis**; Furukawa K et al 2001 J Biol Chem 276:27622.

CDR (cerebellar degeneration-related autoantigen, Xq27.1-q27.2): Autoantigens directed against the cerebellar degeneration protein that occurs in neoplasms of the lung, breast, ovary and Hodgkin's disease (Chen YT et al 1990 Proc Natl Acad Sci USA 87:3077). CDR3 is apparently at 17q25 (Fletcher CF et al 1997 Genomics 45:313).

CDS: Protein-coding sequences in the genome. Raddatz G et al 2001 Bioinformatics 17:98.

CDS1: A fission yeast kinase, an inhibitor of CDC2. Human CDS1 phosphorylates the breast cancer protein (BRCA1) at serine 988 after DNA damage and assists thus cell survival. ▶**CDC2**, ▶**breast cancer**; Boddy MN et al 2000 Mol Cell Biol 20:8758.

CDT1: A fission yeast protein (with similarities to deoxyribonuclease I) required for assembly of the DNA pre-replication complex in concert with CDC22, CDC18/CDC6 and MCM. Its homologs are present in vertebrates. CDTs (cytolethal distending toxins) have the special feature of affecting DNA rather than cellular proteins. The cul-4 ubiquitin ligase restrains replication, which is mediated CDT1. In the cells lacking CUL-4, CDT becomes uncontrolled and additional S phase replications may increase DNA content up to 100 C. Geminin can inhibit the CDT1 component of the replication-licensing factor (Lee C et al 2004 Nature [Lond] 430:913). ▶**C value**, ▶**CDC6**, ▶**CDC18**, ▶**CDC22**, ▶**DNA replication**, ▶**replication fork**, ▶**replication licensing factor**, ▶**ubiquitin**, ▶**MCM**, ▶**geminin**, ▶**chloroplast**; Yanow SK et al 2001 EMBO J 20:4648; Zhong W et al 2003 Nature [Lond] 423:885.

CD-Tagging Methods: Uses, for insertion mutagenesis, a DNA cassette that when inserted into an intron and transcribed and spliced, the mRNA will contain a special tag (guest tag). Upon translation, the polypeptide will also carry a tag (guest peptide). The latter can be identified by a monoclonal antibody, specially prepared for this epitope. The mRNA and the DNA sequences can be identified by PCR. Thus this method simultaneously labels DNA, RNA and the peptide; hence its name, central dogma tagging. ▶**insertional mutagenesis**, ▶**monoclonal antibody**, ▶**epitope**, ▶**PCR**; Jarvik JW et al 1996 Biotechniques 20:896.

CDw32 (FcγRII): An antibody Fc domain receptor. ▶**antibody**; McKenzie SE, Schreiber AD 1994 Curr Opin Hematol 1:45.

CDX1: A homeobox protein regulating intestinal epithelium and it is apparently a suppressor of oncogenesis. ▶**colorectal cancer**, ▶**Barrett metaplasia**; Wong NACS et al 2004 Proc Natl Acad Sci USA 101:574.

Cdx2: A cell fate-determining transcription factor required during the differentiation of the mouse trophectoderm; forming the fetal-maternal interface during blastocysts development. It interacts with Oct3/4 transcription factor (Niwa H et al 2005 Cell 123:917).

ce: Prefix for *Caenorhabditis elegans* DNA, RNA or protein.

► Construction of Plasmid Primer:

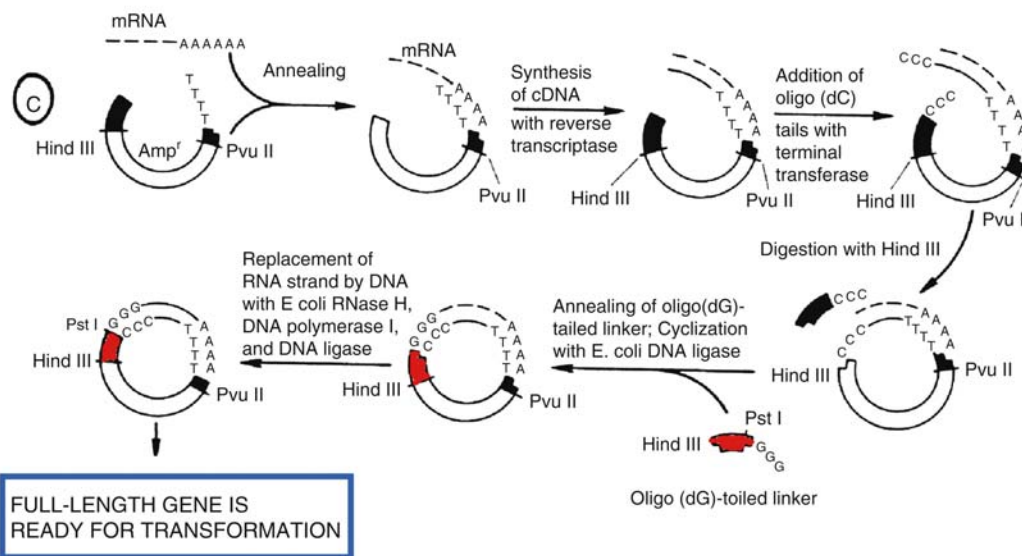

The hybrid plasmid consists of pBR322 + a piece of SV40 (black), the decimals are map coordinates of the virus.

► Construction of Oligo dG Tailed Linkers:

The unshaded part is pBR322, the stippled comes from SV40

► Cloning of the mRNA:

mRNA is extracted from post-lysosomal supernatant of reticulocyte lysate of rabbits made anemic by phenylhydrazine injections. The globin mRNA is recovered in the alcohol precipitate of phenol extract or prepared with the aid of the guanidium thiocyanate methods. The poly(A)-tailed mRNA is annealed to the dT-tailed vector-primer and the first strand of the cDNA is made by reverse transcription. Oligo dC tails are added to both 3'-OH ends. The oligo C ends must be removed by Hind III and the linker (B) is substituted for it. The RNA is removed by 3' to 5' exonuclease activity (RNase H) of the reverse transcriptase and it is replaced by DNA polymerase I-made DNA strand and ligation follows. Propagation by transformation.

Figure C42. (A) Construction of plasmid primer; (B) Construction of oligo dG tailed linkers; (C) Cloning of the mRNA. Okayama M & Berg P Method of isolation full-length cDNA. (Modified after Mol. Cell Biol. 2: 161)

C.E.: An abbreviation for Common Era of historical time.

Cebidae: Families of New World monkeys. *Aotus trivirgatus* 2n = 54; *Aotus trivirgatus griseimembra* 2n = 52, 53, 54; *Ateles geoffroyi* 2n = 34; *Callicebus moloch* 2n = 46; *Callicebus torquatus* 2n = 20; *Cacajao* 2n = 46; *Cebus albifrons* 2n = 54; *Lagothrix ubericolor* 2n = 62; *Pithecia p. pithecia* 2n = 48; *Scaimii sciureus* 2n = 44 ► **primates**

C/EBP (CEBP): CAAT/Enhancer Binding Protein is transcription factor AP1, product of JUN and FOS oncogenes. The protein is essential for the differentiation of granulocytes. Its mutation is common in acute myelogenous leukemia (Pabst T et al 2001 Nature Genet 27:263). These proteins regulate different cellular functions, including adipogenesis. The C/EBP family of proteins affects the storage and suppression of memory (Chen A et al 2003 Neuron 39:655). ► **AP**, ► **JUN**, ► **FOS**, ► **enhancer**, ► **granulocyte**, ► **leukemia**, ► **memory**, ► **aging**; Lekstrom-Himes J, Hanthopolus KG 1998 J Biol Chem 273:28545; McKnight SL 2001 Cell 107:259.

Cebus (capuchin monkey): ► **Cebidae**

Cecropin: ► **antimicrobial peptides**

CED: ► **apoptosis**

Cefotaxime (Claforan): A cephalosporin type general medical antibiotic with relatively mild toxicity to plant cells (see Fig. C43). It is thus widely used to free plant tissue from *Agrobacterium*, infected for the purpose of genetic transformation. ► **genetic transformation**, ► **Agrobacterium**; Husson MO et al 2000 Pathol Biol [Paris] 48:933.

Figure C43. Cefotaxime

Ceiling Principle: A statistical procedure for the conservative estimation of the odds for the likelihood that DNA fingerprints would match. The odds against a chance match is usually determined on the basis of the frequency of a particular genetic marker in a certain population (such as Caucasians, Blacks, Hispanics, Orientals, etc.). The markers used for DNA fingerprint analysis are supposed to be of low frequency, below 10 or 5%, but for the majority of subpopulations such information is not available yet. In such cases they take into account, say, 0.1 as a maximal frequency (a ceiling). The chance that a

particular person would have the same DNA marker as another individual in its group would be $0.1 \times 0.1 = 0.01$. The probability that 8 markers would be identical by chance would be $(0.1)^8 = 1/100,000,000$, and if 0.05 is chosen as a ceiling it would be approximately 2.6×10^{-10} . The world's population of 6 billion is about 23% of 2.6×10^{10} . Some population geneticists disagree with the use of the rather arbitrary "ceilings" and advocate the theoretically more valid use of mean frequencies with the pertinent confidence intervals. Today, more information is being made available on gene frequencies and therefore direct frequencies can be used for the majority of the genes involved. Abandoning the ceiling principle increases the accuracy of establishing individual liabilities and does not allow unwarranted advantage for the criminals. The recommended genetic markers for forensic comparison (in lieu of the ceiling principle) are variable number tandem repeats, VNTR (D2S44, 75 alleles and D1S80, 30 alleles), short tandem repeats, STRs (HUMTHO1, 8 alleles) simple sequence variations, SSV (DQA, 8 alleles, poly-marker [5 loci, 972 combinations]), and mtDNA D-loop with >95% diversity. ► **DNA fingerprinting**, ► **confidence intervals**, ► **allelic frequency**, ► **Frye test**; Slimoewitz JR, Cohen JE 1993 Am J Hum Genet 53:314.

Ceinsulin: An insulin-like growth hormone in *Caenorhabditis elegans*. ► **insulin**, ► **Caenorhabditis**

Celera: A genomics and diagnostics laboratory. <http://www.celera.com/>.

Celery (*Apium graveolens*): The stalks are used as food or the celeriac is a root vegetable; 2n = 2x = 22.

Celiac Disease (coeliac disease, sprue, 6p21.3): In certain individuals the intestinal enzymes do not digest some water-insoluble proteins like the gliadin (glycoprotein in gluten) in wheat (also in other cereals). Intolerance to oats is less common but does exist. This protein then causes inflammation of the intestinal lining and bloating of the abdomen. Its incidence in the general population is about 4/1000 and the genetic recurrence risk in the brothers and sisters of afflicted sibs is about 2 to 3%. The genes responsible for A2-gliadin synthesis were located to the long arm of chromosomes 6A, 6B and 6D of hexaploid wheat. Some gliadin genes are also in chromosome 1. There are substantial quantitative differences among the different chromosomes concerning the production of this protein. In the intestinal endomysium (reticular sheath of muscle fibers), a tissue-specific transglutaminase exists. Deamidation of gliadin opens up epitopes, which bind then HLA-DQ2 on antigen presenting cells and facilitate the recognition by intestinal T lymphocytes. It appears particularly important for the inflammation response

when glutamine 148 is converted into acidic glutamate. The CD4⁺ T cells then stimulate helper T cells (T_H) to secrete cytokines such as TNF- α , which in turn induces the release of metalloproteinases which degrade fibrillar collagen, proteoglycans and matrix glycoproteins. The T_H cells facilitate immunoglobulin-A (IgA) production by B lymphocytes. IgA then turns against gliadin and gliadin complexes.

Some anthropologists suggested that the ancient Egyptians consumed high gliadin wheat varieties or some of the pharaohs were more susceptible to the disease (these families practiced high degree of inbreeding) because of the extended bellies observed on several royal mummies and on the statues of Tutankhamen. About 40% of disease cases are under the control of the HLA-DQ2 genes in humans but one 6p locus, 30 cM from the telomere (thus outside HLA), has been identified for the predisposition. At 19p13.1 in intron 28 of the myosin 9B gene there is an important variant controlling actin remodeling in epithelial enterocytes. As a consequence the intestinal barrier to the uptake of gliadin is diminished and individuals heterozygous for the gene have 2.3 times increased chance for the disease (Monsuur AJ et al 2005 Nature Genet 37:1341). Low-*lod* score putative linkage was observed with several chromosomal sites. Besides the HLA region (6q21.3), significantly increased risk factors were found at 4q27

(van Heel DA et al 2007 Nature Genet 39:827). ▶HLA, ▶immuno-globulins, ▶T cells, ▶T_H, ▶immune system, ▶metalloproteinases, ▶Triticum, ▶glutenin, ▶gynecomastia; King AL et al 2000 Ann Hum Genet 64:479 Sollid LM 2000 Annu Rev Immunol 18:53; Kumar R et al 2002 J Mol Biol 319:593; Fleckenstein B et al 2002 J Biol Chem 277:34109; Schuppan D, Hahn EG 2002 Science 297:2218.

Cell: ▶cell structure, ▶cell comparisons, ▶single cell analytical methods

Cell Adhesion Molecule: ▶CAM

Cell Autonomous: The product of the gene is limited to the cell expressing it; it does not diffuse to other cells.

Cell Body: The main part of the nerve cell containing the nucleus and excluding the axons and dendrites.
▶neurogenesis

Cell Comparisons: Cells of various organisms have common features, yet differences exist that can be compared by the tabulation shown in the table (see Table C2). Prokaryotes in general lack organelles; certain bacteria have something similar, the carboxysome, which processes carbon (Kerfeld CA et al 2005 Science 308:936). There are nomenclature problems when various cell types (phenotypes) need description. It is especially difficult to make

comparisons among various eukaryotic cell phenotypes (including mutants) and their developmental, evolutionary origin among the different taxonomic groups. Bard J et al (2005 Genome Biol 6:R21) proposed ontology for cell types for the major model organisms and it is available free at <http://search.msn.com/results.aspx?q=obo+sourceforge+nbt&FORM=USNO/>, wide-ranging information on cells and tissues: <http://ccdb.ucsd.edu/CCDBWebSite/index.html>.

Cell Cortex: On the inner surface of the animal plasma membrane there is an actin-rich layer of the cytoplasm, mediating movement of the cell surface.

Cell Culture: Generally, the culture of isolated cells of higher eukaryotes, although growing bacteria or yeast is also cell culturing. ▶tissue culture

Cell Cycle: The phases of cell reproduction and growth are G1→S→G2→M and cytokinesis, the generation of two daughter cells from one. The duration of the cell cycle varies among different organisms, and it is influenced by several factors (temperature, nutrition, age, stage, etc.). In *Drosophila* embryos it may be completed within 8 min and in other early embryos the cycle may be completed within half an hour. In other cells the approximate numbers of hours required are shown in the table (see Table C3).

The S and M phases are present in all dividing tissues, the G phases can be clearly distinguished only in cells where the divisions are less fast because of differentiation.

Before the cell enters the cell cycle the pre-replication complex (pre-CR) is assembled. This complex consists of the Origin Recognition Complex (ORC), the cell division cycle 6 protein (Cdc6p), and MCM (mini-chromosome maintenance proteins).

The cell cycle has been studied most frequently in vitro by the dividing egg of mammals manipulated by microinjection of various cellular components or by fusion of cells of different developmental stages. In plants, it is analyzed in somatic cells where division is triggered by the application of hormones

and, in yeast, by accumulating conditional (temperature-sensitive) mutations and then by the introduction of the wild-type allele through transformation. Throughout the cell cycle (except mitosis) RNA and protein synthesis takes place. The G1 phase (Gap 1, named not very felicitously) is actually a phase of cell growth when a commitment is made for DNA replication. This point of commitment is called START by yeast cell biologists, and by animal cell biologists, RESTRICTION POINT.

For START, the cell requires the activity of a cyclin-dependent protein kinase composed of the catalytic subunit of protein CDC28 and one of the three cyclins (C/n1, -2 or -3). After START, cyclin 5 B and cyclin 6 kinases are required. The latter two kinases are inhibited by protein SIC1 and the latter must be inactivated by proteolysis, carried out by the ubiquitin-conjugated CDC34. Some cells may stay very long at this preparatory stage and this is when it is called the G₀ stage. In the S phase, DNA synthesis is completed. The cells cannot enter G2 (Gap 2, another cell growth phase) before the completion of S phase. Several genes were found to cooperate in *checkpoints* that provide clearance before the next phase could be entered. CLB-Cdc28 prevents reinitiation of the S phase by phosphorylating CDC6 and removal of MCM2-7. Thus the cell avoids polyteny or polyploidy. G2 is committed to the preparations of mitosis, a task that follows, if, during interphase, all the nutritional requisites for carrying out mitosis build up. The two G phases and S phase combined are frequently named *interphase*, i.e., the phase between nuclear divisions (mitosis). In very rapidly dividing embryonic tissue, G1 and G2, involved in cell growth, may be extremely brief or even absent and therefore the daughter cells become only half the size of the mother cells by each division. This is possible because the egg cell is generally very large at the time of fertilization. Some mature animal eggs may be thousands or tens of thousands of times larger than an average body cell and it is loaded with nutritious material. In such cases the cell cycle may

Table C3. Approximate number of hours of duration of stages of the cell cycle

| CELL TYPES | G1 | S | G2 | M | TOTAL | SOURCE |

include only S (DNA synthetic) and M (mitosis, nuclear division) phases. Feeding labeled nucleotides, which are then incorporated into the DNA, can identify the S phase. The fraction of the cells doing so, the *labeling index*, can be determined. From the fraction of cells undergoing mitosis in a tissue, the *mitotic index* is derived. The cell division is an extremely complex process, involving the cooperation of a very large fraction of all the genes and affecting the expression of many others. Cell division requires the presence of several *protein kinases* (phosphorylases), *phosphatases*, and other activating proteins such as *cyclins*. The cyclins were named so because they are synthesized during the cycles of mitoses but not much is made during the intervening (interphase) periods. In fission yeast, gene CDC2 (cell division cycle) is involved in the control through its 34 kDa phosphoprotein product (p34^{cdc2}) that is a serine/threonine kinase, activated by cyclins, and the complex becomes a cyclin-dependent protein kinase (CDK). The cyclin-dependent protein kinase associated with cyclin B is also called MPF (*maturation protein factor*). In the phosphorylation, a cyclic-AMP-dependent protein kinase (cAPK) also has a role. MPF-dependent activation of cAMP-protein kinase A (PKA) and degradation of cyclin are required for the passage from mitosis into interphase. There are a large number (over 70) of CD genes. The CDC2 homolog in budding yeast is CDC28. Most of these genes have been well preserved during eukaryotic evolution and homologs are present in yeasts, in animals, and higher plants. There are several different cyclins. The G1 cyclins are cyclin C and a number of different cyclin Ds and cyclin A which when bound to the CDK protein(s) control the onset of the S phase. The mitotic cyclin (cyclin B, encoded by CDC13 in fission yeast) binds to CDK before the onset of mitosis. MYC in cooperation with RAS mediates, also, the progression of the cell cycle from G1 to the S phase through induction of the accumulation of active cyclin-dependent kinase and transcription factor E2F. Actually, similar genes and functions occur in all eukaryotes but they are named differently. CLN and numbers denote the cyclin homolog genes in budding yeast. Remember that in fission yeast usually the genes are symbolized with lower case letters, and + or – superscripts depending on whether wild type (+) or mutant genes (–) are represented. In budding yeast, the wild type allele is capitalized and the mutant is in lower case. In both yeasts the genes are italicized whereas the protein symbols are not. Upon the binding of CDC and cyclin, the conformation of the former is altered allowing the phosphorylation of the threonine at position 161 of CDC2 and the complex becomes a fully active promoter of mitosis. The Thr 161

phosphorylation is mediated by a CDK (cyclin-dependent kinase), called also CAK (CDK-activating kinase). cAPK is autophosphorylated at a Thr197 residue. Cyclin binding is also followed by dephosphorylation of the tyrosine 15 residue by phosphatases. Before the cell can enter the M phase in the majority of organisms, phosphorylation of this protein decreases. In fission yeast other proteins (encoded by genes *wee1*, *nim1*, *mik1*) exert negative control over the passage into the M phase. Eventually, CDC2 protein is dephosphorylated (gene CDC25 regulates a phosphatase activity) and cyclin is degraded making the CDC2 monomers available for another round of association with newly synthesized cyclins. If the DNA is damaged, the CHK1 kinase is activated and that prevents the exit from the G2 phase into the M phase. The MAPKK mitogen-activated serine/threonine kinase is also required for the G2→M transition. The degradation of the cyclins is mediated by ubiquitin-dependent proteolytic cleavage pathways also controlled by MPF. Genes that block entry into the M phase regulate exit from the M phase. The product of gene *suc1*, p13^{Suc1} may be required (among other proteins) for the termination of mitosis (see Fig. C44).

Figure C44. Tumour growth factors checkpoints, genes *wee1* in yeast, *ATM* in animals. In the various phases of the cell, cyclin-dependent kinases (CDKD, CDKE, CDKA, and CDKB) reach their peak activity and at the same time other proteins (promoters and inhibitors) are also changing and balancing each other's effect on the progression of the cell cycle. The diagram shows only the cyclin activities in relation to the mitotic phases and tumor formation checkpoint.

If S phase takes place but mitosis is not completed, endopolyploidy may result, i.e., the chromosome number is multiplied (polyploidy). By this time the organellar material (plastids, mitochondria) are also readied for fission. There are some differences in the cell cycles of yeasts and other fungi from higher eukaryotes. In the former group, the nuclear envelope is present throughout the cell cycle, whereas in the latter it disappears from view from metaphase through telophase and is reformed after late telophase (see Fig. C45). In fission yeast, the cell division resembles that of higher eukaryotes by forming a cell plate in between the two daughter nuclei. In budding

yeast, one of the daughter nuclei moves into an extrusion of the cell, a bud, and eventually grows into a normal size cell. In fungi, the spindle apparatus is located inside the nucleus rather than in the cytoplasm as in higher eukaryotes. These processes require, in addition, other regulatory mechanisms. It must be assured that DNA replication (S phase) produces complete sets of all essential genes and preferably *not* in multiple copies unless such amplification is required. In the regulation of the cells' cycle ubiquitin appears to have an important role. Three yeast proteins CD16, CD23 and CD27 (or their homologs in other organisms) mediate the attachment of ubiquitin to cyclin, resulting in its degradation at the end of mitosis.

Figure C45. Proteolytic controls during the progression of mitosis. The heavy lines indicate activation, the gray lines stand for blocking the transition. The symbols in gray indicate lack of activity and the gray circle stand for degradation. CDC2 = cell division cycle protein 2, PDS and CUT are non-cyclin proteins, APC = anaphase promoting complex.

The initiation of a new cycle is hampered until an inhibitor (p27) is removed from the cyclin-CDK complex. This inhibitor is degraded by ubiquitin, placed on the proteins of the spindle by CD16, before a new S cycle is entered.

As the anaphase initiates the cell cycle becomes irreversible and as the cohesion between sister-chromatids breaks down the spindle fibers pull the new chromosomes (they were until now called chromatids) toward the poles. This process is mediated by the anaphase-promoting protein complex (APC/NR/TSG24), also called *cyclosome*. APC

is an ubiquitin-protein ligase that apparently manages that the chromosome would be properly arraigned in the metaphase plane and other proteins also would be functional. After entering mitosis, CDKs activate the APC complex and it remains active as long G1 phase substrates are available. After degradation of the ubiquitin-conjugating protein E2 (UbcH10), cyclin A stabilizes again and a new cell cycle can restart (Rape M, Kirschner MW 2004 Nature [Lond] 432:588) as CDH1/HCT1 activate APC. Anaphase entry and Mitosis exit are promoted by APC-dependent proteolysis of cell cycle proteins. Thus an oscillatory mechanism alternates between the start and stop of the cycle. CDC20 promotes the degradation of the early-acting proteins and HCT1 assists the degradation of Clb2 type cyclins (see Fig. C46).

The M phase cyclins are now lysed by the 26S proteasome after the telophase is completed. Other protein factors, which are no longer needed, are also ubiquitinated. APC operates through the proteolytic pathway (shown in the diagram). Another proteolytic pathway during the cell cycle is mediated through protein CDC34 ▶ CDC34

The p34^{cdc2} and homologous proteins in cooperation with other factors (MPF) mediate the condensation of chromosomes through activation of H1 histone and control lamins to mediate the breakdown of the nuclear envelope (except in yeast). MPF controls tubulins and actins for the function of the mitotic spindle, etc. The cell cycle is intimately associated with signal transduction pathways, DNA topoisomerases, DNA polymerase, DNA ligase, RNA polymerases, transcription factors, etc. After all these events are successfully passed, the cell divides into two daughter cells and the cycle may be resumed depending also on environmental conditions. Aphidicolin blocks DNA synthesis, hydroxyurea interferes with the formation of DNA nucleotides and therefore DNA synthesis is halted. In case, along with hydroxyurea, caffeine is added an abortive DNA replication and mitosis results in cell death. Some of the mutations involving defective DNA repair inhibit

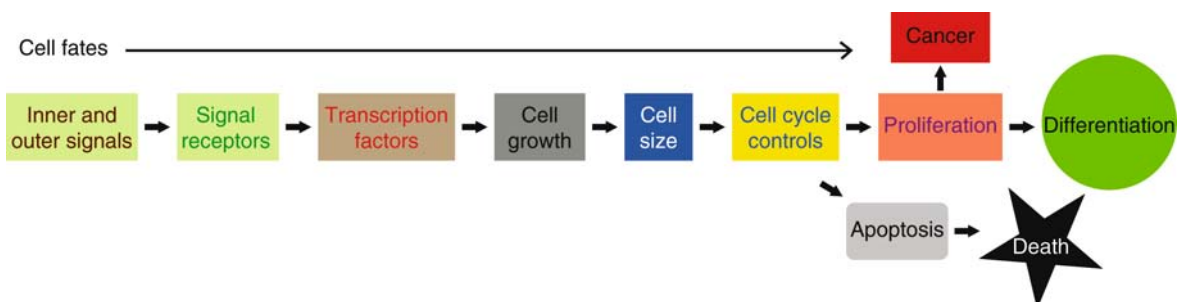

Figure C46. Cell fates

cell cycle and cell divisions. The various growth factors are all directly or indirectly involved with the cell cycle. The p53, p16, p21 proteins are regulators of the cell cycle and some of their mutations no longer control the pace of orderly cell divisions and are thus instrumental in tumorigenesis. Breakdown of some cell cycle signals causes failures in attachment of the spindle fibers to the kinetochore resulting in nondisjunction and aneuploidy. An overview of events leading to the overall fate of cells through the cell cycle can be represented below. A genome-wide analysis of the human cell cycle, cell size, and proliferation by targeting >95% of the protein-coding genes in the human genome using small interfering RNAs (siRNAs) showed that depletion of 1,152 genes strongly affected cell-cycle progression (Mukherji M et al 2006 Proc Natl Acad Sci USA 103:14819).

Meiosis has similar controls but the modulations are different. The primary oocyte is at an arrested G2 stage until a hormonal stimulation pushes the process to the first meiotic phase (reduction division) resulting in the formation of the first polar body in animals. In plants, this is the stage of the megaspore dyad. In mammalian oocytes, the diplotene stage (called dictyotene) may then last from early embryonic development (about 3rd month in humans) to puberty. This is followed by the formation of the second polar body and the egg. In plants, from the four products of the “female” meiosis only one megaspore (most commonly the basal one) remains functional, and unlike in animals, undergoes 3 more divisions to eventually form the egg.

Upon fertilization of the interphase egg, diploidy is restored, and cleavage divisions follow. The cell cycle has central importance for various processes of differentiation (Lee LA, Orr-Weaver TL 2003 Annu Rev Genet 37:545). The p21 protein regulates CDKs and combined with PCNA controls DNA replication. p21 also blocks keratinocyte differentiation. The CAK subunit of TFIIH transcription factor is involved with RNA polymerase II preinitiation complex. Cyclins regulate also tumor suppressor gene RB (retinoblastoma) and MyoD muscle differentiation factor. RB binds to the E2F family of cell cycle transcription factors and the RB-E2F complex blocks transcriptional activation by recruiting histone deacetylase (HDAC). The HDAC-SWI/SNF nucleosome-remodeling complex inhibits the cyclin E and A genes and arrests the cell cycle at the G1 phase and prevents the exit from the G1 phase. The RB-SWI/SNF complex regulates the exit from the S phase. BRG and BRM may assist RB in incapacitating E2F. In the human cell cycle, oligonucleotide array analysis detected the involvement of about 700 genes. More than 1,000 genes appear to control

the cell cycle in plants. The cell cycle in prokaryotes is also a highly organized process although they lack mitosis. In the enteric bacterium *Caulobacter*, about 19% of the 553 genes display cell cycle regulated expression. The participating proteins show fixed topology (Ryan KR, Shapiro L 2003 Annu Rev Biochem 72:367). The *Caulobacter* cell cycle proceeds through an elaborate circuitry of genes/proteins (Biondi EG et al 2006 Nature [Lond] 444:899).

Cell Division: In eukaryotes involving two steps, nuclear division (karyokinesis) is followed by division of the rest of the cell (cytokinesis) (see Fig. C47). The cell cycle is a process of cycling as shown in the diagram, rather than as frequently depicted as a circle. A summary of the end results of the cell cycle is doubling of the chromatids as a consequence of the DNA replication during the S phase and changes in the C values of the nuclei. The estimated number of cell divisions in the germline of human males before puberty is ~30, whereas in the females it is ~22.
 ▶cell cycle, ▶mitosis, ▶cytokinesis, ▶partitioning, ▶for bacterial cell division; Rothfield L et al 1999 Annu Rev Genet 33:423; Nanninga N 2001 Microbiol Mol Biol Rev 65:319; Scholey JM et al 2003 Nature [Lond] 422:746 microarray data relevant to mitosis

Figure C47. The relation between the nuclear cycles and cell divisions. During S phase the amount of DNA doubles and each 1 C chromosome will have 2 C amounts (2 chromatids), and a diploid cell will have a total of 4 C amounts of DNA before mitosis takes place and then cell division (cytokinesis) ensues.

meiosis and gametogenesis: <http://www.germonline.org/>.

Cell Fate: The program that determines the morphology and function of the undifferentiated cells in the embryo. ► [morphogenesis](#), ► [cue](#), ► [fate map](#)

Cell Fractionation: Separation of the different subcellular organelles, generally by differential centrifugation, in variable density media. ► [density gradient centrifugation](#), ► [centrifuge](#)

Cell Fusion: Cell fusion is involved in many cellular processes such as phagocytosis, cell migration, axon growth, and synaptogenesis (see Fig. C48). Influenza virus hemagglutinin and HIV1 envelope protein (both class I viral fusion proteins) contain an inner hydrophobic fusion-peptide that requires proteolytic cleavage before insertion into the target membrane. Intracellular vesicles fuse with the aid of α -helical structures upon recognition by Rab GTPases and SNARE effectors. For the formation of muscle fibers, mononucleated myoblasts fuse with the aid of several proteins. During mammalian fertilization a sperm penetrates the outer layer, the zona pellucida of the egg. That is followed by secretion of lysosome-like

enzymes of the acrosome. Then the sperm enters the previtelline layer and the sperm and egg plasma membranes fuse. Although several proteins participate in this process only a tetraspanin, CD9, has played a critical role in the fusion. In the mammalian placenta, fused trophoblasts separate the maternal and fetal tissues. Macrophage fusing generates multinucleated osteoclasts and giant cells. The former ones have a role in bone resorption and the latter, in immune response. Hematopoietic stem cells can fuse with cardiac myocytes, hepatocytes, Purkinje cells and can differentiate in different ways. The formation of hybridomas is based on cell fusion. Somatic gene therapy requires cell fusion. Several different proteins have been implicated in these fusions (Chen EH, Olson EN 2005 Science 308:369).

Somatic cell fusion is also a means to generate somatic cell hybrids. In contrast to hybridization by gametic fusion when the two nuclei fuse but usually only the maternal cytoplasm is preserved, in the fusion of somatic cells the entire content of the cells is combined in the somatic hybrid. For the fusion to take place, polyethylene glycol, a high concentration of calcium or higher pH medium has been used.

Figure C48. Cell fusion

(Inactivated Sendai virus addition also promotes the fusion of animal cells.) Carbon-fiber ultra-microelectrodes may make possible the fusion of selected cells or cells and liposomes. For the selective isolation of somatic cell hybrids both of the two types of cells generally carry recessive mutations that interfere with the survival of the cells on basic media. For example, thymidine kinase-deficient animal cells die because they cannot synthesize thymidylic acid (DNA); hypoxanthine–guanine phosphoribosyl transferase deficient cells cannot make purine nucleotides (DNA). The fused cells being heterozygous are functional at non-allelic loci, and can selectively be isolated in large cell populations. Somatic cell fusion made important contributions to genetics involving human and other animals because it made possible to carry out allelism tests, facilitated the assignment of genes to chromosomes, identified the functional significance of chromosomal regions (in case of deletions). Somatic cells of very distantly related or entirely unrelated organisms, e.g., chicken and yeast, tobacco and humans, human and rodent cells all can be fused although their further division may not usually be possible. Cell fusion has an important role in fertilization and many developmental events under normal conditions (Shemer G et al 2004 *Current Biol* 14:1587). ▶phagocytosis, ▶synaptic vessels, ▶somatic cell hybrids, ▶fusion of somatic cell [photo], ▶protoplast fusion, ▶microfusion, ▶liposomes, ▶radiation hybrids; see terms used under separate entries; Cocking EC 1972 *Annu Rev Plant Physiol* 23:29; Ephrussi B 1972 *Hybridization of Somatic Cells*, Princeton Univ. Press, Princeton, NJ; Hotchkiss RD, Gabor MH 1980 *Proc Natl Acad Sci USA* 77:3553; McKay R 2002 *Nature Biotechnol* 20:426.

Cell Genetics: Nearly all genetics is cell genetics because geneticists generally think at the cellular level; in the narrow sense this term is applied to the genetic manipulations with isolated cells of multicellular organisms. ▶cell fusion, ▶somatic cell hybrids, ▶fusion of somatic cells, ▶mitotic crossing over, ▶transformation, ▶nuclear transplantation; FL-REX; Ruddle FH, Creagan RP 1975 *Annu Rev Genet* 9:407; Puck, 1974 *Stadler Symp* 6:47; Dudits D et al eds. 1976 *Cell Genetics of Higher Plants*. Akad Kiadó, Budapest.

Cell Growth: In any particular time $N = 2^g N_0$ where N is the final cell number, N_0 = the initial number of cells, and g = the time required for a complete cell cycle. This equation is valid as long there is no limitation on multiplication by nutrients, air, differentiation pattern, etc. In the absence of any limitation, cell growth indicates the cell-doubling process. In fact, as in the above statement, growth is frequently used in place of

cell proliferation. Growth really is an increase in volume or size and not in cell number. ▶proliferation, ▶turbidity, ▶plating efficiency, ▶growth retardation

Cell Hybridization: Fusion of somatic cells. ▶cell fusion, ▶cell genetics

Cell Interaction: The influence of cells on each other during differentiation and development. ▶contact inhibition, ▶nurse cells, ▶morphogenesis, ▶maternal effect genes

Cell Junction: The area involved in the connection and communication between and among cells and extracellular matrices. ▶extracellular matrix, ▶morphogenesis, ▶contact inhibition, ▶transmembrane proteins; Tepass U et al 2001 *Annu Rev Genet* 35:747.

Cell Lethal: Mutations may not be isolated or ascertained because of the cells involved cannot live.

Cell Line: A (homogeneous) population of cells (of eukaryotes) that can be maintained in live (growing) conditions. ▶clone, ▶clonal analysis

Cell Lineages: The traces of the path of growth (multiplication) of the cells through several cell divisions (see Fig. C49). The descent of the germline cells or the signs of visible mutations in the somatic tissues is shown by the pattern of the sectors formed in chimeric organisms. In *Caenorhabditis*, the cell lineage development can be detected by automated time-lapse confocal microscopy in 31 planes at 1 μm apart at a resolution of every minute. The SRARRY-NIGHT computer software aids in identification of the lineage from 4 to a 350-cell stage. This is a relatively simple organism where the embryo development from 1–558 cells is completed in 13 h (Bao Z et al 2006 *Proc Natl Acad Sci USA* 103:2707). ▶clonal analysis, ▶fate maps, ▶nondisjunction, ▶phyllotaxis, ▶founder cells, ▶*Caenorhabditis*; Stern CD, Fraser SE 2001 *Nature Cell Biol* 3:E216; Liu YJ 2001 *Cell* 106:259.

Cell Membranes: Membranes surround all cells and inside the cells there are membrane-enclosed bodies (nucleus, mitochondria, plastids, vacuoles, Golgi bodies, dictyosomes, lysosomes, peroxisome). The endoplasmic reticulum, the mitochondrial crests, and thylakoids are all membranous structures. Cellular imports and exports pass through the membranes by active and passive mechanisms (see Fig. C50). The bulk of the plasma membranes consist of proteins and lipids (phospholipids, cholesterol, other sterols and glycolipids, triacylglycerols, steryl esters, etc.). The composition varies in the different organisms and according to the particular membranes. The

C

Figure C49. Cell lineages. Mutation, deletion, nondisjunction during embryogenesis may potentially be identified during and after embryogenesis if the organism is heterozygous for a distinguishable somatic marker(s). (a) Organization of the apical dome of a wheat plant showing diagrammatically the consequence of nondisjunction. (b) In the monocot apex the leaf initials wrap around the central axis and overlap each other; the humps at the leaves indicate the midribs. The oldest leaf initials are outside. Note that the outmost leaf and the one next below it have their midrib at opposite sides. Sector 1 is very narrow at the surface (old) leaf and it becomes wider in the (younger) ones below. Also, the oldest sector is left from the midrib of the first leaf but it is at the right side of the one just below and again at the left side in the third. Sector (2) representing nondisjunction and twin sectors (black and white) occurred only in one leaf because of a tangential event in a region of the embryonal apex. Sector (3) is a late occurring nondisjunction indicated by the narrow twin sectors. (c) Somatic mutation in a single cell of the mature embryo of the dicot *Arabidopsis*. Three leaves displayed white sectors because they differentiated from the same cell line of the apex. Nonsectorial leaves appeared in-between the mutant sectors because of phyllotaxis

Figure C50. Cell membrane

ultra-structure of the various membranes has common features and specificities. The basic structural element is the lipid bilayer of about 5 to 8 nm in thickness. In the double structure the polar head of the lipid face the aqueous environment and the tails inward are hydrophobic.

Unsaturated lipids are concentrated in the inner layer of the structure. The outer surface of the membrane is also different from the inner surface that envelops organelles or vesicles.

The inner side carries on the surface-charged groups, the outward surface may have a variety of peripheral proteins (glycoproteins) that determine the surface antigenicity of the cells. Some other proteins are integral parts of the membrane sunken in the fluid lipid bilayer. The fluidity is somewhat stabilized

by the presence of sterols. The so-called “seven membrane proteins” traverse the lipid bilayer and form within it a cluster of seven folds, the amino end at the outside and the carboxyl end inward. Other transbilayer polypeptides have hydrophilic domains both outside and inside, and outward are ports for communication (ion channels) with special proteins and lipids (transporters, permeases). Some of the peripheral proteins are attached to the membrane by electrostatic forces and H bonds. The proteins are regulators of membrane bound enzymes (e.g., phospholipase C) and mediate signal transduction. Membranes have a flexible structure to curl up into vesicles that ferry within the cell lipids and proteins in a protected manner. The membranes have the ability to fuse with another membrane at the delivery target.

Exocytosis and endocytosis are the means of traffic. Fusion of the egg with the sperm, fusion between protoplasts of plant cells, somatic cell hybridization, protein synthesis within the endoplasmic reticulum, etc., are mediated by membrane functions. Membranes can be targeted through labeled myristoylated and palmitoylated proteins. Such modifications of the membranes may affect the membrane attached G proteins, involved in signal transduction. Ca^{2+} -regulated exocytosis repairs damaged plasma membranes. (See diagram, ►cell structure, ►fatty acids, ►myristic acids, ►lipids, ►prenylation, ►raft; Reddy A et al 2001 Cell 106:157; Maxfield FR 2002 Current Opin Cell Biol 14:483; Veréb G et al 2003 Proc Natl Acad Sci USA 100:8053; Chernomordik LV, Kozlov MM 2003 Annu Rev Biochem 72:175; newer concepts of membrane structure and function in 2005: Nature [Lond] 438:577–621).

Cell Memory: The properties of differentiated cells that they reproduce through numerous cell divisions are similar specialized cells to what they have been committed. ►differentiation, ►morphogenesis, ►memory immunological; Anfossi N et al 2001 Immunol Rev 181:269.

Cell Migration: Common during animal development. Precursors of the blood cells, the germ cells, neurons, cells of the somites, metastasis, immune surveillance, etc., move through the embryo and are guided by cell surface receptor proteins and aided by the extracellular matrix of fibronectin whereas chondroitin sulfate proteoglycan interferes with the movement. The Kit protein in the membrane of the migrating cells and the ligand Steel factor produced by the cells, which are contacted by the migrant also control the movement. During oogenesis in *Drosophila*, EGF receptor signals passed through a TGF- α -like ligand as a guidance cue. Gastrulation requires cell movement of mesodermal cells through the fibronectin-rich matrix in the blastocoele. Contraction of actin and myosin is aided by changes in focal adhesion (Gupton SL, Waterman-Storer CM 2006 Cell 125:1361). CDC42 stimulates actin polymerization in the forward direction of filopodia and Rac aids the formation of lamellipodia. For cell migration in vertebrates, lysophospholipids are important. The Dock2 proteins regulate lymphocyte migration. ►proteoglycan, ►chondroitin sulfate, ►Steel factor, ►EGF, ►TGF, ►KIT oncogene, ►fibronectin, ►tenascin, ►integrin, ►FAK, ►CDC42, ►Rac, ►filopodium, ►lamellipodium, ►microtubules, ►metastasis, ►actin, ►sphingolipids, ►extracellular matrix; Lauffenburger D et al 1996 Cell 84:359; Fukui Y et al 2001 Nature [Lond] 412:826; Ridley AJ et al 2003 Science 302:1704.

Cell Model: Within large groups of the prokaryotic, animal and plant kingdom the cells have some common essential features. Nevertheless, each cell type of the body has special signaling systems and receptors. Special regulatory networks process the signals. The common functional networks determine cell-specific combinations of cellular machines and are responsible for the observed phenotypes and behavior. The complex animal cells contain an estimated $\sim 100,000$ components (protein, lipid, sugar ion, nucleotide) and each interacts with several others creating an almost incomprehensible complexity. To overcome these difficulties a silico system may be employed to study binary interactions and graph theory applied for the analysis. The final goal is to generate predictive models by relying on all the biological, molecular, mathematical tools. ►networks, ►genetic networks, ►signal transduction, ►graph theory; Ma'ayan A et al 2005 Annu Rev Biophys Biomol Struct 34:319.

Cell Numbers: Cell numbers in: a small *Arabidopsis* plant, about 5×10^6 ; in an *Arabidopsis* seed, about 6,000–7,000; in a wheat embryo, 10 days after fertilization, about 40,000, and 150,000 at maturity (including the scutellum); at the surface of a maize endosperm, about 1,400; in the human body, about 6×10^{15} per 60 kg weight (ca. 1 billion per gram tissue) are found (Robert DeMars, personal comm.) The number of cells in a tissue depends on cell division, cell death, and possibly on migration (in animals). The number of cells per particular structure is affected also by cell size. The local number of cells may be controlled by the tissue environment or extrinsic factors. The number of cells depends primarily on the cell divisional cycles, controlled by a large number of hormones and other proteins. Protein p27 in mouse appears to be a potent inhibitor of the growth of the cell number and cell size by controlling cyclin and cyclin-dependent protein kinases. In diploids the body size apparently depends on cell number rather than size (Trump A et al 2001 Nature [Lond] 414:768) but in polyploids the size of the cells is larger. ►cell cycle

Cell Plate: The precursor of a new cell wall in dividing plant cells. ►cytokinesis; Verma DPS 2001 Annu Rev Plant Physiol Plant Mol Biol 52:751.

Cell Receptors: ►receptors, ►transmembrane proteins, ►signal transduction

Cell Sap: The fluid, non-particulate cell content.

Cell Selection: Each cell of a multicellular organism is expected to have the same array of genes. Polyploidy, deletion, aneuploidy and epigenetic alterations, and

other extrinsic factors may bring about differences in the same cell lineage and can generate competition. (See Khare A, Shauly G 2006 Nature Rev Genet 7:577).

C

Cell Sizes: Cell sizes vary a great deal depending on organisms and function. An *E. coli* cell is about $800 \times 2,000 \text{ nm}^2$. Plant and animal cells generally have a diameter of 20 to 60 μm and their length is much more variable. Some fibrous cells may be 20 cm long. Important regulators of cell size are the S6 kinase, PI3-kinase, and the Akt proteins. The upstream binding factor (UBF1) controls the activity of rRNA synthesis. In yeast cells, several regulatory proteins control ribosome biosynthesis and cell size in response to nutritional cues (Jorgensen P et al 2004 Genes Dev 18:2491). In animal cells, the insulin-like growth factor I/insulin receptor substrate I control about 50% of the growth of cell size in culture (Drakas R et al 2004 Proc Natl Acad Sci USA 101:9272). In budding yeast the gene *WHI3* increases the cell size whereas increasing the number of copies of *CLN3* decreases the cell volume. ▶ [S6 kinase](#), ▶ [cell number](#); Conlon IJ et al 2001 Nature Cell Biol 3:918.

Cell Sorter: Cells can be labeled by cognate antibodies coupled with a fluorochrome or by other incorporated material. In a mixture where only one in a few thousands of cells carries this distinctive label, the latter ones can be separated using an electronic device. When a file of cells passes in front of a laser beam the fluorescent cells receive a different electric charge from the unstained ones. The high intensity electric field in the path then separates the positively charged fluorescing cells from the negatively charged (unstained) ones. ▶ [labeling index](#), ▶ [dielectrophoresis](#), ▶ [cell cycle](#), ▶ [fluorochromes](#), ▶ [antibody](#), ▶ [laser](#), ▶ [segregation distorter](#), ▶ [sex](#), ▶ [selection](#); Asai J et al 1999 Clin Neurol Neurosurg 101:229.

Cell, Stem: The stem cells of animals are capable of differentiation into various types of cells. ▶ [stem cells](#)

Cell Strain: Animal cell culture obtained directly or recently from an organism. It usually has a limited, usually less than 50, generation lifespan. These cultures are not immortalized. ▶ [immortalization](#)

Cell Structure: Living cells are very complex and are crowded by a variety of small molecules and large macromolecules, cytoskeletal filaments, and organelles. Membranes separate some of the structures, e.g., as seen in organelles, but other complexes also display microcompartmentation without separating by membranes. The function of molecules differs under crowded conditions as compared to sparse distribution that is encountered when the contents of

cells are extracted. Artificial, synthetic cell models are being generated for better study of the ongoing processes within cells, which are too complex (Long MS et al 2005 Proc Natl Acad Sci USA 102:5920). (See Fig. C51).

Cell Theory: Cell theory was proposed in the nineteenth century. It states that the cells are the elementary units of life, and they can be produced only from preexisting cells by mitosis (or meiosis). Abiogenetic reproduction of cells, assumed to exist in the seventeenth century, has not been shown yet to exist in the present geological period of the earth. ▶ [origin of life](#), ▶ [spontaneous generation](#)

Cell Therapy: Cell therapy refers to the transfer of specific cells to an organ in the body with the purpose of letting them propagate there and restore a defective function. The transplanted cells may cure diseases such as Duchenne muscular dystrophy, or replace degenerated retinal macula or dopaminergic neurons in Parkinson's disease or bone marrow cells to restore the hematopoietic system or Langerhans islets to fight diabetes, etc. Cell therapy may be part of a cancer treatment. Before radiation or chemotherapy, hematopoietic stem cells may be withdrawn, multiplied, and after the anticancer therapy, reintroduced into the body to restore the immune system. ▶ [gene therapy](#), ▶ [cancer gene therapy](#), ▶ [adoptive cellular therapy](#), ▶ [transplantation of organelles](#), ▶ [xeno-transplantation](#), ▶ [stem cells](#), ▶ [muscular dystrophy](#), ▶ [retinal dystrophy](#), ▶ [Parkinson's disease](#), ▶ [hematopoiesis](#), ▶ [diabetes](#); Strom T et al 2002 Curr Opin Immunol 14:601.

Cell Transformation Assays in Genetic Toxicology: Generally, hamster embryo cells or mouse prostate cells are exposed to chemicals and tumorigenicity is tested after introducing the cells into live animals (rodents). In vitro the transformed cell does not grow in monolayer as do normal cells, but rather forms a dense mass or colony on top of the monolayer. Also, the activation of c-oncogenes (AKR, adenovirus) by chemicals is investigated. ▶ [bioassays in genetic toxicology](#)

Cell Wall: Exists in bacteria, fungi, and plants; animal cells are surrounded only by a membrane. The wall is made of polysaccharides, proteins, and lipids in bacteria. In plants the wall is mainly cellulose (polysaccharide), but lignin, (a hard phenylalanine and tyrosine polymer), suberin (a corky wax), and cutin (a fatty acid polymer) also occur. In fungi the wall may also contain chitin, a linear polysaccharide differing from cellulose by a replacement at the C-2 OH group by an acetylated amino group. More than 1,000 gene products are involved in the synthesis of the plant cell wall and its components (Somerville C

Figure C51. Cell structure. Generalized structure of plant and animal cells by light and electron microscopy. The diagrams do not show the cytoskeleton and various microtubules, filaments or transport vesicles

et al 2004 Science 306:2206). In the cell wall of grasses (1,3;1,4)- β -glucan occurs and it is synthesized by a cellulose synthase-like *CsIF* genes (Burton RA et al 2006 Science 311:1940). ►cell wall

Cell-Free Extract: Cell-free extract is prepared by grinding cells (tissues) in a buffer or other solutions and removal of insoluble particulate material by filtration or centrifugation. Such extracts may be used

for enzyme assays or for the purification of soluble cellular constituents.

Cell-Free Protein Synthesis: Refers to in vitro protein synthesis in the presence of ribosomes, mRNA, tRNA, aminoacylating enzymes, amino acids, and all the complex of translation factors and energy donor nucleotides. ►rabbit reticulocyte assay, ►wheat germ assay

Cell-Free Translation: ►cell-free protein synthesis

Cell-Mediated Immunity: ►immune system, ►T lymphocytes

C

Cell-Mediated Mutagenesis: Chemical mutagen activation is provided by the addition of suitable activated (liver) cells as feeders to the culture. These feeder cells may be genetically modified to express high levels of the activating enzymes. ►activation of mutagens, ►host-mediated assay; Rudo K et al 1987 Cancer Res 47:5861; Langenbach R, Nesnow S 1983 Basic Life Sci 24:377.

Cell-Penetrating Peptides (CPPs): CPPs are 11–34 amino acid residues long and are extremely effective in entering cells. This ability includes, also, transport of various cargoes into the cell, and in some instances traversing even the blood-brain barrier. They are (transportan, penetratin, TAT, and MAP) of different length, cargo delivery, and different penetrating abilities (Hallbrink M et al 2001 Biochim Biophys Acta 1515:101). ►BBB, ►nuclear pore, ►CRM1; Zenklusen D, Stutz F 2001 FEBS Lett 498:150; Galouzi I-E, Steitz JA 2001 Science 294:1895.

Cellular Immunity: Cellular immunity is mediated by the T cells and macrophages. ►T cells, ►macrophage

Cellular Transmission of Tumors: Mediated by allografts, lesions, and biting. Thus, the transmissible agent is the tumor cell itself. ►Tasmanian devil, ►canine transmissible venereal tumor, ►cancer

Cellulase: An enzyme digesting cellulose. Generally, a collection of enzymes is used for removal of the cell wall and gaining plant protoplasts, such as the *Onozuka R-10*. ►protoplast, ►macerozyme, ►cellulose

Cellulose: A polysaccharide consisting of glucose subunits. It strengthens the plant cell wall and forms the plant vascular system. Cellulose is synthesized by cellulose synthase. By spinning disk confocal microscopy, its rate and path of deposition in functional association with microtubules could be revealed (Paredes AR et al 2006 Science 312:1491). ►cellulase, ►cell wall; Delmer DP 1999 Annu Rev Plant Physiol Plant Mol Biol 50:245.

Cellulosome: The macromolecular complex that degrades cellulose and associated polysaccharides (Shoma Y et al 1999 Trends Microbiol 7:275).

CEM15: ►APOBEC3G

CEN: the symbol of centromere DNA sequences. ►centromere

Cenancestor: The most recent common ancestor of two taxa. ►taxon

Cenozoic: A geological period dating back to 75 million years ago when mammals and humans appeared. ►geological time periods

CENP: A protein that is diffusely located in the cytoplasm during G2 and prophase. During prometaphase it associates with the kinetochore until metaphase. At anaphase, it is located in the midzone of the spindle and degraded after cytokinesis. ►cell cycle, ►mitosis, ►spindle, ►kinetochore; ►centromere proteins CENP-A, ►CENP-B, ►CENP-C; Fukagawa T et al 2001 Nucleic Acids Res 29L3796.

Censoring: A statistical concept. Censoring may be due to several different events, the trait cannot be classified because of time factors (too early or too late), use of medication conceals the phenotype, etc. In such cases the mean or the variance may be biased.

Centaurea cyanus: Called blue cornflower; its color is due to a complex of six molecules of anthocyanin and flavone complexed with one ferric, one magnesium and two calcium ions in a supermolecular complex (see Fig. C52) (Shino M et al 2005 Nature [Lond] 436:791). ►pyrrolizidine alkaloids

Figure C52. Centaurea

centiMcClintock: Used by some maize geneticist to indicate the length of a chromosome arm; 1 cMC = 1% of the length of a chromosome arm where a particular gene is situated.

Centimorgan: The unit of eukaryotic recombination; 1% meiotic recombination is one map unit (m.u.) = 1 centimorgan (cM) \approx 10 kb DNA in humans. ►recombination frequency, ►mapping genetic, ►mapping function, ►CentiRay

CentiRay (cR): A chromosomal span within which a break can be induced with 1% probability by a specified dose of X-radiation. 1 cR \approx 3×10^4 bp of DNA. ►radiation hybrid

Centisome: A quantitative unit of genomic sites.

Central Body (centrosome): ►centrosome

Central Core Disease (19q13.1): A nonprogressive muscle weakness; the core of the muscle fibers is generally absent. It is a complex disorder with usually ryanodine receptor defects. ►ryanodine

Central Dogma: The concept that the flow of genetic information follows the path DNA→RNA→Protein; it had to be slightly modified by the discovery of reverse transcriptases and ribozymes (see Fig. C53). ▶[ribozyme](#), ▶[reverse transcriptases](#); Crick FHC 1958 Symp Soc Exp Biol 12:138.

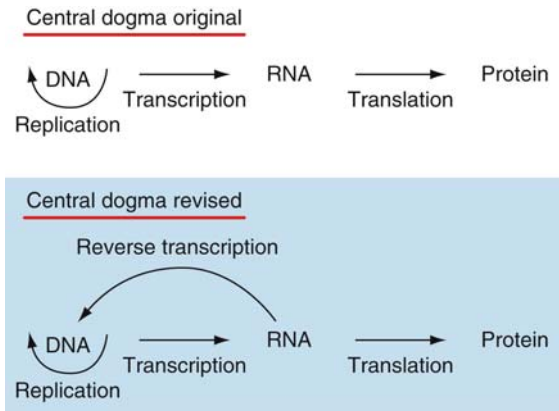

Figure C53. Central dogma

Central Limit Theorem: A variable large sample representing the sum of many components is expected to approach the normal distribution. This basic statistical principle has important implications also for genetics, when population samples and segregation data are evaluated. ▶[normal distribution](#); Klein EK et al 1999 Theor Popul Biol 55 [3]:235.

Central Nervous System: The brain and the spinal cord. ▶[brain human](#)

Central Tendency: A statistical index—such as the median, mean, and mode—of the typical or average distribution of some characteristics of a population. ▶[median](#), ▶[mean](#), ▶[mode](#)

Centric Fusion: The fusion of two telocentric chromosomes into a biarmed single chromosome. ▶[Robertsonian translocation](#), ▶[telocentric chromosome](#), ▶[acrocentric](#), ▶[misdivision](#)

Centric Shift: Changing the position of the centromere and thus the relative arm length of a chromosome by pericentric inversion or transposition. ▶[inversion](#), ▶[transposition](#), ▶[shift](#)

Centrifuge: An instrument for sedimenting or separation of material by centrifugal force according to density. Low-speed centrifuges generally spin the suspended material at less than 5,000–6,000 rpm (revolution per minute), table-top centrifuges usually reach a maximum speed of 10,000–12,000 rpm, high-speed

centrifuges may reach about 20,000 rpm and are usually refrigerated so biological material suffers minimal degradation. Ultracentrifuges, using refrigerated vacuum chambers, may reach much higher speeds and may exceed $300,000 \times g$ force and can separate even molecules. The conversion of revolution per minute into g force is generally done on the basis of tables provided by the manufacturers. The actual centrifugal force $F = \pi^2 S^2 M R / 900$ where $\pi = 3.14159$, S = revolutions per minute, M = the mass in grams and R is the radius in centimeters. It is more convenient to express it as $\times g$ force where $g = 980.665 \text{ cm/s}^2$. Thus, e.g., when the maximal rpm is 20,000, the relative centrifugal force (RCF) may be $41,320 \times g$, but this actually varies from the maximum at the bottom of the centrifuge tube to a lower value at the top, etc. ▶[ultracentrifuge](#), ▶[buoyant density centrifugation](#), ▶[density gradient centrifugation](#)

Centrin: Cellular motor of polar bodies, centrioles. ▶[spindle pole body](#), ▶[mitosis in unicellular protists](#), ▶[spasmoneme](#), ▶[CDC31](#); Middendorp S et al 1997 Proc Natl Acad Sci USA 94:9141; Salisbury JL et al 2002 Current Biol 12:1297.

Centriole: Hollow cylinders formed by nine microtubule triplets surrounded by a dense area in the centrosome. The two centrioles in each centrosome serve as the attachment point for the spindle fibers during nuclear divisions and along with the radial array of microtubules form the two *asters* in animal cells. Centrioles are essential for the formation of centrosomes, cilia and flagella, but are not essential for several aspects of *Drosophila* development (Basto R et al 2006 Cell 125:1375). RanGTP mediates this organization in association with the nucleotide exchange factor RCC1 and other proteins such as γ TurRC (γ -tubulin ring complex) and microtubule-associated protein. The nuclear mitotic apparatus protein (NuMA) is involved in the organization of asters and NuMA also interacts with importin- β , making a link between spindle assembly and nuclear import. ▶[centrosome](#), ▶[centromere](#), ▶[spindle fibers](#), ▶[Ran](#), ▶[RCC1](#); Wiese C et al 2001 Science 291:653; Marshall WF 2001 Curr Biol 11:487; Dammermann A et al 2004 Developmental Cell 7:815; centriole assembly path: Pelletier L et al 2006 Nature [Lond] 444:619.

Centromere: Region of the attachment of chromatids after chromosome replication and of spindle-fiber attachment at the kinetochore (localized within the centromere) during nuclear divisions. The centromere used to be called the primary constriction of the chromosomes because by the light microscopic techniques it frequently appears as a short slender

C

region. (Secondary constrictions mark the juncture of the chromosomal satellites). In some organisms (*Juncaceae*, *Parascaris*, *Spirogyra*, *Scenedesmus*, etc.) the centromeres are “diffuse”, i.e., their position spreads over the length of the chromosome (holocentric, polycentric chromosome). Under some conditions “neo-centromeres” are visible, i.e., the spindle fibers may associate at more than one location within the chromosomes. The cloned centromeric region of yeast extends to a minimum of 150 bp. Although the base sequences in various centromeres of budding yeast are not identical, there is substantial homology. All contain a core (element II) of 83–84 bp that are 93–95% A = T. In addition, there are TCAC and TG identical stretches in flanking element I (11 bp) and on the other flank (element III, ~25 bp) there are GT and TG and T and CCGAA and TAAAA identical sequences that are separated by one to four different bases. The general structure of the yeast centromeres can be represented as shown below.

The regions of the centromere elements (CDEI [8 bp], II [78–86 bp] and III [25 bp]) are less susceptible to nuclease attack than the rest of the chromosomes and this seems to indicate that they are associated with different types of proteins. CDEIII is the site of the centromere-binding factor 3 (CBF3), essential for segregation of the chromosomes.

CDEI contains a nucleotide octamer, similar to the *octa* sequences present in the promoters of several genes where it binds a 39-kDa transcriptional activator protein (Cpflp/CP1/CBF1). The arrangement of these 3 elements is shown (see Fig. C54). Centromere-specific DNAs are not preserved among evolutionarily distant species. The centromeric structure is different in the various eukaryotes and the centromeric activity is epigenetically controlled (Morris CA, Moazed D 2007 Cell 128:647).

Figure C54. Centromere

A number of known proteins, with not entirely known functions, assure the formation of the centromere-kinetochore complex and the attachment of the spindle fiber. The localized centromeres—in contrast to the holocentric ones—may be either *point*

or *regional centromeres*. The point centromere contains about 250 bp, tightly packaged into a nuclease resistant structure and binds only a single microtubule. The point centromere may be arranged around a special nucleosome. Mammalian centromere function depends upon a specialized chromatin organization where distinct domains of CENP-A (centromere-binding protein) and dimethyl K4 histone H3, forming centric chromatin, are uniquely positioned on or near the surface of the chromosome. These distinct domains are embedded in pericentric heterochromatin (characterized by H3 methylated at K9). The mechanisms that underpin this complex spatial organization are unknown. An essential histone variant H2A.Z is a structural component of the centromere. Along linear chromatin fibers H2A.Z is distributed nonuniformly throughout heterochromatin, and centric chromatin where regions of nucleosomes containing H2A.Z and dimethylated K4 H3 are interspersed between subdomains of CENP-A (Greaves IK et al 2007 Proc Natl Acad Sci USA 104:525). The H2B and H4 histones may be altered and another highly variable protein, related to H-3 (Cse4), is present. Cse4 protein apparently interacts with centromere elements I and II, but not III. (Cse4 is an exclusively centromeric protein in *Saccharomyces* like the Cid [centromere identifier] in *Drosophila* or HCP-3 in *Caenorhabditis*). At the centromere a specific histone CenH3 replaces the regular H3 histone (see Fig. C55). The H3.3 histone replaces histones displaced by replication and it serves as a marker for transcribed regions (Henikoff S et al 2004 Trends Genet 20:320).

H-3-like histones are also present in the nucleosomes at the holocentric chromosomes of *Caenorhabditis*. The latter assists chromosome segregation. Point centromeres are found in yeasts (*Saccharomyces cerevisiae*, *Schizosaccharomyces uvarum*, *Kluyveromyces lactii*).

The regional centromeres may consist of several kilobases and may be quite polymorphic. Actually, the *Schizosaccharomyces pombe* centromere is more similar to the mammalian centromeres than to that of the budding yeast. The *S. pombe* centromeres vary between 40 and 100 kb and the core of 4–7 kb may be surrounded by direct and inverted repeats. There is a larger array of proteins associated with the regional centromeres. In the majority of higher organisms the centromere is surrounded by heterochromatin and apparently not transcribed. The budding yeast centromeric DNA (CEN) in chromosome 3 (CEN3) appears to contain an open reading frame capable of coding for a peptide of 52 amino acids. There is no

Figure C55. Centromere, structure. Nucleotide sequences of chromosome 3 centromeric region (627 bp) of yeast. (From Clark L et al 1981 Stadler Genet Symp 13:9)

evidence for transcription to take place, however, in the centromere. Actually, this heterochromatic region suppresses the expression of open reading frames even if they are transposed or inserted in this region, indicating that “silencing” may be essential for the proper function of the centromere in chromosome disjunction. This earlier view may require revision now because in the five centromeric regions of *Arabidopsis*, especially of centromeres 2 and 3, not just transcription but transcriptional hot spots were detected in both strands of the DNA. The transcribed tracts were transposons, retrotransposon-like sequences, but also unique DNA (Yamada K et al 2003 Science 302:842).

The centromeric Swi6p (yeast), HP1 (mammalian) proteins are repressors and *Drosophila* protein *Pc* (*Polycomb*) is a negative regulator of the *Bithorax* (*BXC*) and the *Antennapedia* (*ANTX*) complexes. In the *Drosophila* centromeric region, the 220 bp Bora Bora complex sequences, flanked either 5' or 3' by about a 200 bp “simple” sequence, have been identified. The former is believed to contribute to the kinetochore formation, the latter may control sister chromatid association. The centromeres of mammals display considerable variations and larger

number of proteins including centromere-binding proteins (CENP-A, -B, -C, -D, the kinesin-related MCAK and CENP-E, dynein, INCENPs [move to the microtubules in mitosis], etc). In the centromeric region of a wide range of organisms, a special histone-3-like protein (CENP-A) is present in the nucleosomes and it replaces histone-3 (H3). This protein is presumed to mark the centromere in higher organisms because this appears to be a common feature in yeast to mammals (Lee H-R et al 2005 Proc Natl Acad Sci USA 102:11793). In higher organisms there is no DNA consensus for the centromeric region, unlike budding yeast where a unique, about 125-bp sequence, specifies the centromere. Heterochromatin—usually surrounding the centromere—does not appear to convey determination because the neocentromeres are not heterochromatic.

The centromeres may also have functions during interphase. In the human centromere, the common H3 histone is replaced by a variant CENP-A. In the centromeric chromatin, H3 and CENP-A are interspersed. In human and *Drosophila* centromeric chromatin (CEN), both CENP-A and H3 are dimethylated at lysine 4 sites. This chromatin is continuous across the whole centromeric site and it is different

C

from the common chromatin. CEN chromatin is flanked by heterochromatin with H3 lysine sites di- or tri-methylated. The human centromeric region contains a higher order of 171-bp monomeric tandem repeats, the so-called α -satellite and noncentromeric DNA. The antifungal protein, blasticidin, gene was expressed at sites binding CENP-A but not at H3 methylated at lysine 9, indicating that the formation of CEN chromatin within a repetitive DNA does not prevent gene expression (Lam AL et al 2006 Proc Natl Acad Sci USA 103:4186).

In human cells the centromeres seem to be associated with the nucleolus during interphase. The fact that the centromeres are different yet functional when interchanged seems to indicate that the differences are not all functional specificities. The centromeric DNA in fission yeast is quite different from those of budding yeasts and shows more similarity to the centromeres of higher eukaryotes that are many times larger. The centromeres of higher eukaryotes are composed of repeated sequences and some losses may not necessarily affect the transmission of the chromosomes. Sequencing of the human centromeric regions was difficult because of the extensive duplications. The primate centromeric region repeatedly expanded in central active region during evolution (Schueler MG et al 2005 Proc Natl Acad Sci USA 103:10563). The telocentric chromosomes generated by misdivision usually have impaired transmission and the same is true for the B chromosomes that are prone to nondisjunction.

Recombination is usually much reduced in the centromeric regions. The centromeres contain relatively few genes and pseudogenes, although in *Arabidopsis*, 5 and 12 genes per 100 kb were suggested in two centromeric regions in contrast to 25/100 kb in the normal arms. These genes seem to encode functions of mobile elements, tRNA, regulatory activity and also metabolic steps. Although genes within heterochromatic regions are suppressed, there is evidence for the transcription of some of the genes. The CEN regions include 180-kb repeats.

Although prokaryotes do not have structures exactly homologous to the eukaryotic centromere, the partitioning site of the plasmid DNA (involved in the distribution of the replicated DNA ring) has been called centromere. This partitioning site, *parS*, forms a module including protein ParA (an adenosine triphosphatase) and ParB (a *ParS*-binding protein). Similar to the eukaryotic centromere, prokaryotic genes on the flanks of *ParS* may be silenced.

The availability of cloned centromeric DNAs permitted the construction of yeast artificial chromosomes (YACs). These YACs, when properly constructed (see YACs and yeast centromeric vector), can

be subjected to tetrad analysis. YACs are very useful tools for the physical mapping of larger DNAs. Centromeric proteins determine chromosome segregation and regulate the difference between anaphase I and anaphase II disjunction of chromosomes and chromatids, respectively. ▶mitosis, ▶meiosis, ▶tetrad analysis, ▶centromere mapping, ▶YAC, ▶kinetochore, ▶aster, ▶spindle fibers, ▶microtubule, ▶Roberts syndrome, ▶octa, ▶kinesin, ▶dynein, ▶ α satellite, ▶yeast centromeric vector [for nucleotide sequences], ▶neocentromere, ▶holocentric chromosome, ▶telochromosome, ▶misdivision, ▶centromere A protein, ▶passenger proteins, ▶B chromosome, ▶sister chromatid cohesion, ▶heterochromatin, ▶histones; Copenhaver GP et al 1999 Science 286:2468; Dobie KW et al 1999 Curr Opin Genet Dev 9:206; Gindullis F et al 2001 Genome Res 11:253; Sullivan BA et al 2001 Nature Rev Genet 2:584; Choo AKH 2001 Developmental Cell 1:165; Hennikoff S et al 2001 Science 293:1098; Schueler MG et al 2001 Science 294:109; Hudakova S et al 2001 Nucleic Acids Res 29:5029; Smirnova JB, McFarlane RJ 2002 J Biol Chem 277:19817; Smith MM 2002 Current Opin Cell Biol 14:279; Blower MD et al 2002 Developmental Cell 2:319; Hall IM et al 2003 Proc Natl Acad Sci USA 100:193; human pericentromeric regions: She X et al 2004 Nature 431:857; centromeric proteins: Shueler MG, Sullivan BA 2006 Annu Rev Genomics Hum Genet 7:301.

Centromere A Protein (CENP-A): A 17-kDa histone 3-like protein and part of the centromeric nucleosomes. Its disruption or loss severely affects mitosis and causes fragmentation of the chromatin. Its normal role is to mark centromere organization in the chromosome. ▶centromere, ▶centromere B protein, ▶centromere C protein, ▶CENP, ▶histones; Murakami Y et al 1996 Proc Natl Acad Sci USA 93:502; Sugimoto K et al 2000 Cell Struct Funct 25:253.

Centromere Activation: Transposition of the centromere to a new position within the chromosome. ▶neocentromere, ▶centromere, ▶holocentric

Centromere B Protein (CENP-B): 80 kDa and it binds to the 17-bp CEN-B box that is present in human α -satellite and the mouse minor satellite DNA. CENP-B is not life-essential for mouse yet it leads to lower body weight and testis size. ▶centromere, ▶CENP-A, ▶CENP-C, ▶CENP, ▶ α -satellite DNA; Chen C et al 1999 Mamm Genome 10:13.

Centromere C Protein (CENP-C): 140 kDa; it apparently binds DNA and is essential for embryo survival in mouse beyond 3.5 days after conception. ▶centromere, ▶CENP-A, ▶CENP-B, ▶CENP; Pluta AF et al 1998 J Cell Sci 111 [pt14]:292; Fukagawa T et al 2001 Nucleic Acids Res 29:3796.

Centromere Index: The length of the short arm divided by the length of the entire chromosome $\times 100$.
 ▶ chromosome arm

Centromere Mapping in Fungal Tetrads: ▶ tetrad analysis

Centromere Mapping in Higher Eukaryotes: In heterozygous autotetraploid (triplex: AAAa) or trisomic (duplex AAa) progenies, the greater the proportion of recessive individuals for a particular marker the further is that locus from the centromere because only crossing over between gene and centromere (maximal equational segregation) can produce double recessive gametes. Thus, in very large populations the relative distances can be estimated (see Fig. C56). More precise estimates of gene centromere distance can be obtained in allopolyploids by using telochromosomes that are usually not transmitted through the pollen. The experimental design may be as follows (only one pair of chromosomes is shown in the diagram).

The centromeres of the chromosomes of rice were mapped using RFLP markers in telo- and isotrisomics. The distance was calculated on the basis of linkage intensities of markers on the opposite sides of the centromere, inferred by gene dosage. In mouse, Robertsonian translocations can be exploited for centromere mapping. In most eukaryotes the centromeric region has repeated sequences and these can also be used for centromere mapping of RFLPs. ▶ allopolyploid, ▶ telochromosome, ▶ tetrad analysis, ▶ half-tetrad analysis, ▶ trisomic analysis, ▶ Robertsonian translocation, ▶ maximal equational segregation, ▶ RFLP; Sears ER 1966 Hereditas, 2:370.

Centromeric Fission: ▶ misdivision of the centromere, ▶ telochromosome

Centromeric Fusion: The joining of two telocentric chromosomes into a single bi-armed one.

Centromere Silencing: Through breakage-fusion-bridge or neocentromere formation a single chromosome may acquire more than one centromere. In a maize study, 6/23 chromosome derivatives of breakage-fusion-bridge cycle (between a B chromosome and chromosome 9) contained two centromere-specific

regions (detected by immunolabeling) and were mitotically stable despite expectation according to the notion that dicentric chromosomes so derived would show bridge and breakage. This observation indicates that centromere inactivation may be common in plants (Han F et al 2006 Proc Natl Acad Sci USA 103:3238). ▶ B chromosomes, ▶ breakage-bridge-fusion cycles

Centromeric Vector: ▶ YAC

Centrosome: The center ($\sim 1 \mu\text{m}$) where spindle fibers (microtubules) originate (a microtubule organizing center, MTOC) and develop from a pair of centrioles toward the centromeres during nuclear divisions in animals (and few lower plants). In normal mammalian cells there are two centrosomes at the opposite poles (see Fig. C57). The mother centrosome normally remains anchored to the hub of the *Drosophila* germ stem cell interface and is inherited by the stem cell, whereas the daughter centrosome moves away from the hub and is inherited by the cell that commits to differentiation (Yamashita YM et al 2007 Science 315:518). In the human mammary epithelial cells there may be split centrosomes as an anomaly. Loss of p16^{INK4a} causes splitting of the centriole that can lead to the formation of aneuploidy and genomic instability because multipolar mitoses may take place. Normally, p16^{INK4a} in cooperation with p21 regulate cyclin-dependent kinases and prevent the splitting of the centriole. Such a condition may lead to tumorigenesis. In the mammalian female, meiosis centrosomes are lacking and the chromosomes nucleate and stabilize the bipolar spindle. This task is performed by the *chromosomal passenger complex* containing the Dasra A and B proteins, INCENP (inner centromere protein), Survivin, and the Aurora kinase (Sampath SC et al 2004 Cell 118:187). Ubiquitination and deubiquitination enzymes are required for the association and dissociation of Survivin to the centromeres for chromosome alignment and segregation (Vong QP et al 2005 Science 310:1499). In case the spindle emanates from the centrioles, Ran GTPase releases factors from a pool sequestered by β -importin required for activation of spindle assembly. A pericentriolar material made of γ -tubulin and Asp (asymmetric spindle) protein of 220 kDa surrounds

C

The frequency of chromosomes of constitution indicates the frequency of recombination between locus A and the centromere (●) in the male

Figure C56. Centromere mapping in wheat

C

Figure C57. Centrosome

the centrioles. The γ -globulin ring complex (γ -Turc) can fulfill its function even when it is outside the centrosome (Müller H et al 2006 Science 314:654). Asp has phosphorylation sites for p34 and other mitogen-activated kinases as well as binding domains for actin and calmodulin. The fast growing (plus) ends of the microtubules project into the cytoplasm whereas the slow-growing (minus) ends are embedded into the γ -globulin ring. MAPs (microtubule-associated proteins) are also required for the nucleation at the centrosomes. The division of the centrosome (also called centrosome cycle) is essential for the completion of the cell cycle in animals and it may be blocked by mutation in gene *cdc31*. For the initiation of the division of the centrosome in *Xenopus*, egg calcium, calmodulin and calcium/calmodulin-dependent protein kinase II are required (Matsumoto Y, Maller JL 2002 Science 295:499). The aurora-2/STK15 serine/threonine kinase (encoded in human chromosome 20q13.2) is associated with the centrosome and its amplification interferes with the normal function of the centromere resulting in aneuploidy in common cancer cells. The PML protein also regulates centrosome duplication by suppression of the Aurora protein (Xu Z-X et al 2005 Mol Cell 17:721). CDK2-cyclin E may cause abnormally high proliferation of the centrosomes as it phosphorylates nucleophosmin, a centrosomal protein. Hsp90 is also a component of the centrosomal core, along with several other proteins. The deficiency of the p53 tumor suppressor protein results in multiple centrosomes and unequal distribution of chromosomes. Similar are the consequences of defects in PLK1 and an ataxia telangiectasia (*rad3*)-related (ATR) mutation. Plants do not have such distinct structures. Recently, mutations affecting the centrosomes have been isolated. The centrosome is paternally derived during fertilization in the majority of the animal species. Depending on the sperm donor, the size of the

aster may vary. The centrosome is required also for DNA synthesis during the cell cycle. Defect of centrosomes may lead to aneuploidy and cancer and centrosome anomalies contribute to several human diseases (Badano JL et al 2005 Nature Rev Genet 6:194). ▶mitosis, ▶centrioles, ▶p16^{INK4}, ▶p21, ▶centromere, ▶spindle, ▶microtubule, ▶nucleation, ▶kinesis, ▶dynein, ▶importin, ▶RAN, ▶spindle pole body, ▶aster, ▶centrosomin, ▶multipolar spindle, ▶Cdk; ▶p34, ▶actin, ▶calmodulin, ▶p53, ▶Hsp90, ▶aneuploidy, ▶survivin; ▶aurora, ▶promyelocytic leukemia; Brinkley BR 2001 Trends Cell Biol 11:18; Stearns T 2001 Cell 105:417; Bornens M, Piel M 2001 Curr Biol 12:R71; Bornens M 2002 Current Opin Cell Biol 14:25; Meraldi P, Nigg EA 2002 FEBS Lett 521:9; Andersen JS et al 2003 Nature [Lond] 425:570; centrosome-centriole duplication: Leidel S, Gönczy P 2005 Developmental Cell 9:317.

Centrosomin: One of the essential protein components of the centrosome. ▶centrosome; Vaizel-Ohayon D, Schejter ED 1999 Curr Biol 9:889.

CEPH (Centre d'Étude du Polymorphisme Humain): A France-based research institute located in Paris, where human cell lines are collected and maintained from four grandparents, two parents and their multiple children in order to map their genes and study their transmission. The institute is involved in the study of the human genome. (See <http://www.cephb.fr>).

Cephalic: Involves the head or indicates the direction toward the head.

Cephalohepatorenal Syndrome: ▶Zellweger syndrome

Cephalosporin Type Antibiotics: These antibiotics derived their name from *Cephalosporium acremonium* and include a number of natural and semi-synthetic antibiotics. The latter may be resistant to the enzyme penicillinase. Their action involves interference with the cross-linking of the peptidoglycans of the bacterial cell wall. ▶ β -lactamase, ▶lactam, ▶antibiotics, ▶penicillin; Clin Microbiol Infect 2000 Suppl. 3:1.

Ceramides: Ceramides are structural units of sphingolipids, a fatty acid attached by $-NH_2$ linkage to a sphingosine molecule. Ceramides mediate stress responses, apoptosis, cell cycle arrest, and senescence. ▶sphingolipids, ▶Farber's disease, ▶CAP [ceramide activating protein]; Hannun YA, Luberto C 2000 Trends Cell Biol 10:73.

Cerberus: A factor expressed in the organizer of *Xenopus* embryos, causing the development of

ectopic heads, duplicated hearts and livers. (It was named after the mythological three-headed monster guarding the gate of the underworld). ►organizer, ►ectopic expression

Cercopithecidae (Old World monkeys): *Allenopithecus nigroviridis* 2n = 48; *Cercocebus torquatus* 2n = 42; *Cercopithecus aethiops sabaeus* 2n = 60; *Cercopithecus ascanius* 2n = 66; *Cercopithecus cephus* 2n = 66; *Erythrocebus patas* 2n = 54; *Macaca fascicularis* 2n = 42; *Macaca mulatta* 2n = 42; *Miopithecus talapoin* 2n = 54; *Papio* spp. 2n = 42; *Presbytis melalophos* 2n = 44; *Presbytis senex* 2n = 44. ►primates

Cerebellum: A hind part of the brain supposed to be involved in the coordination of movements. Recent information indicates that the cerebellum acquires and discriminates among sensory informations rather than directly controlling movements. The Purkinje cells in the cortex are involved in the information output. Each Purkinje cell is innervated by the *mossy fiber system* (up to 200,000 parallel fibers originating from the deeper layers of the cerebellum) and by a single *climbing fiber* originating from the oliva (a mass of cells) below the surface of the cerebellar cortex. ►Purkinje cells, ►cerebrum, ►brain human

Cerebral Cholesterinosis (CTX): Human chromosome 2q33-qter, recessive deficiency of sterol-27 hydroxylase, mitochondrial P-450 and other mitochondrial proteins as well as adrenodoxin reductase cause lipid (cholesterol) accumulation in the tendons, brain, lung, and other tissues. ►mitochondria, ►cholesterol, ►adrenodoxin; Rosen H et al 1998 J Biol Chem 273:14805.

Cerebral Gigantism (Sotos syndrome): A rare autosomal dominant (5q35, 3p21 or 6p21) condition involving excessive bone growth, dysmorphism, and usually mental retardation. Male-to-male transmission is predominant because of paternal microdeletions or chromosome rearrangements. ►mental, ►retardation; Douglas J et al 2003 Am J Hum Genet 72:132; Miyake N et al 2003 Am J Hum Genet 72:1331.

Cerebral Palsy: ►palsy

Cerebro-Costo-Mandibular Syndrome (CCMS): A mental retardation accompanied by defects of the palate, small jaws (micrognathia), misplaced tongue (glossoptosis), rib-vertebral malformation (costovertebral abnormality), and other anomalies. Autosomal dominant or recessive inheritance may be involved. (See Plotz FB et al 1996 Am J Med Genet 62:286).

Cerebro-Oculo-Facio-Skeletal Syndrome (COFS, 10q11): A recessive, progressive brain (microcephaly, atrophy), eye and joint anomaly with resemblance to the Cockayne syndrome and to the CAMFAK syndrome. Defective nucleotide exchange repair may be involved. ►Cockayne syndrome, ►Martsolf syndrome, ►CAMFAK, ►CAHMR; Graham JM et al 2001 Am J Hum Genet 69:291.

Cerebrosides: Cerebrosides are sphingolipids; sugars linked to a ceramide. In the membranes of neural cells the sugar is generally galactose and in other cell membranes it is generally glucose. ►sphingolipids

Cerebrotendinous Xanthomatosis: Same as cerebral cholesterinosis.

Cerebrum: The major part of the brain in two lobes, filling the upper part of the cranium. ►brain, ►human, ►cerebellum

Cerenkov Radiation: Cerenkov radiation occurs when charged particles pass through an optically transparent material at speed exceeding that of light causing emission of visible light. Cerenkov radiation is used in high-energy nuclear physics, and also in molecular biology, for the detection of charged particles and to measure their velocity.

Cernunnos: ►XRCC

Ceroid Lipofuscinosis (NCL): Ceroid Lipofuscinosis is, apparently, autosomal recessive (assigned to several chromosomes). Brown ceroid (wax-like) deposits in several internal organs, including the nervous system, causes spasms and mental retardation. The infantile subtype (CNL1) was located to chromosome 1p32 and it involves rapidly progressing mental deterioration due to a deficiency of palmitoyl protein thioesterase. Its prevalence is about 1/12,500. CNL3 (16q12.1) or Batten disease/Vogt-Spielmeyer disease involves neuronal degeneration, loss of brain material, and retinal atrophy. The affects are either a lysosome-associated membrane protein or neuronal synaptophysin. Its prevalence at live birth is $\sim 4-5 \times 10^{-6}$ to 5×10^{-5} . CLN2 (11p15.5, Jansky-Bielschowsky disease) is a late juvenile type. The late-infantile neuronal ceroid lipofuscinosis (CLN5, 13q22) was attributed to a pepstatin-insensitive lysosomal peptidase or lysosomal transmembrane protein. CLN6 (15q21-q23) is another late infantile form. Some other variants with granular osmiophilic deposits and others have also been described. ►epilepsy, ►mental retardation, ►prevalence, ►pepstatin, ►Batten disease, ►synaptophysin, lipofuscin; Lehtovirta M et al 2001 Hum Mol Genet 10:69; Gao H et al 2002 Am J

Hum Genet 70:324; Batten disease: <http://www.ucl.ac.uk/ncl/>.

C

Certation: Competition among elongating pollen tubes for fertilization of the egg. Genetically-impaired pollen tubes are at a disadvantage and this may cause a distortion of the phenotypic ratios because certain phenotypic classes may not appear, or may appear at a reduced frequency. ▶[gametophyte](#), ▶[gametophyte factor](#), ▶[male sterility](#), ▶[cytoplasmic male sterility](#), ▶[segregation distortion](#), ▶[selection conditions](#), ▶[meiotic drive](#), ▶[last-male sperm precedence](#); Nilsson H 1915 Lunds Univ. Aarskr. N.F. Adf.2 (12):1; Konishi T et al 1990 Jap J Genet 65:411.

Ceruloplasmin: A blue copper-transporting glycoprotein in the vertebrate's blood. It is located in human chromosome 3q. ▶[aceruloplasminemia](#), ▶[Wilson's disease](#)

Cervical Cancer: Cervical cancer appears to be associated with infection by the human papilloma virus, however, there seems to be a genetic predisposition to susceptibility. Vaccine has been approved for protection. ▶[papilloma virus](#), ▶[Pap test](#), ▶[uterus](#)

Cervix: ▶[uterus](#)

Cesium: An alkali-metal element; its salts CsCl (MW 168.4) and Cs₂SO₄ (MW 361.9) are used as density gradient solutions for preparative and analytical ultracentrifugation, respectively. ▶[ultracentrifugation](#), ▶[buoyant density](#)

CETP (cholesterylester transfer protein): Mediates the catabolism of HDL and the transfer of cholesterol to the liver, and may be thus antiatherogenic. ▶[HDL](#), ▶[atherosclerosis](#)

Cetyl Trimethylammonium Bromide (CTAB): A detergent suitable for the precipitation of DNA. Generally used in a stock solution in 0.7 M NaCl. (See formula at CTAB).

Cetylpyridinium Bromide (CPB): A cationic detergent used for the precipitation of (radiolabeled) oligonucleotides.

CFP (cyan fluorescent protein): CFP can be used for in vivo staining and detected by FRET microscopy. ▶[FRET](#); Galperin E, Sorkin A 2003 J Cell Sci 116:4799.

CFTR (cystic fibrosis transmembrane conductance regulator): ▶[cystic fibrosis](#)

CFU (colony-forming unit): Number of cells/mL capable of propagation in in vitro culture. ▶[pfu](#)

CG: Dinucleotide is where the cytosine is most commonly methylated in vertebrates. The so-called

maintenance methylase enzyme acts on it when paired in a complementary manner in the DNA. The methylation may be transmitted through DNA replication. ▶[methylation of DNA](#)

CGAP (cancer gene anatomy project): The cancer gene anatomy project attempts to identify the function(s) of all human genes, one time estimated to be 60,000 to 150,000. The number now appears to be ~30,000—or less. (See <http://www.ncbi.nlm.nih.gov/ncicgap/>).

CGH: ▶[comparative genomic hybridization](#)

CGIAR: An international food and agricultural policy institute.

cGMP: A cyclic guanosylmonophosphate, a second messenger. Cyclic-di-GMP is a ubiquitous second messenger in bacteria. It is synthesized by a soluble guanylyl cyclase enzyme (sGC). ATP inhibits this enzyme through binding to an allosteric purinergic site of the protein. sGC is an intracellular sensor of ATP that couples nitrogen oxide-dependent cell functions with metabolic and energetic signaling. ▶[cAMP](#), ▶[second messenger](#), ▶[nitric oxide](#); Ruiz-Stewart I et al 2004 Proc Natl Acad Sci USA 101:37; Jena U, Malone J 2006 Annu Rev Genet 40:385.

C2H2: A ubiquitous zinc-finger regulatory protein domain.

CH₅₀: An *in vitro* assay for the activity of the complement. ▶[complement](#)

Chaetae: The bristles of insects and sensory organs of the peripheral nervous system (see Fig. C58). The large ones called macrochaetae are mechanical sensory organs and the smaller ones of different types are microchaetae (a fraction of them are chemoreceptors). ▶[tormogen](#), ▶[trichome](#), ▶[microchaetae](#)

Figure C58. Chaetae

Chagas Disease: A nonhereditary potentially fatal disease caused by infection by *Trypanosoma cruzi*. ▶[Trypanosoma](#), ▶[paratransgenic](#), ▶[kinetoplast](#); Cohen JE, Gürtler CE 2001 Science 293:694.

Chain-Sense Paradox: Expresses the problem of conformational switch from B to Z DNA. ►DNA types

Chain Shuffling of antibodies: ►phage display

Chain Termination: ►transcription termination and nonsense codons, ►initiator codon, ►DNA sequencing (Sanger method)

Chalaza: The site on the plant seed where the funiculus unites with the ovule. Points in the bird eggs where the yolk is connected to the eggshell. ►hilum

Chalcones: Phenylalanine is converted to *trans*-cinnamic acid and cinnamoyl-CoA that, through a condensation reaction, yields chalcone (see Fig. C59). A series of other plant pigments (flavonones, flavones, flavonols, anthocyanidins, etc.) are derived through single gene-controlled biochemical steps. The Rs in the formulas (see diagram) stand for, H, OH, CH or OCH₃ residues, respectively, in the different pigments. ►*trans*-cinnamic acid, ►anthocyan

Chalones: Chalones are water-soluble glycoproteins which can inhibit mitosis.

Chambon's Rule: Splice points at the ends of intervening sequences are generally GT.....AG (except in tRNA genes and other minor classes of genes). ►introns, ►splicing

Chameleon Proteins: Chameleon proteins contain a short amino-acid sequence that may fold either as an α -helix or a β -sheet depending on its position. ►protein, ►structure

Chanarin-Dorfman Disease (ichthyotic neutral lipid storage disease, CDC, human chromosome 3p21):

A triglyceride storage disease with defective long-chain fatty acid oxidation. The basic defect involves an esterase/lipase/thioesterase protein. Within the cells, triacylglycerol droplets are found and liver, muscle, eye anomalies may accompany ichthyosis. ►ichthyosis; Lefèvre C et al 2001 Am J Hum Genet 69:1002.

Chance: Statistical probability or uncertainty. ►probability, ►likelihood

Change of State: Different levels of methylation of a genetic sequence. ►Spm

Channel: A path through which signals (molecules) can be transmitted. ►hemichannel

Channeling (tunneling): The transfer of a common metabolite between two enzymes in a sequential and parallel function (see Fig. C60). For e.g., a mutation may shut down (✋) the carbamyl phosphate pool leading to arginine synthesis but an overflow through a "tunnel" from the carbamyl phosphate precursor in the pyrimidine pathway may substitute for the defect and eliminate the dependence on exogenous arginine because of the channeling (\Rightarrow) of the accumulated carbamyl-P_{pyr} into the arginine pathway when another mutation blocks (✋) the pyrimidine path. Tryptophan synthase, glutamine phosphoribosylphosphate amido-transferase and asparagine synthetase, and other multi-functional enzymes also display this phenomenon. Channeling may go both ways between two metabolite pools. ►regulation of gene activity; Ovádi J, Srere PA 2000 Int Rev Cytol 192:255; Huang X et al 2001 Annu Rev Biochem 70:149.

Channeling: Channeling is the topologically constrained intramolecular recombination of transposons. Such

Figure C59. Chalcones and related pigments

Figure C60. Channeling

an event may lead to the formation of a new element rather than to its destruction.

Channelopathy: ►ion channels

Chaos: A system extremely sensitive to minute perturbations, that are also called the “butterfly effect.” Although in common usage of the word chaotic conditions are meant to be uncontrollable and unpredictable because many degrees of freedom should be dealt with simultaneously. There are, however, high dimensional systems where the “attractor” (the dynamics) is low dimensional. Among the infinite varieties in the system, one can be selected and stabilized by minute changes in one parameter. The task is to locate the critical points in a multitude of “noise.” Various mathematical algorithms have been worked out to deal with the problems. Systems of chaos are characterized by nonlinear dynamics. The control of chaotic systems have great relevance to biology and genetics where a large number of genetic (epistatic), epigenetic and environmental factors interact, such as the chaos in the heart, the neuronal information processing, epileptic seizures, development, differentiation, etc. Chaos control (anticontrol) may then be applicable to harness the system and manipulate controls over it even when all the details are not understood. ►fractals, ►algorithm; Williams GP 1997 *Chaos theory tamed*. Taylor & Francis, Bristol, Philadelphia; Bar-Yam Y 1987 *Dynamics of complex systems*. Addison-Wesley, Reading, Massachusetts.

Chaotrope: The interaction between ion-protein complexes is more attractive than uncomplexed proteins. This is also called salting-out. When the interaction between protein-ion complexes is more repulsive (kosmotrope) than in uncomplexed proteins, salting-in is observed. (See Curtis CA et al 2002 *Biotechnol Bioeng* 79:367)

Chaperone: A protein mediating the conformational change or assembly of polypeptides (usually) without becoming a permanent part of the final product (e.g., the heat-shock protein families Hsp70 and Hsp 60,

rubisco, etc.). Their major function is prevention of inappropriate conformation, aggregation, and interaction with incorrect ligands. Chaperones may restore to native conformation some aggregates in case the denaturation is not irreversible. In eukaryotes, a class of chaperones (CLIPS) is engaged in folding the nascent proteins or the newly misfolded ones and another group of chaperones assist in the restoration or disposal of environmentally damaged proteins (Albanèse V et al 2006 *Cell* 124:75). The chaperones come in greatly different molecular sizes that are shown in their designation (in kDa). snRNAs may mediate the folding of rRNAs (Weeks KM 1997 *Curr Opin Struct Biol* 7:336). An RNA-dependent ATPase may chaperone RNAs (Mohr S et al 2002 *Cell* 109:769). The heat-shock proteins may also play a role in signal transduction by modifying the folding of steroid hormone receptors. The chaperones may be classified into the Hsp70 (heat-shock protein 70) and into the chaperonin families such as the Hsp60s. Hsp60 also mediates regeneration from blastema. The chaperones recognize short extended polypeptides rich in hydrophobic residues that are released upon ATP hydrolysis. Chaperones may facilitate protein degradation within the cells. The chaperonins are large oligomeric ring complexes. The mitochondrial proteases (Lon, Apg3p, Rca1p) can carry out chaperone functions and assemble mitochondrial proteins. The small *intramolecular chaperones* (IMC) are different from the *molecular chaperones* inasmuch as they do not require ATP for folding, are very highly specific and not reusable, and can change the structure of mature proteins. Misfolding of proteins may lead to the development of Alzheimer’s disease, prions, etc. ►heat-shock proteins, ►HSE, ►chaperonins, ►Hsp70, ►HSP, ►DnaJ, ►GroEL, ►flexer, ►PDI, ►PPI, ►CLIPS, ►antichaperone ►protein folding, ►prion, ►cue, ►trigger factor, ►Alzheimer’s, disease, ►prion, ►blastema; Ellis RJ, van der Vies SM 1991 *Annu Rev Biochem* 60:321; Frydman J 2001 *Annu Rev Biochem* 70:603; Dobson CM 1999 *Trends Biochem Sci* 24:329; Rutherford SL 2003 *Nature Rev Genet* 4:263.

Chaperonins (cpn): Ring proteins (chaperonin 60 and 10) mediate the assembly of 12 identical phage (λ, T4, T5)-encoded polypeptides and these serve as the template for lining up the phage head precursors. Chaperonin 10 releases the phage proteins from chaperonin 60 (see Fig. C61). Homologous proteins occur in bacteria and mitochondria and chloroplasts of eukaryotes. Their most essential function is (generally ATP- and K⁺-dependent) folding of proteins. The best known chaperonin proteins belong to two families: the GroEL/GroES (include Hsp60 and rubisco binding proteins) and the TRiC. These

Figure C61. Chaperonin

form a porous cylinder of 14 subunits. The folding of proteins has numerous implications for normal function of proteins as well as for pathological conditions. The thermosome (TF55/TCP1) chaperonins occur in the thermophilic Archaea bacteria. The latter are related to other cytosolic chaperonins of eukaryotes (animals and plants). The *cytosolic chaperonins* (CCT, ca. $2-3 \times 10^5$ complexes per mammalian cell) function similarly to the organellar chaperonins (ATPase activity, folding nonnative proteins) although structurally they are different. All chaperonins have the molecular mass of 800–1,000 kDa, built of ca. 60 kDa subunits, ($\alpha, \beta, \gamma, \epsilon, \zeta, \eta, \delta, \theta$) encoded by *Cct* genes. The GroES heptamer has 10 kDa subunits. The folding takes place within a GroEL chamber after it has entered through the small GroES capping proteins. ▶[chaperones](#), ▶[heat-shock](#), ▶[proteins](#), ▶[GroEL](#), ▶[TRiC](#), ▶[TCP-1](#) rubisco, ▶[Cpn60](#), ▶[Cpn21](#), ▶[Cpn60](#), ▶[Cpn10](#), ▶[7B2](#); Ang D et al 2000 Annu Rev Genet 34:439; Gottesman ME, Hendrickson WA 2000 Curr Opin Microbiol 3:197; Thirumalai D, Lorimer GH 2001 Annu Rev Biophys Biomol Struct 30:245; Hartl FU 2001 Cell 107:223; Levy-Rimler G et al 2002 FEBS Lett 529:1.

Char Syndrome: ▶[patent ductus](#), ▶[arteriosus](#)

Character: Character, in genetics, is a trait that may or may not be expressed through inheritance. It also includes any symbol used for conveying information, e.g., letters, numerals, punctuation marks, etc.

Character Displacement: Character displacement occurs when two species occupying similar but not identical habitat share a common area and in this shared zone each differ more from the other regarding a particular trait(s) than in the nonshared area.

Character Matrix: A device for classifying different groups regarding a trait as “have it (1)” or “not (0).” On this basis, then, a *similarity index* can be obtained and the distinguished groups are called operational taxonomic units (OTU). If the differences are counted or measured a *distance matrix* is obtained (see Fig. C62). On the basis of the similarities/differences branching

phenograms or *dendrograms* can be constructed. ▶[species](#); Ward BB 2002 Proc Natl Acad Sci USA 99:10234.

Figure C62. Character matrix

Character Process Model: The character process model analyzes the changes in a trait during a process and the correlation of stages of the process according to the expanded formula: $G(s,t) = v_g(s)v_g(t) \rho_g(|s - t|)$ where v_g = genetic variance, s and t are stage/time variations and $\rho_g(|s - t|)$ = genetic correlation between stages/time.

Charcot-Marie-Tooth Disease (CMT, hereditary motor and sensory neuropathy): CMT is known in multiple forms with autosomal recessive, dominant, or even Xq13-linked types. Its frequency is about 0.0004. The disease affects the nervous system and hearing; it is debilitating but not lethal. The average age of onset is early teens but it manifests more clearly by the late 20s. The defect Type 1B involves human chromosomes 1p21-23 or HNPP at 17p12-p11.2 encoding myelin 22. Dominant intermediate DI-CMT genes were assigned to 10q24-q25.1 (Verhoeven K et al 2001 Am J Hum Genet 69:889) and 1p34-p35 (Jordanova A et al 2003 Am J Hum Genet 73:1423). The latter locus was shown to involve tyrosyl-tRNA synthetase (Jordanova A et al 2006 Nature Genet 38:197). The chromosome 1p36.2 mutation of MFN2 GTPase involves a defect in mitochondrial fusion (Zuchner S et al 2004 Nature Genet 36:449). Its presence can be detected by genetic screening in the affected families. In the basic defect, connexin 32 encoded at Xq13.1 has also been implicated. The type 2 disease was found to be associated with human chromosome 1q21.2-q21.3, 3q13-q22, and 7p15. The latter location encodes at least 10 mutations in the glycyl-tRNA synthetase (GlyRS, GARS) gene responsible for CMT. The crystal structure of human GlyRS affects the sides of the protein dimer interface. The CMT phenotype, however, does not correlate with aminoacylation activity (Nangle LA et al 2007 Proc Natl Acad Sci

C

USA 104:11239). The chromosome 3 muscle weakness, foot ulcers are due to mutations in RAB7, an endosomal protein (Verhoeven K et al 2003 Am J Hum Genet 72:722). The recessive demyelinating dual-specificity phosphatase (myotubularin-related protein-2) is encoded at 11q22. Another recessive demyelinating form encodes (11p15) a “pseudophosphatase,” an inactive phosphatase (Azzedine H et al 2003 Am J Hum Genet 72:1141). This disease may also be caused by a duplication due to unequal crossing over in the peripheral myelin gene (chromosome 17) induced by a transposable element resembling *mariner* in *Drosophila*. The defective human chromosome 17p11.2 gene expressed in mice can be successfully corrected phenotypically by ascorbic acid (Passage E et al 2004 Nature Med 10:396). An autosomal recessive form is determined by chromosome 8q21.1 (GDAP1) and in 1p36 another locus has been implicated. An axonal form of the disease maps to 19q13.3 encoding the two PDZ domain proteins, periaxins. In the mouse the *trembler* mutation and some others are involved in hypomyelination. ▶neuropathy, ▶connexins, ▶myelin, ▶genetic, ▶screening, ▶MLE, ▶MITE, ▶mariner, ▶hypomyelinopathies, ▶RAB, ▶Pelizaeus-Merzbacher disease, ▶HNPP, ▶PDZ, ▶domain; Leal A et al 2001 Am J Hum Genet 68:269; Sherman DL et al 2001 Neuron 30:677; Zhao C et al 2001 Cell 105:587; Cuesta A et al 2002 Nature Genet 30:22.

Chargaff's Rules: In double-stranded DNA, nucleotides are paired as A = T and G = C. ▶hydrogen, ▶pairing, ▶DNA. Therefore, the amount of adenine equals that of thymine, and the quantity of guanine is about the same as that of cytosine in double-stranded DNA. In the majority of organisms AT is not equal in amount to GC. The recognition of this fact contributed significantly to the construction of the Watson-Crick model of DNA. Chargaff's second rule states that if a sufficiently long (>100 kb) strand of genomic DNA that contains *N* copies of a mono- or oligonucleotide, it also contains *N* copies of its reverse complementary mono- or oligonucleotide on the same strand. This rule has rather general validity for coding and noncoding sequences, except in some mitochondrial DNAs. Inversions and inverted transposition could be a major contributing if not dominant factor in the almost universal validity of this rule (Albrecht-Buehler G 2006 Proc Natl Acad Sci USA 103:17828). ▶Watson and Crick model; Forsdyke DR, Mortimer JR 2000 Gene 261:127.

CHARGE (coloboma, heart anomalies, choanal atresia, [obstruction of the nasal passageway by bony malformation], retardation, genital and ear anomalies): A complex human disease association syndrome,

which is about 8% familial (incidence at birth $\sim 8 \times 10^{-5}$). Chromosomes 14q22-q24.3 and 22q11 have been implicated but unequivocally not demonstrated. A 2.3 Mb microdeletion at chromosome 8q12 was found in many CHARGE-affected individuals (Vissers LE et al 2004 Nature Genet 36:955). A CHARGE-like X-chromosomal syndrome has also been reported. The majority of affected individuals have mutations in the chromodomain helicase DNA-binding domain (8q12.1) or in the semaphorin-3E gene ▶coloboma, ▶familial, ▶chromodomain, ▶semaphorin

Charge-Coupled Devices (CCDs): CCDs are used for highly sensitive imaging of fluorescence, bioluminescence, and tomography. The devices are based on semiconductors arranged in a manner that the output of one serves as input for the next.

Charge Clusters: Charged residues (amino acids) in proteins are distributed nonrandom and these proteins are frequently involved in transcription activation, developmental control, and membrane receptor activities. Charged clusters may contribute to protein folding, protein-protein and protein-nucleic acid interactions. Charge cluster are much more common in eukaryotes than in prokaryotes (Karlin S 1995 Curr Opin Struct Biol 5:360). ▶amino acids, ▶protein folding, ▶protein interactions, ▶regulation of gene activity

Charges tRNA: The transfer RNA carries an amino acid. ▶tRNA, ▶protein synthesis, ▶aminoacyl tRNA synthetase

Charge-to-Alanine Scanning Mutagenesis: ▶homolog-scanning mutagenesis

Charomids: Charomids are specially constructed phage lambda-derived vectors. The constructs must be of a minimum of 38 kb otherwise they cannot be packaged into infectious particles. A conventional cosmid vector is 5 kb, therefore, the minimal size of an insert would be 33 kb. When the fragment to be cloned is much smaller, charomids are used that carry repeating units of about 2 kb fragments of plasmid pBR322 in head-to-tail arrangement as space fillers. Thus, depending on the nature of charomids, they can be used for cloning DNAs from 2 to 45-kb length. In *recA⁻* bacteria (ED8767) these vectors are quite stable and can be used just like cosmids. ▶cosmids, ▶vectors, ▶Rec; Saito I, Stark GR 1986 Proc Natl Acad Sci USA 83:8664.

Charon Vector(s): Charon vectors are modified phage λ plasmids (pronounce kharon; named after the mythical ferryman who carried dead souls through the

infernal Styx river). The Charon vectors are primarily replacement vectors, i.e., they can place DNA into deleted parts of the stuffer region (between λ genes J and N, see diagram at lambda phage). There are a large number of Charon vectors with somewhat different features. Charon 4 was used mainly to generate eukaryotic genomic libraries. In the replacement (stuffer) region there are E.coRI of 6.9 kb and 7.8 kb containing the β -galactosidase (*Lac Z*) and the biotin (*bio*) genes, respectively. Successful replacement is recognized by the inability of *lac*- bacteria carrying this vector to develop blue color on Xgal medium because the vector cannot provide the galactosidase function any more. Replacement of the *bio* gene results in biotin dependence in a similar way. The vector is also *Spi*⁻ (wild type lambda phages are unable to grow in bacteria containing prophage P2 and have the designation *Spi*⁺ [sensitive to P2 interference]). The *Spi* selection is inoperable with Charon 4. Charon vectors that have lost the *red* and *gam* functions [required for recombination] can grow in P2 lysogens and are called *Spi*⁻. The bacteria have the *rec*⁺ gene (mediating recombination) and the phage has its own *chi* element (a substrate for the *recBC* system of recombination) or the inserted foreign gene contains one (mammalian DNA has numerous *chi* elements). Also, *supE* and *SupF* (amber suppressors) must be present in the host to allow for selection of recombinant libraries by in vivo recombination because the vectors *A* and *B* genes carry amber mutations (chain termination codon UAG). Besides the EcoRI sites there is an XbaI site in the stuffer region that accepts an up to 6-kb insertion. Charon 32 vector permits cloning DNA fragments at EcoRI (substitution up to 19 kb), HindIII (substitution up to 18 kb) and SacI sites (insertion up to 10 kb). In these cases *recA*⁻ hosts suffice because the vector is *gam*⁻. When Charon 32 is used as a substitution vector for EcoRI-SalI, SalI-XhoI, or EcoRI-BamHI fragments the host must be *recA*⁺ because *gam* is lost. Charon 34 and Charon 35 are suitable for cloning fragments up to 21 kb at polycloning sites, using BamHI, EcoRI, HindIII, SacI, XbaI, and SalI, as well as their combinations. These vectors retain *gam* functions. Charon 40 is useful for cloning fragments from 9.2 to 24.2 kb. In the stuffer region there are 16 restriction sites in opposite orientation near the ends. The poly-stuffer can be broken down into small fragments by the use of restriction enzyme NaeI (GCC↓GGC) and can be collected by precipitation with polyethylene glycol. The vector retains *gam*. ▶**vectors**, ▶**lambda phage**, ▶*Spi*⁺, ▶*supC*, ▶*supD*, ▶*SupE*, ▶*supF*, ▶*supG*, ▶*supU*, ▶**restriction enzyme**, ▶**Xgal**, ▶**Lac operon**; Chauthaiwale VM et al 1992 Microbiol Rev 56:577.

C

CheA, CheB, CheR, CheC, CheD, CheW, CheY, CheZ:

Bacterial cytoplasmic proteins mediating the transduction signals of chemoeffector through transducers to switch molecules. CheA is an autophosphorylating (histidine) kinase that phosphorylates also CheY and CheB. CheY also autophosphorylates spontaneously in a few seconds and the process is accelerated by CheZ. CheA is central to information processing by the four transducers in cooperation with CheW. CheR, CheB: cytoplasmic bacterial proteins mediating the return of the chemotaxis excited cells to the normal state (adaptation). CheR is a methyltransferase; CheB is a methylesterase. CheC is phosphatase. CheD is a receptor-modifying deamidase. CheC inhibits CheD and CheD stimulates CheC. ▶**effector**, ▶**transducer**, ▶**proteins**, ▶**autophosphorylation**, ▶**esterases**, ▶**transferases**, ▶**enzymes**, ▶**chemotaxis**, ▶**excitation**, ▶**switch genetic**, ▶**chemotaxis**; Sourjik V, Berg HC 2000 Mol Microbiol 37:740; Bray D 2002 Proc Natl Acad Sci USA 99:7; Charon NW, Goldstein SF 2002 Annu Rev Genet 36:47; Chao X et al 2006 Cell 124:561.

Checkpoint: Critical phases in the progress of cell division where the cycle can be stopped and kept, and yet, when conditions become appropriate, progress may be resumed (see Fig. C65). The main role of the check point is to prevent progression to G₂ phase until the S phase is completed. There may also be a check point at the G₂ phase preventing the completion of the cell cycle. The checkpoint indicates a step initiating a new direction in the progression; before the cell embarks on a new path, the preceding steps must be completed. The purpose of the checkpoints is to prevent mitosis of defective cells. Several proteins have now been identified in different organisms to mediate checkpoints. The checking is generally mediated by different cyclin-dependent kinases, CDKs.

In yeasts there are fewer checkpoints whereas in animal cells different ones specialize for each checkpoint. The CDKs may be activated/deactivated by phosphatase/kinase action and, in addition, binding proteins, cyclin kinase inhibitors (CKI) and other modifiers may participate. These proteins are also subject to proteolytic destruction. In multicellular higher organisms apoptosis is also involved, and that does not stop the cell cycle at a stage but eliminates the cell with a defect.

In yeasts, a network of checkpoints have been identified including *RAD9*, *RAD17*, *RAD24*, *RAD53*, *DDC1*, *PDS1*, *POL2*, *PRI1*, *RFC5*, *MEC3*, *MEC1* genes. Protein 14-3-3 σ is also a component of the G₂ checkpoint; in the absence of its function the cell cycle fails to stop and proceeds to death. Protein 14-3-3 normally binds Cdc25 phosphorylated at Ser²¹⁶ and the cell cycle proceeds but phosphorylated CDC25 is ferried out of the nucleus after DNA damage and the G₂ checkpoint is abrogated. Chk1 phosphorylates CDC25 at 216. Protein 14-3-3 σ is transcribed upon the action of p53 and it sequesters cyclin B1 and CDC2 in the cytoplasm and prevents their entry into the nucleus and thus the cell cycle is not completed when the DNA is damaged. ►cell cycle, ►SCF, ►replication at the S phase in eukaryotes, ►p56^{chk1}, ►PIK, ►FK506, ►PIK, ►FK506, ►RAD, ►APC, ►ATM, ►ATR, ►protein 14-3-3, ►p21, ►p53,

Chediak-Higashi Syndrome (CHS): An autosomal recessive defect of the cytotoxic T cells in human chromosome 1q42.1-q42.2. The afflicted individual displays reduced pigmentation of the hair and eyes, avoidance of light, reduction in the number of neutrophilic lymphocytes (neutropenia), high susceptibility to infections, and lymphoma. In the heterozygotes the lymphocytes appear abnormally granular. Similar diseases occur in many mammals. Molecular investigations reveal a defect in a protein with carboxy-terminal prenylation and multiple potential phosphorylation sites (LYST). It may be involved as a relay integrating cellular signal response coupling, mediated through the lysosomes. Its mouse homolog is the *beige* locus. ►albinism, ►lymphocytes, ►neutrophil, ►lymphoma, ►Hermansky-Pudlak syndrome; Stinchcombe J et al 2004 Science 305:55.

CHEF: CHEF stands for contour-clamped homogeneous electric field that alternates between two orientations. Multiple electrodes along a polygonal contour generate the electric field. The method applies the principles of electrostatics (statical electricity) to gel electrophoresis of very large molecules such as the entire DNA of small chromosomes. ►pulsed gel electrophoresis

Cheirology (dactylogy): The study of hands, fingerprints. ►fingerprinting

Chelation: The holding of a hydrogen or metal atom between two atoms of a single molecule. Hemin and chlorophyll are chelated. Chelation may improve solubility of metals. It is also used for relieving metal poisoning.

Figure C65. Checkpoint. (Diagram modified after Sanchez, Y. et al 1999 Science 286: 1166)

ChemBank: A free database of more than 2,000 small molecules of potential applications for perturbing biological systems. ►[chemical genetics](http://chembank.med.harvard.edu/); <http://chembank.med.harvard.edu/>.

C

Chemical Biology: Uses interdisciplinary approaches for the translation of basic science into the needs of societal problems such as control of disease, providing insights into the proteome of pathogenesis, drug development, engineering new diagnostic systems, etc. ►[synthetic biology](#)

Chemical-Genetic Profiling: Identifies the effects of chemicals/groups of chemicals on physiology and on particular genes. The information obtained can reveal the action of drugs on proteins. Two-dimensional clustering analysis and probabilistic sparse matrix fertilization analyses are tools employed. (Parsons AB et al 2006 Cell 126:611).

Chemical Genetics: Develops small molecules that can modify proteins or nucleic acids and thus alter gene function. In parallel synthesis, small molecules and peptides are synthesized in separate containers in a combinatorial manner. In the split-pool procedure a mixture of beads is initially split in several containers and the first amino acid is attached to the beads. Then all the beads are pooled and re-split into separate containers/wells, where the second amino acid is hooked to the first one. This process allows the synthesis of millions of chemicals by only a few hundreds of reactions (Smukste I, Stockwell BR 2005 Annu Rev Genomics Hum Genet 6:261). The results may be applicable to the development of drugs and reveal developmental mechanisms. ►[ChemBank](#), ►[combinatorial chemistry](#); Bishop AC et al 2000 Nature [Lond] 407:395; Tan DS 2002 Nature Biotechnol 20:561.

Chemical Mutagens: These include an extremely large number and wide variety of different chemical groups (see Fig. C66). Their effectiveness varies within a great range. About 80% of the chemical mutagens are also carcinogens. Some of these agents pose health hazards as industrial, agricultural, and medical chemicals. A much smaller fraction is used for the experimental induction of mutation for research purposes. A not-comprehensive classification includes (i) DNA base and nucleoside analogs 5-bromouracil or 5-bromodeoxyuridine (BuDR), 2-aminopurine (2-AP).

These compounds are of relatively very low efficiency and can be utilized only under highly selective conditions in microbial populations. They act, primarily, either through incorporation at the wrong place in the DNA or by replacing their normal counterparts followed by mispairing (tautomeric

5-Bromouracil

2-Aminopurine

Figure C66. Chemical mutagens

shift) and in both cases causing base substitution. (ii) Chemical modifiers of nucleic acid bases such as nitrous acid (HNO_2) that oxidatively deaminates cytosine into uracil, adenine into hypoxanthine (resulting actually in A→G transitions) and guanine into xanthine (causing lethal effects because of interference with replication). Nitrous acid is not an effective mutagen for higher eukaryotic cells because of the high protein content of the chromosomes and nitrous acid also has a destructive effect on proteins, but it was used very advantageously for tobacco mosaic virus and other viruses. Nitrous acid may nitrosate, however, several plant products (black pepper, beer [if the barley is improperly dried], soybean and faba bean products and cruciferous vegetables [cabbage, etc.]). Hydroxylamine targets primarily cytosine and thus changes a G≡C pair into A = T. (iii) Alkylating agents of a diverse group such as sulfur- and nitrogen mustards, epoxides, ethyleneimins, unsaturated lactones (aflatoxin), alkyl and alkene sulfonates are powerful mutagens for different organisms. The nitrogen mustards induce, primarily, chromosome breakage like X-rays and are frequently referred to as radiomimetic agents.

The mustards are no longer used as laboratory mutagens because of the relatively low efficiency compared to their lethal effects and because the risks involved in routine handling. Among these, the most commonly used alkylating mutagens are methyl and ethyl methanesulfonate ($\text{CH}_3\text{SO}_2\text{OCH}_2\text{CH}_3$) that are highly effective in practically all organisms. They alkylate the guanine at the 7 position but the major mutagenic action results from the alkylation of the O^6 of guanine. To a lesser extent, they alkylate mutagenically other bases too. Alkylation may also break the linkage between the ribose and the N9 of the purines resulting in depurination and breakage of the DNA strand. (iv) N-nitroso compounds such as

nitrosamines, nitrosoureas, methyl-nitro-nitrosoguanidine (MNNG, $C_2H_5N_5O_3$), etc., are very potent mutagens. The latter one predominantly induces point mutations at pH 6 but it must be handled in the dark as it rapidly decays in the light. (v) A variety of compounds that produce free radicals such as hydrazines and hydrazides, hydrogen peroxide or organic peroxides, aldehydes and phenols are mutagenic but usually not employed for the induction of mutation, except perhaps maleic hydrazide that induces high frequency chromosomal breakage. (vi) Acridine dyes (proflavin, acriflavin, acridine orange, etc.) are intercalating agents and induce frameshift mutations at neutral pH. ►physical mutagens, ►radiomimetic, ►alkylation, ►biological mutagenic agents, ►environmental mutagens, ►depurination, ►chromosome breakage, ►frameshift, ►tautomeric shift, ►laboratory safety, ►chemicals hazardous; Ames test; Hollaender A (ed) 1971–80 Chemical mutagens. Principles and methods for their detection. Plenum, New York.

Chemical Mutation: Chemical mutation alters the active site of an enzyme by modifying the (tertiary) structure of the protein. The biologically relevant chemical space represents only a small fraction of the estimated 10^{60} types of molecules. ►protein structure

Chemical Products: Natural compounds have been classified into structural categories with the aim of developing greater utilization on the basis of properties (Koch MA et al 2005 Proc Natl Acad Sci USA 102:17272). ►chemical space

Chemical Space: Chemical space includes all possible organic molecules, including, and beyond, all C-containing molecules in the biological systems. The majority of the potential drugs used in medicine are smaller than 500 D. ►chemical products; Dobson CM 2004 Nature [Lond] 432:824.

Chemicals, Hazardous: The total number of chemicals identified exceeds 6 million. The various industries use over 60,000 chemical compounds and an estimated 700 new chemicals are introduced annually for various uses. Since the biological effects (mutagenicity, carcinogenicity) of only a relatively small fraction are known with certainty, the majority of chemicals should be regarded with appropriate caution. ►environmental mutagens, ►chemical mutagens, ►carcinogens, ►laboratory safety; <http://toxnet.nlm.nih.gov/>.

Chemiluminescence (chemoluminescence): Chemiluminescence is the production of light without heat by chemical reaction.

Chemiosmotic Coupling: Chemiosmotic coupling uses a pH gradient through a membrane to drive energy requiring processes. ►chemosmosis

Chemoattractant: ►chemotaxis

Chemoautotroph: An organism that obtains energy from inorganic chemical reactions.

Chemoeffectors: Refers to elicit bacterial response by bacterial signal transducers in chemotaxis.

Chemogenomics: Chemogenomics seeks out potential new drug targets by proteomic technology. Genes identified by genomic analysis are expressed as proteins. Potential drug-like libraries are tested to see whether the compounds bind the protein targets. The outcome of these tests facilitates either the selection or synthesis of additional, improved, structurally similar compounds. Selected molecules are then tested in biological systems for therapeutic effectiveness. ►combinatorial chemistry; Agrafiotis DK et al 2002 Nature Rev Drug Discovery 1:337.

Chemoheterotroph: An organism that obtains energy from the breakdown of organic molecules.

Chemokines (chemotactic cytokines): Chemicals (moving proteins) involved in defense systems or much activation by chemical agents. Chemokines are classified according to their cysteine motifs into CXC, CC, C, and CX3C groups. Chemokines are participants in specific inflammatory responses and some of them are identical to specific lymphokines. Chemokines also lure the lymphocytes to the sites of infection and inflammation. These small proteins have four conserved cysteines of which two are either adjacent or one other amino acid is in between the two. Chemokine α is represented by IL-8 and others encoded in close vicinity to each other in human chromosome 4q12-q21. On the surface of human neutrophils, 20,000 high affinity receptors have been found. They are encoded in human chromosome 2q34-q35. The β chemokine family includes MIP and the others are homologous to 28–73%, and are encoded in close linkage in human chromosome 17q11-q21. The MIP/RANTES receptor is encoded in 3q21. Chemokines cause a rise of free calcium, release of microbicidal oxygen radicals and bioactive lipids, storage granules containing proteases from neutrophils and monocytes, histamine from basophils and cytotoxic proteins from eosinophils. Chemokines interact with seven-transmembrane G protein-coupled receptors, CCR, CXCR and CX3CR. The CXC or α chemokines act on neutrophils and T cells; the CC or β chemokines such as the monocyte chemoattractant protein (MCP-1) act on monocytes, basophils, eosinophils, T cells (NK) and dendritic cells but usually not on neutrophils. Chemokines

trigger the activation of phosphoinositide kinase (PIK). Chemokines mediate cell polarization in differentiation, movement HIV-1 infection, and immune response. Homo- or heterodimerization of the chemokine receptors activate specific signaling pathways.

Eotaxins select only eosinophilic and basophilic granulocytes. Lymphotactin and fractalkine select monocytes and neutrophils. Chemokines interact with seven-transmembrane, G protein-coupled receptors of about 40 kDa size. ▶**lymphokines**, ▶**RANTES**, ▶**MIP**, ▶**fusin**, ▶**cytokines**, ▶**CCR**, ▶**CXR**, ▶**blood**, ▶**histamine**, ▶**antimicrobial**, ▶**peptides**, ▶**radical**, ▶**SDF**, ▶**acquired immunodeficiency syndrome**, ▶**lymphoid organs**, ▶**G proteins**, ▶**signal transduction**, ▶**PIK**; Cyster JG 1999 *Science* 286:2098; Mellado M et al 2001 *Annu Rev Immunol* 19:397; Mellado M et al 2001 *EMBO J* 20:2497; Schwarz MK et al 2002 *Nature Rev Drug Discovery* 1:347; Allen SJ et al 2007 *Annu Rev Immunol* 25:787.

Chemolithoautotroph: An organism that, for biosynthesis, relies on inorganic material and inorganic chemical energy. ▶**chemoheterotroph**

Chemoprevention of Cancer: Chemoprevention of cancer is generally based on regulation of cell division, ligands of nuclear receptors, selective modulation of the estrogen receptors, vitamin D analogs, inhibitors of cyclooxygenase, NF-κB, anti-inflammatory agents (curcumin [anti-cancer phenolic], resveratrol [antioxidant], caffeic acid [phenolic antioxidant]), chromatin modifiers (histone deacetylase inhibitors, methyl transferases), agents that control signal transduction (herceptin), and enhancers of the SMAD complex pathway which boost TGF-β signaling that is usually down-regulated in some cancers. ▶**cancer therapy**, ▶**nuclear receptors**, ▶**cyclooxygenase**, ▶**SMAD**, ▶**TGF**, ▶**herceptin**, ▶**NF-κB**; Sporn MB, Suh N 2002 *Nature Rev Cancer* 2:537.

Chemoreceptor: A gene product activated by chemical signal(s). In *Caenorhabditis* ~1,000 seven-transmembrane receptors genes have been identified which may be chemoreceptors although only half of them seems to be functional. Yet this is the largest gene family in this nematode. ▶**olfactogenetics**, ▶**taste**; Gestwiczki JE, Kiessling LL 2002 *Nature [Lond]* 415:81.

Chemosensitivity: The administered drugs affect many genes at the same time and the response of individual genes in different patients may vary. By exposing cells to various compounds at different concentrations, the 50% growth inhibition (GI₅₀) can be scored. The most sensitive and the most resistant cell lines can then be evaluated with the aid of microarray

hybridization. The information so derived may be of help for predictions of drug response, e.g., by cancer patients. ▶**multidrug resistance**, ▶**microarray hybridization**; Staunton JE et al 2001 *Proc Natl Acad Sci USA* 98:10787.

Chemosmosis: A chemical reaction across membranes.

Chemosterilant: A chemosterilant prevents or controls reproduction by natural or synthetic chemicals. ▶**sex hormones**, ▶**contraceptive**, ▶**busulfan**; Magdum S et al 2001 *J Appl Entomol* 125:589.

Chemostat: An apparatus for culturing bacteria at a steady level of nutrients, aeration, temperature, etc., so cell divisions are continuously maintained. ▶**bioreactor**; microchemostat: Balagaddé FK et al 2005 *Science* 309:137.

Chemotaxis: The movement toward chemical attractants and away from chemical repellents. Bacteria have very high sensitivity receptors for chemical signals. The receptors upon binding the chemical ligand propagate in clusters on the bacterial surface but single receptors also exist and thus they can adapt (respond) to a very wide concentration range (five orders of magnitude) of the chemicals. The receptor then transmits the signal through PLC and PIK to the cellular interior for further processing. In response to chemoattractant signals, the PI3K enzyme and its product PIP₃ accumulate on the plasma membrane on the side of the chemoattractant and the PIP₃-degrading PTEN and its product PIP₂ localize in a complementary pattern. Effector proteins dock to PIP₃ and induce polarization and regulate cytoskeleton function (Gamba A et al 2005 *Proc Natl Acad Sci USA* 102:16927). The cytoskeleton is highly polarized in migrating *Dictyostelium discoideum*. F-actin is in the anterior part of the cell and myosin II in the lateral and posterior regions. Extracellular 3',5' cyclic monophosphate activates its surface receptors, which transmit the signals when associated with trimeric G proteins. A number of additional proteins (phospholipase C, phosphoinositides, etc.) regulate the chemotactic pathway (Kimmel AR, Parent CA 2003 *Science* 300:1525). Macrophages, neutrophils, eosinophils, and lymphocytes are attracted to a wide variety of substances causing inflammation and the chemotactic mechanisms are basically similar to that of *Dictyostelium*. ▶**actin**, ▶**myosin**, ▶**G protein**, ▶**phosphoinositides**, ▶**phospholipases**, ▶**CheA**, ▶**blood cells**, ▶**PLC**, ▶**PIK**, ▶**PTEN**; Mori I 1999 *Annu Rev Genet* 33:399.

Chemotaxonomy: The study of evolutionary relatedness on the basis of chemical compounds.

Chemotherapy: The curing of a disease by chemical medication or fighting cancerous proliferation by antimitotic (cytostatic) chemicals. ▶**cancer**, ▶**cancer**

therapy, ►cytostatic, ►multiple drug resistance, ►genetic medicine, ►biomarkers; Huang Y 2007 Cancer Metastasis Rev 26:183.

Chemport: Provides links to important databases and scientific publications (electronic journals), patent offices, etc.: <http://chemport.org/html/english/about.html>.

Cheney Syndrome (acroosteolysis): An autosomal dominant bone disease with similarities to pycnodysostosis, but here, rather than hardening of some of the bones (osteosclerosis), bone loss (osteoporosis) was accompanied with early loss of teeth, laxity of the joints, etc. In this syndrome the stature of the patients was not necessarily short. ►pycnodysostosis

Chernobyl: ►atomic radiation

Cherry (*Prunus cerasus*): $x = 7$, but a wide variety of diploid and polyploid forms are known.

Cherubism: The dominant (4p16.3) proliferation of the lower (mandibula) or upper (maxilla) jawbone usually beginning at age 2–5 years and receding after puberty. The distortion of the face pulls down the lower eyelids and the eyes seem to be gazing upward. The distorted teeth and visual anomalies may remain (see Fig. C67). Fibroblast growth factor (FGF3) mapping to the same general area may be involved. Recent evidence indicates mutations in the SH3-binding protein SH3BP2. SH3BP2 is a regulator of M-CSF (macrophage colony stimulating factor) and rank ligand RANKL (Ueki Y et al 2007 Cell 128:71). ►FGF; ►macrophage colony stimulating factor, ►TRANCE; Mangion J et al. 1998 Am J Hum Genet 65:151; Tiziani V et al ibid. p.158; Ueki Y et al 2001 Nature Genet 28:125.

Figure C67. Cherubism

Chestnut (*Castanea* spp): A monoecious tree, $2n = 2x = 24$.

Chestnut Color: In horses it is due to homozygosity for the d allele; actually this color is expressed when the genetic constitution of the animals is $AAbbCCdd$.

Chetah: *Acionyx jubatus*, $2n = 38$.

Chi Elements (χ , crossing-over hotspot instigator): Chi elements are crossing-over hot spots-inciting DNA sequences in both prokaryotes and eukaryotes. The prokaryotic chi elements have the consensus

5'-GCTGGTGG-3' and nicking by the RecBCD complex takes place 4 to 6 bases downstream during recombination. In phage DNA chi sequences are required for the function of the bacterial genes *RecBC* coding for exonuclease V. The product of phage gene *gam* inhibits this enzyme. In *E. coli* there are about 500 to 600 chi elements. Chi promotes recombination in a region within 10 kb from its location. It may be activated by double-strand breaks within a range several kb downstream. Chi probably facilitates the production and availability of free 3' end for recombination. The hepatitis B virus encapsidation signal carries a 61-bp sequence (called 15AB) and is a hotspot for recombination; a cellular protein binding to this sequence appears to be a recombinogenic protein. The same nucleotide sequence (5'-CCAAGCTGTGCCTTGGGTGGC-3') has been identified with approximately 80% homologies also in the rat, mouse, and human genomes. Note the pentanucleotides in bold, they are present also in the prokaryotic chi elements as shown above. It appears that this element is responsible for some of the chromosome rearrangements observed in hepatocarcinomas. ►crossing over, ►recombination, ►rec, ►hepatoma, ►molecular mechanisms of recombination; Anderson DG et al 1999 J Biol Chem 274:27139; Lao PJ, Forsdyke DR 2000 Gene 243:47.

Chi forms: Recombinational intermediates representing consummated chiasmata. ►chiasma

Chi square (χ^2): A statistical device for testing the goodness of fit to a particular (null) hypothesis.

$$\chi^2 = \sum \frac{[\text{observed number} - \text{expected number}]^2}{\text{expected number}}$$

where Σ stands for sum. When the degree of freedom is 1, the use of the Yates correction may be justified and the formula becomes:

$$\chi^2 = \sum \frac{[|\text{observed} - \text{expected}| - 0.5]^2}{\text{expected}}$$

The Yates correction may be applied for other degrees of freedom in case the size of any particular class is 5 or less. It may be a better practice, however, to avoid using this correction factor and keeping in mind that our chi square figure is conservative. Although the χ^2 is very useful it must be remembered that it has a general weakness because it was derived from the principles of normal distribution but it is actually applied for discrete classes. An alternative to the above χ^2 statistics is the likelihood ratio criterion χ^2_L which is easier to compute in some cases and may give a more realistic estimate: $\chi^2 = 2 \sum \text{observed} \times \ln \left(\frac{\text{observed}}{\text{expected}} \right)$; the degree of freedom is calculated the same way as in other cases.

A slightly different type of formula is used in tetrad analysis to determine whether the frequency of

$\chi^2 = \frac{(PD-NPD)2}{PD+NPD}$ parental ditype (PD) tetrads really exceeds that of the nonparental ditypes (NPD). In linkage PD should exceed that of NPD. When the population size exceeds 30, use $\sqrt{2\chi^2 - \sqrt{2n - 1}}$ as a normal deviate. ▶chi square table, ▶homogeneity test, ▶association test, ▶degrees of freedom, ▶tetrad analysis, ▶lod score

Chi Square Table: The chi square table displays the probability of a greater χ^2 . Determine the value of the χ^2 by using the chi square formulas. Locate the nearest higher value in the body of the table (see Table C4) on the appropriate line of degrees of freedom (df). On the top line at the intersecting column you find the corresponding level of probability (P).

For a particular degree of freedom, the smaller χ^2 value indicates a better fit to the theoretical expectation (null hypothesis). By statistical convention when $P > 0.05$, the fit is not questionable, when P is between 0.05 and 0.01 the fit is more or less in doubt. When P is below 0.01 the null hypothesis is no longer tenable. (In the majority of statistical books more extensive χ^2 tables can be found)

Chiari Malformation: A variable cranial and neurological anomaly and syringomyelia with autosomal dominant inheritance. ▶syringomyelia

Chiasma (plural chiasmata): A chromatid overlap in prophase (appearing through the light microscope like the Greek letter chi [χ]), resulting in genetic exchange between bivalents. If the number of chiasmata truly represents the points of genetic exchange of chromosomes, from the cytological observation of chiasma frequency the length of the genetic map could be inferred because each crossing over corresponds to 50% recombination (see Fig. C68). Thus the number of chiasmata multiplied by 50 should be equal

to the sum of map distances. For example, C.D. Darlington observed 3 chiasmata in chromosome 3 of maize, thus $3 \times 50 = 150$. In fact, according to the modern map, the length of this chromosome is about ~ 167 m.u. According to B. Lewin the number of chiasmata per meiocyte in *Drosophila melanogaster* was 6.6 and $6.6 \times 50 = 300$ and the new cytogenetic map appears to be of ~ 297 m.u.

Recent analyses of plant recombination and chiasma data find that the frequency of recombination is higher than the chiasma frequency.

Figure C68. Multiple chiasmata in a male grasshopper chromosome. (Courtesy of Dr. B. John). Schematic representation of one chiasma in each arm

This revelation may or may not affect the general validity of the correspondence suggested earlier because of the cytological difficulties obtaining very precise estimates on chiasmata. Also, the recombination data may have some inherent errors even if mapping functions are used. It is well known that interference varies along the length of the chromosome and according to species, etc., and no general mapping function can fully appreciate that fact. Chiasmata take place as the bivalents represent 4 strands (chromatids).

In about 6–10% of the X chromosomes there are no chiasmata, whereas 60–65% of the bivalents display one, and 30–35% show two, but a higher number of chiasmata is very rare. The frequency of chiasmata usually varies between male and female meiosis and it is usually higher in the latter. The occurrence of

chiasmata may display substantial variations even within a bivalent. There is evidence that the occurrence of chiasma facilitates orderly segregation of the chromosomes and reduces nondisjunction. In the majority of organisms chiasmata are rare at the tip and at the centromeric regions. Special genes regulate chiasmata. In *Saccharomyces* the Rad50 protein (an ATP-dependent DNA-binding protein, localized at interstitial sites) seems to be involved in the development of the axial structure of chromosomes, pairing, and recombination. ▶meiosis, ▶crossing over, ▶recombination frequency, ▶mapping genetic, ▶interference, ▶chromatid interference, ▶isochores, ▶achiasmate, ▶desynapsis, ▶sister chromatid cohesion, ▶separin, ▶mapping function, ▶association point, ▶recombination nodule, ▶nondisjunction, ▶count-location models, ▶stationary renewal; Tease C 1998 Chromosoma 107:549; Meneely PM et al 2002 Genetics 162:1169.

Chiasma Interference: ▶chromatid interference, ▶interference

Chiasma Terminalization: ▶terminalization of chromosomes

Chiasmata (plural of chiasma): ▶chiasma

Chicago Classification: The Chicago classification of human chromosomes was based on banding and morphology and it has been refined since 1966. ▶human chromosomes, ▶Denver classification, ▶Paris classification

Chick Pea (*Cicer arietinum*): The grain legumes representing the pulses. The chromosome number is generally $2n = 2x = 16$.

Chicken: *Gallus domesticus* $2n = \text{ca. } 78$. There are two sex chromosomes, ZW in the heterogametic females and ZZ in homogametic males. There are also 38 pairs of autosomes of widely different sizes. The microchromosomes have only 5 million to 20 million base pairs, and their G-C level is relatively high and repetitions are relatively low. The macrochromosomes are about two orders of magnitude larger. Genome size in $\text{bp/n} \cong 1.2 \times 10^9$. Estimated gene number 20,000–23,000. About 2,200 loci have been mapped with a total length of $\sim 4,000 \text{ cM}$. A physical map of the genome is available (Wallis JW 2004 Nature [Lond] 432:761). Segmental duplications in the chromosomes are relatively short ($>10 \text{ kb}$) and generally limited to within the chromosome rather than among chromosomes. Recombination rates vary and the rates are much higher in the short minichromosomes ($\sim 2.8 \text{ cM/Mb}$) versus macrochromosomes ($\sim 6.4 \text{ cM/Mb}$). Their average rate in human chromosomes is 1–2 cM/Mb.

A draft sequence of the Asian chicken (red jungle fowl, *Gallus gallus*, female shown at left) genome is available (see Fig. C69). When aligned with the human sequences, long blocks of synteny are conserved (Int. Chicken Genome Consortium. 2004 Nature [Lond] 432:695). About 60% of the protein-coding genes have a single human homolog, and the identity of the homologs is 75.3%, in contrast the human-mouse homologs with $\sim 88\%$ consensus. The chicken genome lacks genes for vomeronasal receptors, casein milk proteins, salivary-associated proteins, enamel proteins, α -interferon, etc. The OR5U1/OR5BF-1-like (olfactory receptor) genes contribute to the majority of the 283 olfactory genes, a number comparable to that in humans, although olfaction in chickens is somewhat debated. Some other protein families are either under- or over-represented in the chicken relative to other vertebrates. Among red jungle chicken, in Broiler and Silkie breeds the average single nucleotide polymorphism is 2.8 million (Int. Chicken Polymorphism Map Consortium. 2004 Nature [Lond] 432:717). The chicken genome exhibits only 51 retroposed duplicates in contrast to humans that show more than 15,000.

Figure C69. Jungle fowl

The number of retrotransposons (CR1)—resembling the L1 elements of mammals—is about 200,000 in the chicken genome. Most of the CR1 elements are probably inactive currently. Processed pseudogenes are relatively rare in chickens. Copia and gypsy elements are absent. Retroposons with Long Terminal Repeats (LTR) are of the mammalian type. Only two types of DNA transposons were detected.

Transgenic chickens can be produced at relatively low cost. Their speed of development and the production of a flock and potentially appropriate glycosylation of target proteins have led to the use of

C

chickens as a bioreactor for therapeutically needed proteins (Lillico SG et al 2005 Drug Discovery Today 10(3):191). Lentiviral vectors derived from equine infectious anemia virus were designed to minimize the potential for homologous recombination. Humanized ScFv-Fc mini-antibody (miR24), derived from a mouse monoclonal antibody—shown to have potential for the treatment of malignant melanoma—or human interferon 1a carrying vectors were injected in the oviduct and produced functional proteins as a component of the abundant egg white. The high-titer vector was introduced into packing cell lines or injected beneath the blastoderm of the un-incubated egg. Injected embryos were cultured for 21 days through hatching. The chicks were then raised to sexual maturity; the roosters with semen positive for the transgene were mated with wild-type hens, and the offspring were screened for the presence of the transgene (Lillico SG et al 2007 Proc Natl Acad Sci USA 104:1771). ▶DT40, ▶antibody, ▶interferon, ▶melanoma; consensus genetic map: Groenen M et al 2000 Genome Res 10:137; genes; inbred lines; functions; Brown WRA et al 2003 Nature Rev Genet 4:87; historical significance of poultry genetics; Pettitt JN, Mozdziaik PE 2007 Proc Natl Acad Sci USA 104:1739; <http://poultry.mph.msu.edu/>; <http://www.tigr.org/tdb/tgi.shtml>; <http://www.chicken-genome.org>; <http://www.genome.iastate.edu/chickmap/dbase.html>; variations in the chicken genome; <http://chicken.genomics.org.cn>; chicken genome; http://www.ensembl.org/Gallus_gallus/index.html.

Chickenpox: A highly contagious skin disease of children and young adults with possible serious complications, caused by the Varicella zoster virus. Vaccination is very effective (Nguyen HQ et al 2005 New Engl J Med 352:450). ▶shingles, ▶Varicella zoster virus

CHILD syndrome (congenital hemidysplasia [asymmetric symptoms] with ichthyosiform erythroderma and limb defects): CHILD syndrome is caused by deficiency of 3- β -hydroxysteroid- δ -8, δ -7 isomerase at Xp11.23-p11.22 (EBP) or by the NAD(P)H steroid dehydrogenase-like protein at Xq28 (NSDHL, ichthyosis, Conradi-Hünemann syndrome).

Chimaerin (chimerin): A family of Rac-GTPase-activating proteins. ▶Rac, ▶epiboly

Chimera: A mythological monster that had a serpent's tail, goat's body and lion's head, and vomited flames through her mouth. (See also chimera below).

Chimera: A mixture of genetically different tissues within an individual or other structures of two or more different fused elements; frequently it displays visible sectoring. The term is used also for embryos that

contain both animal and human genetic material although fertilization of human eggs with animal sperms or animal eggs with human sperm is prohibited in all countries. Within a hybrid plant seed the embryo is diploid, the endosperm is usually triploid and the seed coat is maternal, making it essentially a triple chimera. In the armored scale insects the chimerism is complex. The three polar bodies, products of the female meiosis, are not eliminated as in the majority of the animals, but the three cells fuse. Subsequently, they may fuse with one cell of the diploid embryo and give rise to the pentaploid *bacteriome*, which accommodates the symbiotic bacteria of the mother. This pentaploid cell lineage then coexists with the diploid tissues during development. In most scale insects the paternal genome is eliminated as the common fate of sex determination. Such elimination does not take place, however, in the bacteriome. Thus, the bacteriome has a two haploid maternal chromosome set plus one male haploid set (Normark BB 2004 PLoS Biol 2:298). The word is adopted from the mythological monster of lion head-goat body-serpent tail (see Figs. C70 & C71). ▶periclinal chimera; ▶mericlinal chimera; ▶multiparental hybrids; ▶sex determination; ▶marmoset

Figure C70. Chimera, ancient Greek bronze statue

Figure C71. Chimeric plant

Chimeraplasty: Chimeraplasty was designed to repair (with the aid of Rec A, MutS) single nucleotide defects in mammalian (human) cells and also in

plants. The perfected procedure is expected to also create specific mutations. The complementary DNA is hybridized with 2'-O-methyl-RNA to protect the construct from nuclease attacks. The delivery is by injection in liposomes and it is supposed to be taken up by a sialoglycoprotein receptor. The targeting in this system is supposedly excellent. The initial experiments involved mismatch repair in the Crigler-Najjar cells and hepatocytes. During the years following the first reports the reproducibility was quite disappointing in several laboratories and the applicability of the procedure is now questionable at best. ▶[RecA](#), ▶[MutS](#), ▶[mismatch repair](#), ▶[liposome](#), ▶[sialic acid](#), ▶[Crigler-Najjar disease](#); Stephenson JJ 1999 Am Med Assoc 281:119; Taubes G 2002 Science 298:2116.

Chimeric Clones: Chimeric clones result when two segments of DNA derived from noncontiguous regions of the chromosomes are joined together. A high level of homologous recombination may cause this. These joined areas are cloned together (co-cloning). Co-cloning is disadvantageous for the construction of physical maps. ▶[chimeric DNA](#), ▶[physical map](#)

Chimeric DNA: ▶[recombinant DNA](#)

Chimeric Plasmids: Chimeric plasmids contain genetic sequences from other genomes along with their own DNA. ▶[plasmid](#), ▶[vector](#)

Chimeric Proteins: May be used to gain additional function(s) by the same molecule. That can be constructed by adding new domains. The desired domain may be provided with “sticky ends” through PCR procedures. The sticky ends are supposed to pair with homologous portions of a target in a single-strand vector and after replication one of the new strands of the double-stranded DNA will contain the sequences coding for a polypeptide corresponding to the donor molecule. Chimeric proteins may also be obtained by the use of translational fusion vectors. ▶[primer extension](#), ▶[translational gene fusion](#), ▶[vector](#); Louis JM et al 2001 Biochemistry 40:11184.

Chimeric YAC: Produced when more than one piece of DNA is ligated to the same vector arm. It is generally undesirable for chromosome walking toward a particular locus because it may direct toward different direction(s) than the region of interest. ▶[YAC](#), ▶[chromosome walking](#)

Chimpanzee (*Pan troglodytes*, $2n = 48$): The chromosome number of the great apes higher than that in humans (46) because in humans chromosome 2 is fused from two chromosomes. The ape chromosomes have been renumbered recently according to the human system (McConkey EH 2004 Cytogenet

Figure C72. Chimpanzee

Genome Res 105:157). Chimpanzee is the closest to humans among the great apes by DNA sequences (see Fig. C72). Human diverged from the chimpanzee line about 6 million years ago. A newer estimate, based on 167 nuclear protein-coding genes, suggests the divergence was 4.98–7.2 millions years ago (Kumar S et al 2005 Proc Natl Acad Sci USA 102:18842). The divergence between the human and chimpanzee X chromosomes appears more recent than the rest of the genome. This is interpreted that after the initial divergence of the two species genetic exchanges occurred again before the final separation (Patterson N et al 2006 Nature [Lond] 441:1103). The mean pair-wise sequence difference (MPSD) among chimpanzees is about four times higher (0.13%) than among humans (0.037%). Similarly, the mtDNA is more variable among different chimpanzee subspecies. This information indicates also the longer evolutionary history of this ape. The average divergence from the human nucleotide sequence is ~1.23%. One of the most important genes separating human from apes is FOXP2, responsible for the development of speech. The nonsynonymous/synonymous nucleotide substitution rate in 13,454 human-chimpanzee genes is low, 0.23, higher however than that in mouse-rat comparisons, 0.13. The same index is about the same as that among humans, ~0.23–0.20. About 33% of the longer deletions in humans are human-specific but in chimpanzee only 17% are chimpanzee-specific. There are ~7,000 Alu elements in humans but only 2300 in the chimpanzee genome. L1 element number is about the same in the two genomes. There are about 35 million nucleotide, 5-million indel difference and many chromosomal rearrangement changes between the two species. Many human disease genes have counterparts—some with different variants—in the chimpanzee genome (Li W-H, Saunders MA 2005 Nature [Lond] 437:50; The Chimpanzee Sequencing and Analysis Consortium 2005 Nature [Lond] 437:69).

Figure C73. Bonobo, chimpanzee, and hominid

One third of the human chromosomal duplications are not represented in chimpanzee. Chimpanzee-specific hyper-expansion (more than 100 copies) represents major quantitative differences between the two species. Segmental duplications had more impact on the differences than base substitutions (Cheng Z et al 2005 *Nature [Lond]* 437:88). Preliminary data indicate that 83% of the coding sequences of chimpanzee and humans differ at the amino acid level (Tateno Y et al 2005 *Nucleic Acids Res* 33: D25–28), complicating the evolutionary views. A detailed comparative map is available between the corresponding human chromosome 21 and the chimpanzee chromosome 22 indicating nearly 68,000 indels in addition to SNPs and a rather complicated evolution of these chromosomes (Watanabe H et al 2004 *Nature [Lond]* 429:382). A draft of the entire genome sequence became available in 2005 (*Nature [Lond]* 437, 1 Sept.). A report on the finished sequences of the chimpanzee Y chromosome (Kuroki Y et al 2006 *Nature Genet* 38:158) has been criticized (Hughes JF et al 2006 *Nature Genet* 38:853) and defended (Kuroki Y et al 2006 *Nature Genet* 38:854). Gene expression pattern in five different tissues of chimpanzee and humans displayed modest differences only. The transcriptome of the brain differs less between the two species than in other tissues although genes expressed in the brain accumulated more changes in humans. In the human lineage an unknown gene (MGC 8902), containing a functionally unknown domain (DUF1220), is repeated 212 times. This domain is highly expressed in the brain and the increase in humans, chimpanzees and macaques was found in the proportion of 49, 10 and 4, respectively, suggesting it to be an important factor in human evolution (Popesco MC et al 2006 *Science* 313:1304). In the intergenic sequences of protein-coding genes of the human cerebellum a noncoding RNA gene (HAR1F) is critically expressed with reelin in the cortical region during the period of 7 to 19 weeks of gestation. Several other evolutionarily, highly accelerated (HAR) areas occur in humans and they regulate neurodevelopment and therefore they are considered critical for the separation of humans from chimpanzee and other apes and for the continued evolution of humans (Pollard KS et al

2006 *Nature [Lond]* 443:167). The transcriptome of the testis shows more differences than brain, heart, liver, and kidney tissues. In general, genes expressed in more tissues show fewer differences in expression than those expressed in a single tissue (Khaitovich P et al 2005 *Science* 309:1850). Results based on 14,000 genes indicate that the number of positively selected genes is substantially smaller in humans than in chimps, despite a generally higher nonsynonymous substitution rate in humans. These observations are explainable by the reduced efficacy of natural selection in humans because of their smaller long-term effective population size, but refute the anthropocentric view that a grand enhancement in Darwinian selection underlies human origins (Bakewell MA et al 2007 *Proc Natl Acad Sci USA* 104:7489).

Chimpanzee populations in the wilds of Cameroon, Africa, may contain antibodies in 29–35% of the individuals to the SIVcpz immunodeficiency virus, a close relative of HIV-1. This indicates chimpanzees to be a source of human infection by HIV-1, the causative agent of acquired immunodeficiency. The reclusive populations were tested for nucleic acids and antibodies from fecal samples found in the forests (Keele BF et al 2006 *Science* 313:523).

Chinese Restaurant Syndrome: An adverse reaction (headache, stiffness of the neck and back, nausea, etc.) to the flavor enhancer monosodium glutamate in certain foods such as soy sauce, hot dog, etc. It may be controlled by a recessive gene. ▶monosodium glutamate; Walker R, Lupien JR 2000 *J Nutr* 130 (4):1049S.

ChIP (chromatin immunoprecipitation): ChIP assay can be used to identify definite regulatory sequences in the DNA by the use of antibodies against specific transcription factors. Chip-on-Chip (Chip-chip) uses immunoprecipitation of a DNA–protein complex and this then is followed by a microarray hybridization for mapping and quantifying the enriched short sequence (Bullwinkel J et al 2005 *J Cell Physiol* 206:624; Kondo Y et al 2004 *Proc Natl Acad Sci USA* 101:7398). ▶immunoprecipitation, ▶ChIP-chip; Zeller KI et al 2001 *J Biol Chem* 276:48285.

CHIP (channel-forming integral protein): A member of water transporters to various types of cells and tissues in cellular organisms. Chip interacts with several homeodomain proteins involved with differentiation and development of eukaryotes. In humans, the aquaporin-1 gene in chromosome 7p14 encodes it.

Chip: An electronic circuit within a single piece of semiconducting material, e.g., silicon. ▶semiconductor

Chip: ▶microarray hybridization, ▶protein chip

ChIP-chip: Chromatin immunoprecipitation followed by detection of the products using a genomic tiling array. ▶ChIP, ▶tiling; Buck MJ, Lieb JD 2004 Genomics 83:349.

Chipmunk: *Eutamias amoenus* 2n = 38; *Eutamias minimus* 2n = 38; *Funambulus palmarum* 2n = 46; *Funambulus pennanti* 2n = 54; *Glaucmys volans* 2n = 48.

CHIP-PET: DNA is immunoprecipitated and cloned into a library and then converted into paired-end (PET) ditags. Concatenated CHIP-PET library is sequenced. ▶immunoprecipitation, ▶paired-end diTAG

Chiral compound: ▶enantiomorph

Chirality: The dissymmetry of a molecule, i. e., its plane mirror image cannot be brought to coincide with itself. ▶enantiomorph (see Fig. C74).

Figure C74. Chiral isomers

Chironomus Species (2n = 8): Chironomus species are favorable organisms (dipteran flies) for cytology because of the very conspicuous differences in the banding of the salivary gland chromosome among species and within species, reflecting the activity of genes by the pattern of puff formation. ▶giant chromosomes, ▶puff, ▶Rhynchosciara, ▶Sciara; Phillips AM et al 2000 Methods Mol Biol 123:83.

Chitin: Poly-N-acetylglucosamine is part of the exoskeleton of insects, of other lower animals, and of the cell wall of fungi (see Fig. C75). Chitin is apparently absent from mammalian cells yet chitinase exists and may play a role in IL-13 pathway of Th2 induced asthma (Zhu Z et al 2004 Science 304:1678). The chitinase enzyme plays a role in the protection of plants against fungal and insect damage. In chitinases the nonsynonymous mutations in the DNA exceed the synonymous ones, indicating the tendency of adaptive

evolution in the plant defenses. ▶host-pathogen relations, ▶insect resistance, ▶exoskeleton; Bishop JG et al 2000 Proc Natl Acad Sci USA 97:5322; Zhang B et al 2002 Mol Plant Microbe Interact 15:963.

Figure C75. Chitin

Chk1: A 476 amino acid G2 cell cycle phase checkpoint serine/threonine kinase, which prevents the cell to enter the M phase in case the DNA is damaged. CDC25 protein phosphatase in yeasts and human cells dephosphorylate CDC2 at tyrosine 15 and thus activate it and turn on the cell cycle. CDC25 phosphorylated at serine-216 by Chk1 binds to proteins 14-3-3, such as RAD24, and the complex brings about the cell cycle arrest while the DNA damage is corrected. CDC25 is basically a cytoplasmic protein but it enters also the nucleus to activate CDC2 under normal conditions. After the cell is damaged, e.g., by irradiation, RAD24 facilitates the nuclear export of CDC25 and the checkpoint arrest is created. Chk1 heterozygosity by haploinsufficiency can contribute to tumorigenesis by inappropriate entry into the S phase of the cell cycle, accumulation of DNA damage during replication and failure to restrain entry into mitosis (Lam MH et al 2004 Cancer Cell 6:45). ▶cell cycle, ▶protein 14-3-3, ▶Cdc25, ▶checkpoint, ▶p53, ▶Cdc2, ▶Cdc25, ▶haploinsufficient; Chen P et al 2000 Cell 100:681.

CHK2: A checkpoint kinase, a mammalian homolog of RAD53 in *Saccharomyces cerevisiae* and Cds1 of *Schizosaccharomyces pombe*. This protein is phosphorylated in response to replication arrest or DNA injury. In vitro CHK2, like CHK1, phosphorylates CDC25C and thus prevents entry into mitosis and seems to be involved with ATM. ▶CDC25, ▶ATM, ▶RAD53, ▶p53, ▶ataxia, ▶FHA; Ward IM et al 2001 J Biol Chem 276:47755.

Chlamydia: A pathogenic bacteria. *C. pneumoniae* (1.23 Mb) causes respiratory injuries, atherosclerosis and is a sexually transmitted pathogen; *C. trachomatis* (1.05/1.07 Mb) causes blindness. Several other chronic diseases may be affected by *Chlamydia* and by other microbes. (See Zimmer Z 2001 Science 293:1977).

Figure C76. The life cycle of *Chlamydomonas*

Chlamydomonas eugametos ($n = 7$): A unicellular green alga.

Chlamydomonas reinhardtii: A unicellular green alga showing both haploid and diploid stages. (see Fig. C76). The fusion of (+) and (−) mating type gametes (that are not identifiable by morphology) gives rise to diploid cells that immediately undergo meiosis and release haploid zoospores. This progeny can be subjected to unordered tetrad analysis. On solid media they produce only rudimentary flagellae but in liquid culture they are flagellated. The zoospores may readily divide by mitosis but they sexually differentiate under nitrogen starvation and gametic fusion follows. Their basic chromosome number $n = 8$ (1.2×10^6 bp). This sequenced genome contains 17 linkage groups including 15,143 genes (Merchant SS et al 2007 Science 318:245). They contain one large chloroplast (with about 196-kbp DNA). Chloroplast genes normally show uniparental inheritance in 99% of the progeny. When the male (*mt*−) cells are irradiated with UV before mating, biparental plastids are formed. The heterozygotes for plastid genes (cytohets) display recombinations of plastid genes in their single-plastid progeny. Recombination is either reciprocal or nonreciprocal among the plastid genes. On this basis, strictly genetic maps could be constructed for the circular plastid DNA. Physical maps are also available and are used mainly for determining gene positions. Molecular analysis revealed that one plastid gene *psa* (a photosystem protein) contain three exons; exon 1 is 50 kb away from exon 2 and from this exon 3 is 90 bp apart. In between, there are several other transcribed genes. Further complication is that exon 1 is in opposite orientation to the other two. It is supposed that for the expression of this gene transsplicing is used, i.e., (in contrast to the regular, common mechanism of splicing neighboring exons), here distant transcripts are brought together in the mRNA. The mitochondrial DNA is about 15.8 kb. Some alga mutants (*minutes*) are apparently mitochondrial and resemble

petites in yeast. Since insertional mutagenesis became feasible, genetic and molecular analysis of the photosynthetic apparatus is greatly facilitated. Gene targeting, transformation, homologous recombination, site-directed mutagenesis, etc. techniques are available. [The name of this alga is often spelled as *Chlamydomonas reinhardi*.] ▶petite colony mutants, ▶chloroplast DNA, ▶chloroplast genetics, ▶eyespot, ▶mitochondria, ▶biolistic transformation; Rochaix J-D 1995 Annu Rev Genet 29:209; Rochaix J-D et al (eds) 1998 The molecular biology of chloroplasts and mitochondria in chlamydomonas. Kluwer, Dordrecht, Holland; Harris EH 2001 Annu Rev Plant Physiol Mol Biol 52:363; Grossman AR et al 2004 Annu Rev Genet 38:119; <http://www.chlamy.org>.

Chlamydospore: A thick-walled persistent asexual spore.

Chloracne: An eruption on the skin caused by exposure to chlorine and related compounds.

Chlorambucil: [p-(di-2-chloroethylamino)phenyl]butyric acid]: A radiomimetic nitrogen-mustard derivative causing primarily deletions and translocations. It had been used as an antineoplastic drug and it is also a carcinogen. ▶radiomimetic, ▶carcinogen

Chloramphenicol: An antibiotic affecting peptidyl transferase in bacterial and mitochondrial protein synthesis (see Fig. C77). In human populations about 5×10^{-5} of the individuals may be very sensitive to the drug and develop anemia. ▶cycloheximide, ▶mitochondrial human disease

Figure C77. Chloramphenicol

Chloramphenicol Acetyltransferase (CAT): The CAT gene has been extensively used as a reporter for transformation in cell culture by becoming resistant to the antibiotic chloramphenicol and thus selectable.

►antibiotics, ►transformation

Chlorate: Chlorate has been used for the isolation of nitrate reductase deficient mutations that are not poisoned by chlorate. Some mutations, however, are hypersensitive to chlorate. Chlorate-sensitivity is apparently based also on uptake problems. ►nitrate reductase

Chlorenchyma: A tissue with green plastids (chloroplasts).

Chloride Diarrhea, Congenital: A recessive defect involving ion transport, encoded in human chromosome 7q31. ►chlorate

Chlorodeoxyuridine: ►bromodeoxyuridine

Chloronema: A gametophytic cell row in mosses. ►gametophyte

Chlorophyll: Magnesium-porphyrin complexes (chlorophyll-a, -b, protochlorophyll, bacteriochlorophyll) in green plants and bacteria, receptors of light energy for carbon fixation and photosynthetic phosphorylation. The synthetic pathway: α -ketoglutaric acid \rightarrow δ -aminolevulinic acid \rightarrow porphobilinogen \rightarrow protoporphyrin IX \rightarrow Mg-protoporphyrin \rightarrow protochlorophyllide a \rightarrow chlorophyllide a \rightarrow chlorophyll a [and chlorophyll b]. When Mg is removed from porphyrin pheophorbide results and the grayish color appears. Genetically-determined failure to open the pheophorbide ring is responsible for the retention of greenness during senescing (Asrmstead I et al 2007 Science 315:73). ►Calvin cycle, ►chlorophyll-binding proteins; Suzuki JY et al 1997 Annu Rev Genet 31:61; Grossman AR et al 2004 Annu Rev Genet 38:119; degradation pathway: Hörtensteiner S 2006 Annu Rev Plant Biol 57:55.

Chlorophyll-Binding Proteins (CAB, chlorophyll A and B binding proteins, light-harvesting chlorophyll protein complex, LHCP): Chlorophyll-binding proteins are situated in the membrane of the thylakoids. They modify the plane of orientation of chlorophylls. Due to this modification the chlorophyll does not fluoresce when excited by visible light (as it would do without CAB). The light energy absorbed by (an antenna) chlorophyll is rather transferred to a neighboring chlorophyll molecule and then excites this second chlorophyll while the first one returns to the ground state. This *resonance energy transfer* is continued to further neighbors until the *photochemical reaction center* is reached. In this molecule an electron is raised to a higher energy orbital, and this

electron is transferred to the *electron transfer chain* of the chloroplast resulting in an electron hole (empty orbital). The electron acceptor thus gains a negative charge and the lost electron by the reaction center is replaced by another electron coming from a neighbor molecule, which therefore becomes positively charged. As a consequence, the light sets into motion an oxidation-reduction chain and the generation of ATP and NADPH. About 16 genes encode the CAB complex, and a LHCP system has also been identified. The red algae and cyanobacteria, which have only chlorophyll a, use phycobilisomes for light harvesting. Several types of accessory pigments (carotenoids, pteridins, phycoerythrobilin, etc.) may be associated with the light-harvesting complex. ►photosynthesis, ►photosystems, ►photophosphorylation, ►Calvin cycle, ►phycobilins, ►Z scheme; Grosman AR et al 1995 Annu Rev Genet 29:231; LHC structure; Liu Z et al 2004 Nature [Lond] 428:287.

Chloroplast: The green, chlorophyll-containing organelle of plant (algal) cells where photosynthesis takes place. It contains several rings of DNA that are transcribed and translated. The chloroplast genome of higher plants encodes about 60 to 80 proteins. Other plastid proteins (about 3,500) are imported from the cytosol and some of the proteins are under the control of the nucleus and the chloroplast genome. The division of the chloroplast DNA follows a mechanism similar to that of the prokaryotic nucleoid. Although plastid and nuclear divisions can be uncoupled, the cell cycle and plastid divisions are coordinated for normal development (Reynaud C et al 2005 Proc Natl Acad Sci USA 102:8216). ►chloroplasts, ►chloroplast genetics, ►evolution of organelles, ►Cdt1; Osteryoung KW, McAndrew RS 2001 Annu Rev Plant Physiol Plant Mol Biol 52:315.

Chloroplast Endoplasmic Reticulum: ►nucleomorph; ►endoplasmic reticulum

Chloroplast Envelope: A double membrane, which surrounds this organelle and controls the uptake of metabolites and the transport of proteins encoded by nuclear genes. Furthermore, it participates in the biosynthesis of many plastid molecules. A few of the plastid envelope components are coded, however, by ctDNA. ►chloroplasts

Chloroplast Genetics: The most successfully studied in the *Chlamydomonas* alga. *C. reinhardtii* has only one chloroplast with about 80 cpDNA molecules of 196 kbp each. The transmission of the cpDNA genome is largely uniparental, i.e., inherited most commonly through the mt^+ (comparable to egg) cytoplasm although in 1–10% of the cases biparental transmission may take place (alfalfa, *Oenothera*). The chloroplast nucleoid (DNA) transmitted by the

mt^- mate is usually completely digested in *Chlamydomonas* within 10 minutes after zygote formation, whereas the mitochondrial nucleoid still remained intact. Specially, e.g., in conifers, uniparental male transmission may also exist. The uniparental mt^+ transfer may sometimes be spurious in cases when the coding of the subunits of a particular protein is under the control of nuclear and organelle genes, respectively. In diploid vegetative zygotes of *Chlamydomonas* the biparental transmission of the extranuclear genes is most likely. Incubation in dark or postponing the meiosis by nitrogen starvation, however, favors uniparental transmission (see Fig. C78).

In higher plants, the transmission of the plastid is usually through the female but biparental or only

male transmission also occurs. The plastid nucleoids may be eliminated from, or degraded in, the sperms during the first or second nuclear division in the pollen, or they are left behind when the generative nucleus enters the egg.

In tobacco the frequency of transmission of transgenes through the pollen into the cotyledons of F1 seedlings was 1.58×10^{-5} (at 100% cross-fertilization); transmission into the shoot apical meristem was significantly lower, 2.86×10^{-6} (Ruf S et al 2007 Proc Natl Acad Sci USA 104:6998). In another experiment, plastids from the transgenic plastids of the male tobacco were transmitted (10^{-4} – 10^{-5}) frequencies indicating again that the transgene can be reasonably well contained if it is carried by the plastids

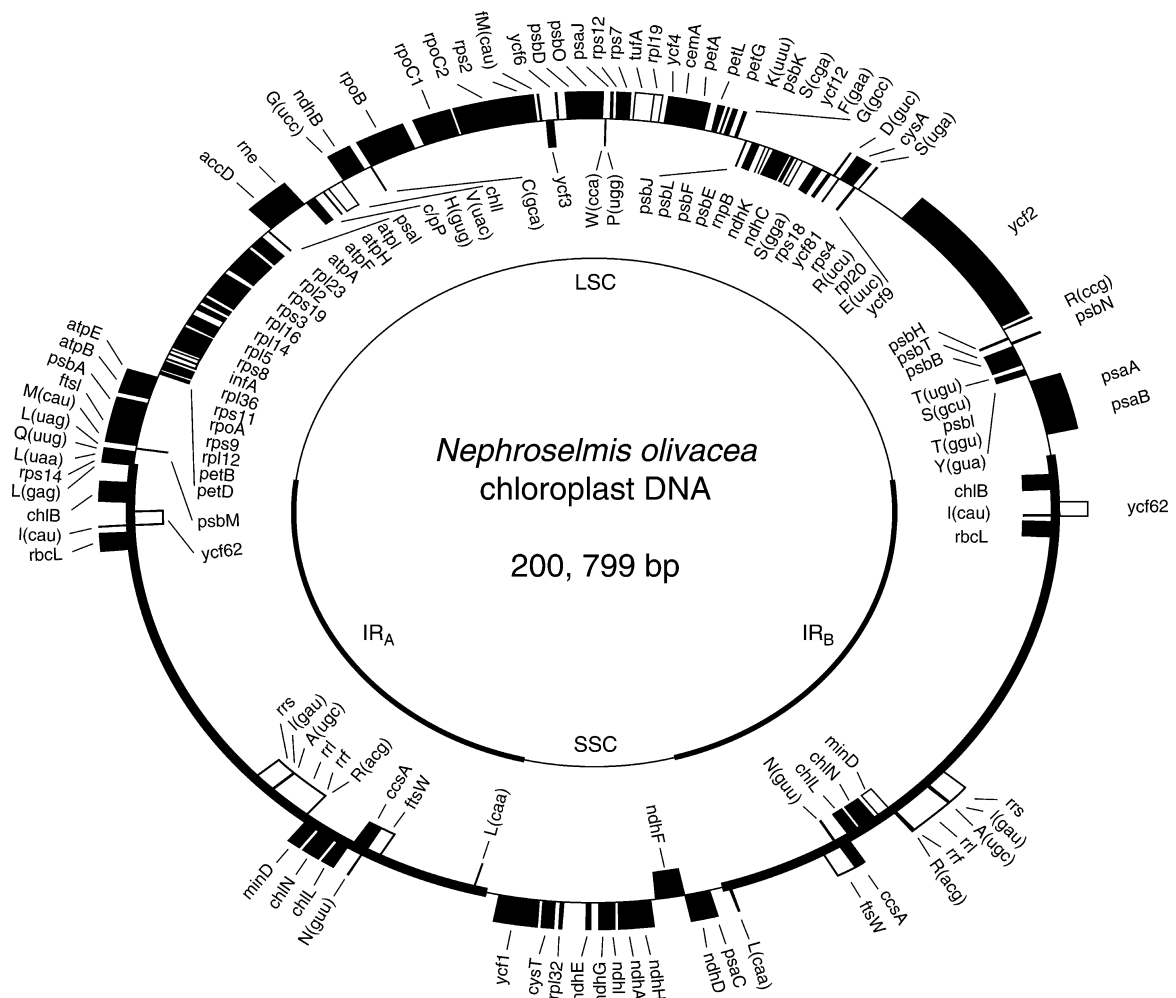

Figure C78. Chloroplast genetics. The chloroplast DNA map of the alga *Nephroselmis*. Lsc: large single-copy sequences, ssc: small single copy sequences. genes outside the large circle are transcribed clockwise and the inner set is transcribed counterclockwise. The thicker lines on the inner circle represent the two copies of the rRNA genes (IR). The gene sequences differ from some other algae and land plants. (From Turmel M et al 1999 Proc Natl Acad Sci USA 96:10248)

Figure C79. Mutant plastids in *Arabidopsis* induced by a nuclear mutator gene. At left in the top bloc, a normal chloroplast is shown. Because of the presence of the mutator, within single cells, morphologically different plastids are visible. The mutator shows biparental recessive inheritance. The plastid mutations are transmitted only through the egg. The mutator effect in *Arabidopsis* has been attributed to defects in the mitochondrial DNA. A similar mutator gene in *Oenothera* appears to be responsible for template slippage during DNA replication, however the mutations are transmitted through the chloroplast DNA. (From Rédei GP 1982 Genetics. Macmillan, New York)

rather than by the nucleus (see Fig. C79). It was an interesting observation that the entire plastome (not only a fragment of it) and also the mitochondria were simultaneously transmitted at this rate (Svab Z, Maliga P 2007 Proc Natl Acad Sci USA 104:7003).

The most common algal mutations (at different loci) require acetate as the carbon source because they cannot fix CO₂. Antibiotic resistance (or antibiotic dependent) mutations involve the rRNA or ribosomal proteins. Fluorodeoxyuridine is a specific mutagen for cpDNA. Arsenate and metronidazole are selective for nonphotosynthetic mutations. Photosynthesis defective mutations (nuclear or cpDNA) can also be screened under long-wave-length UV. Also, in higher plants, streptomycin, spectinomycin (16S rRNA) lincomycin (23S rRNA), etc., resistance mutations could be induced and isolated.

The partial inactivation of the mt⁺ cells by UV permits the transmission of cpDNA genes by the mt⁻ cells and this makes possible recombinational studies. However, some progeny cells are heteroplasmic even

after 3 divisions of the zygote. In the cpDNA, only closely situated genes display linkage with about 1 kb/map unit. Mapping is practical by physical methods: either by deletional analysis or by positional cloning, or in interspecific crosses when RFLP exists by co-segregation with restriction endonuclease fragments (*C. eugametos* x *C. moewusii*). The nature of the recombination map was hotly debated until it turned out that genes within the inverted repeats map as if the area would be linear, whereas a recombination of genes outside this region reflects the circular nature of the cpDNA. A single recombination between two circular molecules may result in a cointegrate. Recombination of cpDNA genes in higher plants also occurs albeit apparently quite rarely. The chloroplasts usually do not “synapse.” Within cells of interspecific (intergeneric) somatic fusion in the *Solanaceae* recombination of antibiotic resistance markers has been demonstrated.

Co-segregation of mitochondrial traits (cytoplasmic male sterility and chloroplast antibiotic markers)

C

was also shown. Transforming of appropriate genes (Atrazine resistance) into the cell nucleus, using T-DNA vectors, may alter chloroplast functions. Transformation—using biolistic procedures—of cpDNA can be accomplished at high frequencies (up to 1×10^{-4}) in *Chlamydomonas* and higher plants. The insertion takes place around the passenger and vector junctions and the insert replaces the resident copy in the nucleoid.

The insertion takes place by site-specific recombination and thus it is nonrandom. In tobacco the integration may be the outcome of multiple recombination events. Co-transformation of antibiotic resistance genes situated in the inverted repeats and photosynthetic genes (situated in the unique regions) can be accomplished by the simultaneous use of two vectors. Alternatively, the bacterial *aadA* gene (that detoxifies antibiotics) is used. The gene is equipped by cpDNA transcription and translation elements and surrounded by the appropriate target sequences. Whether or not the transformation involves correction of a resident gene or insertion of a foreign gene (e.g., *uidA* [glucuronidase]), the integration requires homologous recombination within the flanking sequences. Transformation has also been achieved by direct transfer and integration of the cloned gene into protoplasts in the presence of polyethylene glycol or by the biolistic methods. Under selective conditions sorting out of the transgene takes place rapidly.

The segregation and sorting out of chloroplast genes were subjected to analysis by the methods of population genetics and computer simulation. The biological observations do not seem to support the stochastic models of sorting out.

Mobile genetic elements as Group I introns, encoding the I-CreI (or I-CeuI) endonuclease and locating in the large ribosomal subunit gene or in the cytochrome b gene (I-CsmI endonuclease) in *mt*⁺ (mating type) plastid nucleoids, have been found in different *Chlamydomonas* chloroplasts. The I-CreI endonuclease has a recognition site of 24 bp. These mobile elements resemble those of I-Sce in the mitochondria of yeast.

The promoter regions of the cpDNA genome are similar to that of prokaryotes. There are generally 10 nucleotides between the TATA box (TATAAT or longer) and the first translated codon and again 17–19 bases separate the TATA box from the 5'-TTGACA promoter consensus at about -35. Internal and further upstream promoters have also been identified. Many genes are transcribed into polycistronic RNAs. In spinach, 18 major RNAs were made from a single polycistronic transcript. The 3' termini of the transcripts generally contain inverted repeats that have probably only some processing and/or stabilizing functions along with some 5'-untranslated sequences. Higher

plants appear to have a second DNA-dependent RNA polymerase, which is encoded by the nucleus (Liere K et al 2004 Nucleic Acids Res 32:1159). This polymerase transcribes a different set of chloroplast genes. Binding proteins (3') seem to be involved in the processing of the RNA. Despite common ancestry with bacterial translation, chloroplast translation is more complex and involves positive regulatory mRNA elements and a host of requisite protein translation factors that do not have counterparts in bacteria. Previous proteomic analyses of the chloroplast ribosome identified a significant number of chloroplast-unique ribosomal proteins that expand upon a basic bacterial 70S-like composition (Manuell L et al 2007 PloS Biol 5[8]:e209). Some observations indicate that polycistronic transcripts may bind to the ribosomes and translated without processing, perhaps with reduced efficiency. Translation of the chloroplast mRNA appears to be light-regulated. Apparently, an activator protein binds to the upstream untranslated region of the mRNA and the regulation is mediated through the redox state of this protein. Endonucleolytic processing of the transcripts may provide alternative leader sequences and binding sites for transcription factors. Ribosomal proteins may exert activation also by induction and modulation of translation. The chloroplast mRNAs are not capped and the initiation of transcription is regulated in a manner similar to that in prokaryotes. In the untranslated upstream regions (UTR) there are binding sites for nuclear encoded proteins that regulate transcription. Other proteins may bind to the 3' downstream sequences. Nuclear proteins mediate translational control (Choquet Y, Wollman F-A 2002 FEBS Lett 529:39). The chloroplast DNA most commonly encodes ~30 tRNAs. In the plastids of nongreen plants, the tRNA gene number is reduced to about half. ▶chloroplasts, ▶chloroplast mapping, ▶physical mapping, ▶ctDNA, ▶RFLP, ▶cointegration, ▶deletion mapping, ▶biolistic transformation, ▶transformation of organelles, ▶β-glucuronidase, ▶mutation in cellular organelles, ▶heteroplastidic, ▶sorting out, ▶introns, ▶twintrons, ▶maturase, ▶mitochondrial genetics, ▶transcription, ▶ribosomes, ▶σ, ▶translation, ▶mating type, ▶polycistronic, ▶promoter, ▶nucleoid, ▶binding protein, ▶processing, ▶redox reaction, ▶RNA editing, ▶endosymbiont theory, ▶nucleomorph, ▶metronidazole; Sugiura M et al 1998 Annu Rev Genet 32:437; Jarvis P 2001 Curr Biol 11:R307; Hagemann R 2000 J Hered 91:435; Rodermel S 2001 Trends Plant Sci 6:471; Ogihara Y et al 2002 Mol Genet Genomics 266:740; genome database: <http://chloroplast.cbio.psu.edu/>.

Chloroplast Import: The chloroplasts do not have structures for through-membrane traffic comparable

to the nuclear pores. Four proteins are involved in import through the outer membrane of the chloroplast envelope and two with import through the inner membrane (IAP = import intermediate associated proteins). Proteins enter the chloroplasts through the Toc (transport outer chloroplast membrane) complex (M_r 159K). The 159K complex may contain Toc132 or Toc120. Toc86 has proteolytic function, Toc34 appears to be a GTP-regulated import receptor, and Toc75 forms a transport channel within the membrane. Toc75 is immunologically related to heat-shock protein 70. Two others (also called IAP34 and IAP85) are guanosine triphosphate-binding proteins. Protein transport within the chloroplast and into the thylakoid lumen requires proteins SecA and SecY, homologous to translocation proteins present in bacteria. In addition, plastocyanin and the 23-kDa and the 17-kDa subunits of the oxygen-evolving complex (OEC) are involved in thylakoid transport. The Clp chaperone may also be involved in folding the imported proteins in the chloroplast stroma. [▶mitochondrial import](#), [▶Clp](#), [▶Sec](#), [▶plastocyanin](#); Bauer J et al 2001 Cell Mol Life Sci 58:420.

Chloroplast Mapping: In some algae the chloroplasts can be mapped by genetic means, a not completely natural process in most lower or higher plants. In addition, in higher plants, the number of chloroplasts per cell may be quite high and recombination is a process involving, simultaneously, multiple events. Physical maps, based on molecular techniques, are much more practical and provide more detailed information on the organization of the plastid genome. In the majority of higher plants (about 150 kbp) and *Chlamydomonas* algae (about 195 kbp) the 16, 23, 4.5 and 5 S ribosomal RNA genes occur in two repeats, separated by a long and a shorter sequence, coding for about 35 tRNAs and about 100 proteins. There are also different organizations. In *Euglena* alga, with about 145-kbp genome, the repeated rRNA clusters are adjacent. In *Pisum* (pea) the genome is only about 120 kbp and the 16S and 23S rRNA genes are located in a single cluster. In the first completely sequenced higher plant chloroplast genome of tobacco (155844 bp) the inverted rRNA repeats include 25,339 bp and the two single copy sequences contain 86,684 and 18,482 bps. (For more details see Sager R 1972 Cytoplasmic genes and organelles, Academic Press, New York; Shinozaki K et al 1986 EMBO J 5:2043–2049; Palmer JD 1991 In: Bogorad L, Vasil IK (eds), Molecular biology of plastids. Academic Press, San Diego, California, pp. 5–53A; [▶chloroplasts](#), [▶chloroplast genetics](#)).

Chloroplast stroma: The fluid phase of the chloroplast content is the site of CO₂ fixation, RUBISCO,

the Calvin cycle, chlorophyll synthesis, metabolism of amino acids, fatty acid synthesis, etc. Proteins can be exchanged among plastids. [▶RUBISCO](#), [▶Calvin cycle](#)

C

Chloroplasts: Chloroplasts are chlorophyll-containing organelles (2–20 μ m) in green plants with double-stranded circular DNA (cpDNA of 120–180 kbp in 10–100 copies/plastid) genetic material and a capacity of transcription and translation. Chloroplasts of higher plants contain about 3,000 proteins but only about 5% are encoded within this organelle. Some of the proteins are under dual (nuclear and plastid) genes. The cpDNA codes for 16S, 23S, 5S and 4.5S ribosomal RNAs and has ribosomes of about 70S size, resembling those of prokaryotes. This genome codes for about 100 polypeptides and 35 different RNAs (rRNA, tRNA). The genes are frequently transcribed into polycistronic RNA, resembling bacterial gene clusters. Their rRNA genes (10–30 kbp) are generally inversely repeated in land plants. Eighteen genera of the legumes *Fabaceae* do not have such inverted repeats. The unique sequences have a small (15–25 kbp) and a large (80–100 kbp) tract. *Pelargonium hortorum* (geranium) displays a 76-kbp repeat and this includes also some usually “unique” sequences (genes) here, though duplicated. The cpDNA usually contains other inverted repeats. The cpDNA of *Chlamydomonas* algae is larger (195–294 kbp) but has similar inverted repeats, and the unique sequences consist of two, about equal tracts with gene order differing from land plants. They have a recombination system acting among the different repeats. The *Euglena* cpDNA is similar in size (130–152 kbp) to that of land plants yet it lacks the two inverted repeats of rRNA, but it has triple tandem repeats and two-fold tandem 16S rRNA genes. The tRNAs are clustered 2–5, each. Variations are found in several miscellaneous genes too. Other algae show additional variations. The colorless algae and plants (*Epifagus*) have smaller genomes (about 70 kbp) and lacks about 95% of the genes encoding the photosynthetic apparatus, yet they have genes required for protein synthesis (rRNA, 17 tRNAs, 80% of the ribosomal proteins, etc.).

Figure C80. Stacked thylakoids form granum

C

The major function of chloroplasts is photosynthesis. Actually, the chloroplasts reduce CO₂ and split water and release O₂. Enzymes of the chloroplast stroma convert CO₂ into carbohydrate. Some of the chloroplast genes have introns and some sequences in the cpDNA have homologies with both nuclear and mitochondrial and *E. coli* DNA. In bleached mutants or in antibiotic-sensitive plants callus growth can be maintained on carbohydrate-supplied culture media. The genetic code in the plastid DNA is the universal one, unlike in mitochondria. Nuclear genes encode several plastid functions and the proteins or RNAs may be imported into the plastids from the cytosol with the assistance of transit peptides. An assembly of nuclear and plastid genes encode some of the plastid protein subunits. The chloroplast genome has apparently evolved through endosymbiosis from an ancestral prokaryote(s). The size of the chloroplasts varies from 1 to 3 µm in diameter and about 2 to 3 times as much in length. The double membrane enclosing its content has no pores.

The internal flattened membrane vesicles called *thylakoids* are stacked into *grana* and they harbor the photosynthetic apparatus. The grana are connected by the *stroma lamellae*. The stroma is the fluid phase of the chloroplasts. The photosynthetic apparatus of green bacteria and some lower algae is structurally simpler. ▶chloroplast genetics, ▶plastid male transmission, ▶cpDNA, ▶ribosomal RNA, ▶plastid number, ▶compatibility of organelles and the nuclear genome, ▶introns, ▶spacers, ▶chlorosome, ▶chromatophore, ▶chloroplast envelope, ▶chloroplast endoplasmic reticulum, ▶FtsZ, ▶photorespiration, ▶photosystems, ▶evolution by base substitutions, ▶organelle sequence transfer, ▶differentiation of plastid nucleoids, ▶endosymbiont theory, ▶nucleomorph, ▶nucleoid, ▶transformation of organelles, ▶retrograde regulation, ▶Dinoflagellates, ▶*Plasmodium*; Osteryoung KW, McAndrew RS 2001 *Annu Rev Plant Physiol Plant Mol Biol* 52:315.

CHO (Chinese hamster ovary cells): CHO are frequently used for mutation studies in cell culture because hemizyosity permits the identification of recessive mutations in these diploid cells ($2n = \pm 44$). ▶radiation hybrid; Puck TT 1974 *Stadler Symp* 6:47.

Cholecystokinin: A peptide (neuropeptide) hormone controlling appetite and several other physiological processes related to steroid hormones. ▶obesity; Malendowicz LK et al 2001 *Endocrinology* 142:4251.

Cholelithiasis (gallstone, human chromosome 1p): The genome-wide association indicates a role for hepatic cholesterol transporter (ABCG8) (Buch S et al 2007 *Nature Genet* 39:995).

Cholera Toxin: The cholera toxin causes the severely debilitating intestinal efflux of water and Na⁺ as a consequence of infection by the *Vibrio cholerae* bacterium. This enterotoxin enzyme mediates the transfer of adenylate from NAD⁺ to the Gs subunit of G_{sα}-protein. ADP-ribosylation factors also play an important role (O'Neal CJ et al 2005 *Science* 309:1093). As a consequence, G_{sα} stops acting as a GTPase. Therefore, adenylate cyclase continuously synthesizes cAMP resulting in the disturbance of the water and salt balance. Until recently, the etiology of the disease posed some tough questions because very often the *Vibrio* appeared entirely harmless. It has been shown that toxin production depends on the acquisition of the *ctx* gene complex from the filamentous phage CTX. The *ctx* complex can then be transferred from one bacterium to others. The information transfer requires that the bacterium have active pili. These toxin-coregulated pili (TCP) are encoded within the pathogenicity islands (VPI) of the *Vibrio*. The pathogenicity-island itself is also a single stranded DNA phage. The new information explains the difficulties of immunization against this infection affecting hundreds of thousands in certain years, particularly in South-East Asia. ▶G-proteins, ▶G_s, ARF, ▶pilus, ▶pathogenicity island, ▶*Vibrio*

cholerae; Tsai B et al 2001 Cell 104:937; restricting *Vibrio* propagation by phage; Jensen MA et al 2006 Proc Natl Acad Sci USA 103:4652.

Cholestasis: Cholestasis includes recessive benign recurrent intrahepatic (liver) cholestasis (BRIC or Summerskill syndrome) and recessive familial intrahepatic cholestasis (PFIC1 or Byler disease), a more serious form of impaired bile flow. Both are located at human chromosome 18q21-q22 and should be named FIC1 (familial intrahepatic cholestasis). The normal alleles encode a P-type ATPase most likely involved in the transport of amino phospholipids. The similar PFIC2 is at 2q24 and controls a bile salt export pump. PFIC3 is a mutation of the multidrug resistance glycoprotein gene at 7q21. Cholestasis-lymphedema is a severe childhood disease of the bile. Farnesoid X hormone receptor antagonists may have potential for clinical treatment of cholestasis (Stedman C et al 2006 Proc Natl Acad Sci USA 103:11323). ▶[bile salts](#), ▶[farnesoid receptor](#), ▶[ATPase](#), ▶[phospholipid](#), ▶[ABC transporters](#), ▶[cirrhosis of the liver](#), ▶[steroid 5-beta reductase](#); Bull LN 2002 Current Op Genet Dev 12:336.

Cholesterols: Cholesterols are amphipathic (lipid) molecules with a polar head and a non-polar hydrocarbon tail, and are found in membranes (▶[cell membranes](#)). Cholesterols are the principal sterols in animals; they occur also in plants (stigmasterols, sitosterol) and in fungi (ergosterol). Bacteria generally lack sterols (see Fig. C81). Cholesterols are synthesized from acetate through mevalonate, isoprenes, and squalenes to a four-ring steroid nucleus. The principal regulatory enzyme is 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase. Most of the cholesterol synthetic activity takes place in the liver and used as bile acids (cholesteryl esters). The excess cholesterol is generally degraded into bile acids and is catalyzed by the cytochrome P450 cholesterol 7 α -hydroxylase (CYP7A1). The farnesoid X receptor (FXR), and 4 other orphan nuclear receptors are involved in the transcriptional control. The level of bile acids also regulates the activity of CYP7A1. A small heterodimer partner (SHP) and the liver receptor homolog 1 (LRH-1) modulate the process. Cholesterols are parts of membranes and steroid hormones, and are precursors of vitamin D. Cholesterols are indispensable for numerous functions and are generally synthesized in sufficient amounts by the human body, although dietary cholesterol may increase its level. Accumulation of excessive amounts of cholesterol bound to low-density lipoproteins (LDL) may lead to occlusion of the blood vessels (atherosclerotic plaques) leading to coronary heart disease. Familial combined hyperlipidemia (low density lipoproteins) seem to be

controlled at 2p25.1, and loci 9p23 and 16q24.1 seem to be responsible (lod score > 2.0) for the low level of high-density lipoprotein cholesterol. Several other loci are involved in the control of the lipoproteins at variable levels of significance and differently by ethnicity (Pajukanta P et al 2003 Am J Hum Genet 72:903). HMG-CoA and Δ^7 -reductase deficiency result in embryonic malformation in rodents. The Δ^7 -reductase deficiency in humans results in the Smith-Lemli-Opitz syndrome. Δ^7 -reductase and Δ^{24} -reductase control the step preceding cholesterol from 7-dehydrocholesterol and desmosterol, respectively. Recessive desmosterolosis (1p31.1-p33) is due to a defect of 3 β -hydroxysterol Δ^{24} -reductase (Waterham HR et al 2001 Am J Hum Genet 69:885). Defects in cholesterol transport and uptake are also deleterious to embryonal (brain) development in mice. The receptors of the LDL and VLDL lipoproteins are apparently of minor importance for the embryo but deficiency of the scavenger receptor (SR-BI) expressed on the surface of the mouse yolk endodermal cells and within the placenta may cause embryo lethality. Similarly deficiency of LDL receptor-related protein (LRP) involves lethality. Defects in another lipoprotein receptor, megalin, cause death after birth by holoprosencephaly (a neural tube defect) and other anomalies. Cholesterols modify the hedgehog protein involved in developmental signaling. Cholesterol biosynthesis is regulated through the LXR receptors. LXR α forms a dimer with receptor RXR and they bind to a DNA response element after being activated by two oxysterols. LXR α -deficient mice are unable to convert efficiently cholesterols to bile acids. The N-terminal basic helix-loop-helix leucine zipper domain of SREBP-2 (sterol regulatory element-binding protein 2) is a nuclear transcription factor of cholesterol and unsaturated fatty acid metabolism (Lee SJ et al 2003 Science 302:1571). Scap protein binds SREBP and moves it and the binding proteins from the endoplasmic reticulum to the Golgi apparatus where SREBs are processed by Site-1 and Site-2 proteases to active fragments, which enter the nucleus and facilitate the expression of genes in cholesterol synthesis and uptake. When cholesterol accumulates in the endoplasmic reticulum, Scap/SREB are not transported by COP coated vesicles, the processing stops and the target gene activity declines. Insig (insulin-introduced gene) binding retains Scap in the endoplasmic reticulum and SREBP is degraded by proteasomes (Goldstein JL et al 2006 Cell 124:35). ▶[lipids](#), ▶[sphingolipids](#), ▶[lanosterol](#), ▶[Scap](#), ▶[Insig](#), ▶[prenylation](#), ▶[familial hypercholesterolemia](#), ▶[raft](#), ▶[high-density lipoprotein](#), ▶[hypertension](#), ▶[myocardial infarction](#), ▶[CETP](#), ▶[Wolman disease](#), ▶[Niemann-Pick disease](#), ▶[Smith-Lemli-Opitz syndrome](#), ▶[Tangier disease](#), ▶[CHILD syndrome](#),

Cholic Acid ($C_{24}H_{40}O_5$): Bile acid produced from cholesterol by 7α -hydroxylase and 12α -hydroxylase enzymes. Defects in the genes CYP7A1 (8q21.13) and CYPB1 (8q21.3) that encode these enzymes may result in cholestasis (blockage of bile) and cirrhosis of the liver (fibrous alteration of the parenchymal tissue). ►cholesterol, ►cirrhosis of the liver, ►farnesoid receptors

Choline: In the form of acetylcholine, choline is a neurotransmitter and affects the development of the brain. Choline is also a methyl donor for methionine and contributes to the biosynthesis of membranes and in signaling phospholipids, sphingomyelin, phosphatidylcholine, etc. It is recommended that pregnant and lactating mothers include 450–550 mg/day, respectively, in their diet. Lysophosphatidylcholine is a ligand of the immunoregulatory G2A receptor; a defect in this mechanism may lead to autoimmune disease and atherosclerosis. ►acetylcholine, ►sphingolipids, ►autoimmune disease, ►atherosclerosis; Kabarowski JHS et al 2001 Science 293:702.

Cholinesterase: Hydrolase that splits acyl groups from choline, and is required for the normal functioning of the nervous system. Organophosphorus insecticides (parathion, chlorpyrifos, [Dursban], diazinon, and the nerve gas, sarin, can poison cholinesterase. Paraoxonase (PON1), an enzyme associated with high-density lipoproteins, may detoxify organophosphate compounds but substantial human polymorphism exists in PON1. About 1/2,500 people lack cholinesterase activity and may suffer life-threatening paralysis if succinylcholine anesthetic is used before/during surgery. ►pseudocholinesterase; Stewart R

2001 Lancet 358:73; Walker AW, Keasling JD 2002 Biotechnol Bioeng 78:715.

Chondriolite: The nucleoid of the mitochondrion. ►nucleoid, ►mitochondria

Chondriome: The genome in the mitochondria.

Chondriosome: An old name for the mitochondrion. ►mitochondria

Chondrocyte: A cartilage cell of mesenchymal origin that can secrete collagen and glucosaminoglycans (polysaccharides with alternating sequences of more than one type of sugar). Bone morphogenetic protein function is essential for chondrogenesis (Yoon BS et al 2005 Proc Natl Acad Sci USA 102:5062). ►cartilage, ►SOX, ►nitric oxide

Chondrodysplasia (CD): In the autosomal *dominant* form (Conradi-Hünemann disease) excessive bone formation occurs at the epiphysis (bone ends). The additional characteristics of this disease are other abnormal bone formations and relatively rare (in less than 30% of afflicted cases) cataracts and skin anomalies. The dominant CPDX2 Conradi-Hünemann syndrome gene at Xp11.22-p11.23 encodes a 3β -hydroxysteroid- Δ^8, Δ^7 -isomerase involved in cholesterol biosynthesis, converting cholest-8(9)-en- 3β -ol into cholest-7-en- 3β -ol (lathosterol). Excessive calcium deposits accompany the autosomal recessive forms and hence the name chondrodysplasia punctata, as the name punctata refers to the spotted calcification of the cartilage. The stippled appearance of the cartilage in this condition is similar to that in the Zellweger syndrome. Cataracts develop in about two-thirds of the cases. The symptoms may be phenocopied by maternal exposure to the warfarin pesticide that depletes vitamin K-dependent blood coagulation. However, a form of autosomal CD punctata accompanied by a deficiency in the hereditary blood coagulation factor may be cured by vitamin K. Another *dominant X-chromosomal* dwarfism gene (supposedly at Xq28) also manifests bald or scar-like spots (“punctata”) apparently caused by lower peroxisomal functions. The rare autosomal dominant Murk Jansen type CD is characterized by short legs, extreme disorganization of the limb (metaphysis) and foot bones, and defects of the spine, pelvis, and fingers. This type of CD, like most other forms, involves the accumulation of calcium, but also shows reduced phosphate levels in the blood. The basic defect is in the gene encoding the parathyroid hormone-related peptide involving replacement of histidine²²³ by arginine. The autosomal recessive Hunter-Thompson acromesomelic chondrodysplasia (the shortening of the limbs is most pronounced in the distal bones) is caused by defects in the

cartilage-derived morphogenetic protein (CDMP1), a member of the TGF- β superfamily of growth factors. The *metaphyseal chondrodysplasia* (McKusick type) is a recessive 9p1 short-limb dwarfism accompanied by sparse blonde hair; it is caused by mutation RNase MRP. *Rhizomelic chondrodysplasia punctata* (RCDP1, 6q22-q24) is caused by mutation of the peroxin 7 gene (DAPAT) but similar symptoms occur in other diseases involving peroxisomes. The Schmid type metaphyseal chondrodysplasia (6q21q22.3) is a defect in the α chain of collagen X. Mutations in the diastrophic dysplasia sulfate transporter (DTDST/SLC26A2, 5q32-q33.1) are responsible for several diseases (multiple epiphyseal dysplasia, neonatal osseous dysplasia, diastrophic dysplasia, achondrogenesis Type 1B) due to the deficiency of inorganic sulfate uptake required for the normal formation of glycosaminoglycan-containing extracellular matrix. The reduced sulfate uptake affects several tissues but primarily the cartilage (Forlino A et al 2005 Hum Mol Genet 14:859). *Jeunal asphyxiating thoracic dysplasia* (JATD) is genetically heterogeneous, with one locus at chromosome 15q13. A screen of 12 consanguineous JATD pedigrees was found to identify three families showing patterns consistent with linkage to a locus in chromosome 3q24-3q26. This autosomal recessive chondrodysplasia often leads to death in infancy because of a severely constricted thoracic cage and respiratory insufficiency. It frequently involves also retinal degeneration, cystic renal disease, and polydactyly. The basic defect is the mutation of an intraflagellar transport protein, IFT80 (Beales PL et al 2007 Nature Genet. 39:727). ▶dwarfism; ▶vitamin K; ▶vitamin K-dependent blood clotting factors; ▶antihemophilic factors; ▶peroxisome; ▶collagen; ▶Zellweger syndrome; ▶Smith-Lemli-Opitz syndrome; ▶Schwartz-Jampel syndrome; ▶asphyxiating thoracic dystrophy; ▶TGF; ▶GDF; ▶microbodies; ▶warfarin; ▶RNase MRP; ▶peroxins; ▶collagen; ▶CHILD syndrome

Chondroitin Sulfate: A heteropolysaccharide composed of alternating units of glucuronic acid and acetylglucosamine; related compounds form the ground substance, an intracellular cement, of the connective tissue. ▶mucopolysaccharidosis, ▶spondyloepiphyseal dysplasia

Chondrome: The complete set of the mitochondrial genes. ▶mtDNA

CHOP (Children's Hospital of Philadelphia): The future home of the Center for Applied Genomics, a database for human diseases and drug development.

CHOP: ▶GADD153

Chopase: Chopase is a term used for a recombination enzyme breaking DNA double strands versus the "nickase" which cuts only the single DNA strand. ▶recombination molecular mechanisms

Chordin: ▶organizer, ▶bone morphogenetic protein

Chordoma (7q33): An apparently dominant, rare, and malignant tumor of the notochordal remnants that may metastasize. ▶notochord, ▶metastasis; Kelley MJ et al 2001 Am J Hum Genet 69:454.

Chorea: Chorea refer to complex, involuntary, jerky movements. ▶Huntington's chorea, ▶benign hereditary chorea

Chorea-Acanthocytosis (CHAC, 9q21): Chorea-acanthocytosis is a neurodegenerative and erythrocyte-related malformation with an onset generally between ages 25 to 45. The basic defect is due to the 3,174-amino acid protein, chorein. ▶acanthocytosis; Ueno S-i et al 2001 Nature Genet 28:121.

Choreoathetosis, Kinesigenic Paroxysmal (PKC): PKC refers to recurrent involuntary movements caused by a neurological dominant defect at 16p11.2-q12.1. Males are three to four times more frequently affected than females.

Chorion: The chorion is the outermost envelope of the mammalian embryo (fetus); in arthropods, fishes etc., it is the non-cellular membrane surrounding the egg. ▶amnion, ▶allantois, ▶chorionic villi, ▶trophoblast

Chorionic Villi: The thread-like protrusions or tufts on the surface of the chorion. They are used in amniocentesis. ▶amniocentesis

Chorismate: A precursor of the biosynthesizers tryptophan, phenylalanine, tyrosine, and various derivatives. In the following pathway, the enzymes involved are shown in parenthesis. Phosphoenolpyruvate + Erythrose-4-phosphate → (2-keto-3-deoxy-D-arabino-heptulosonate-7-phosphate synthase) → 2-Keto-3-deoxy-D-arabino-heptulosonate-7-phosphate → (dehydroquinase synthase) → 3-Dehydroquinase → (3-dehydroquinase dehydratase) → 3-Dehydroshikimate → (shikimate dehydrogenase) → Shikimate → (shikimate kinase) → Shikimate-5-phosphate → (enolpyruvylshikimate-5-phosphate synthase) → 3-Enolpyruvylshikimate-5-phosphate → (chorismate synthase) → Chorismate. ▶tryptophan, ▶tyrosine, ▶phenylalanine, ▶phenylketonuria, ▶alkaptonuria; Dosselaere F, Vanderleyden J 2001 Crit Rev Microbiol 27:75.

Choroid: An inner layer of the eyeball supplying blood to the optical nerves. ▶retinal dystrophy

Choroidal Osteoma: An autosomal dominant eye neoplasia with bony-like cells. Choroidal sclerosis and choroid plexus calcification are autosomal recessive conditions. ▶choroid

C

Choroid Plexus: Choroid plexus forms in the blood-brain barrier and produces cerebrospinal fluid. ▶BBB

Choroideremia: A X-linked recessive atrophy of the choroid and the retina. ▶choroid, ▶retina, ▶eye diseases

Choroidoretinal Degeneration: Choroidoretinal degeneration is a type of X-linked retinitis pigmentosa, distinguished by a brilliant patch at the macula of the eye. ▶retinitis pigmentosa, ▶macula, ▶macular degeneration, ▶macular dystrophy, ▶foveal dystrophy

Chotzen Syndrome (Saethre–Chotzen syndrome, acrocephalosyndactyly, ACS): ACS is the dominant inheritance of syndactyly of fingers and toes, asymmetric and narrow head, etc., encoded in human chromosome 7p21–p22 by a gene appearing homologous to *Twist* of *Drosophila*, coding for a 490 amino acid protein containing a basic helix-loop-helix motif. *Twist1* and the related *Hand2* dimerization and phosphorylation seem to be responsible for limb-related defects (Firulli BA et al 2005 Nature Genet 37:373). ACS may involve haplo-insufficiency. ▶syndactyly, ▶Apert syndrome, ▶Robinow syndrome, ▶limb defects, ▶craniosynostosis syndromes, ▶helix-loop-helix, ▶*Twist*; Yousfi M et al 2002 Hum Mol Genet 11:359.

CHR: ▶cluster homology region, ▶CDF, ▶corticotropin releasing factor

CHRC (chromatin-accessibility complex): ▶nucleosome

Christmas Disease: ▶antihemophilic factors

Chromaffin Cell: Chromaffin cells are specifically receptive to staining by chromium salts.

Chromalveolate Hypothesis: The chromalveolate hypothesis suggests that a monophyletic super assemblage (*chromalveolata*) and a single secondary endosymbiosis of a red alga formed the four major lineages of protists—cryptophytes, haptophytes, heterokonts, and alveolates. Plastids have subsequently been eliminated. This evolutionary hypothesis did not gain general acceptance.

Chromatid: A chromosomal strand containing one DNA double helix (see Fig. C82). After replication, each chromosome usually contains two chromatids, held together at the left and right sides of the centromere. ▶chromosome, ▶centromere

Figure C82. Chromatid

Chromatid Bridge: Whenever dicentric chromosomes are formed (paracentric inversion heterozygotes, breakage-bridge-fusion cycles, ring chromosomes) the spindle fibers pull the chromosomes to the opposite poles; at one region the chromosomal material is stretched (not unlike a stretched rubber band) and this thin connecting tie is called the chromosome bridge (see Fig. C83). The bridge eventually breaks and this leads to an unequal distribution of genes to the poles, resulting in duplications and deficiencies in the daughter cells. ▶breakage-bridge-fusion cycles, ▶bridge, ▶inversion, ▶ring chromosome, ▶bridge

Figure C83. Chromatid bridge

Chromatid Conversion: ▶tetrad analysis

Chromatid Interference: Crossing over within a chromatid reduces the chance for another to occur. Chromatid interference can genetically be determined by a tetrad analysis, where in the absence of chromatid interference, 2-strand, 3-strand, and 4-strand double crossing over should occur in the proportion 1:2:1. Any deviation from this proportion is chromatid interference. The evidence for positive chromatid interference is rare. ▶double crossing overs, ▶interference, ▶coincidence; Zhao H et al 1995 Genetics 139:1057; Copenhaver GP et al 2002 Genetics 160:1631.

Chromatid Segregation: Chromatid segregation takes place after recombination and in case of polysomy exerts a detectable effect on the segregation ratios. In the mouse, the left-right dynein motor gene mutation may alter the laterality of visceral organs and also selectively affect chromatid segregation (Armakolas A, Klar AJS 2007 Science 315:100). ▶autopolyploidy, ▶trisomy, ▶situs inversus viscerum, ▶dynein

Chromatin: The material forming the eukaryotic chromosome (DNA, RNA, histones, and non-histone proteins) is known as chromatin. The DNA in the chromatin of a chromosome stretches from telomere to telomere and attracts the various acidic proteins and RNA present in the matrix. The DNA has short bp (80–100). An “average” eukaryotic chromosome

at metaphase may be 10 to 15 μm long but the DNA in it may be 100,000 times longer when fully extended. The problem of accommodation is comparable to fitting a 2.5 km long thread into a 2.5 cm long skein 3 mm across the diameter. The folding must be extremely orderly and stable to assure perfect synapsis preceding recombination and still flexible enough to make possible error-free replication within a few hours. The elementary DNA double helices form nucleosomal structures with supercoiled stretches of histone proteins. When the majority of the protein is digested away from the DNA, the remaining structure appears in the form of a protein scaffold with DNA loops attached. The regions where the DNA is attached to the nuclear matrix is called MAR (matrix attachment region). The MAR sequences are generally rich in AT. They seem to contain transcriptional activators and recognition sites for topoisomerase II. Chromosomes condensed by various nuclear stains (Giemsa stain, a mixture of basic dyes) display characteristic C (centromeric region) and G bands that helps to identify several regions along the chromosomes. The nature of the specificity of the G staining is not known. That *rotational positioning* of the nucleosome in which the histone octamer is facing away from the minor groove of the DNA permits DNase I to cleave the chromatin into 10 bp sequences. *Translational positioning* of the nucleosomes in the chromatin defines the position of the nucleosomes relative to the site of transcription initiation of a gene about 300 to 150 bp away. In yeast, the MFa2 repressor regulates positioning. When a histone octamer is at the TATA box, transcription is hindered. Histone 1 is a repressor of all three eukaryotic RNA polymerases. During active transcription the nucleosomes are apparently not removed but only reconfigured. Genes in the chromatin may be attached to the nuclear scaffold at areas of their separation and thus are insulated from each other by these 'boundary elements'. The locus control element (LCR) in the chromatin seems to regulate the activity of groups of genes. Genes that are co-expressed are frequently clustered in the chromatin. These *open chromatin* regions are thus distinguished from the *closed chromatin* regions lacking active genes (Roy PJ et al 2002 Nature [Lond] 418:975). ▶stains, ▶FISH, ▶chromosome painting, ▶chromosome banding, ▶nucleosome, ▶chromosomal proteins, ▶heterochromatin, ▶euchromatin, ▶high mobility group of proteins, ▶histones, ▶histone variants, ▶on-histone proteins, ▶nucleosome, ▶nuclease hypersensitive sites, ▶LCR, ▶nuclease-sensitive sites, ▶prochromatin, ▶antichromatin, ▶chromatin code; Widom J 1998 Annu Rev Biophys Biomol Struct 27:285; Cremer T, Cremer C 2001 Nature Rev Genet 2:292; Gasser SM

Chromatin Assembly Factor (CAF): During genetic repair, the chromatin and the nucleosomal organization of the cell have to be destabilized and after repair reorganized. The nucleosomal structure, replication complex, the various transcription factors, etc., must be restored after excision of the DNA defects. This process requires a series of sequentially interacting proteins, commonly known as CAFs. ▶chromatin, ▶Rad53, ▶histone variants; Emili A et al 2001 Molecular Cell 7:13.

Chromatin Code: The chromatin code is the hypothesized system regulating the folding of chromatin fibers of eukaryotes. ▶chromatin

Chromatin Diminution: Chromatin diminution occurs when pieces of chromosomes are excised or entire genomes are fragmented to generate minichromosomes. Such a phenomenon is normal during the 2nd to 8th cleavage divisions of *Ascaris* and related nematodes and during the formation of the macronuclei of ciliated protozoa. The fragments may be reintegrated again into much larger chromosome(s) in the generative cell nuclei or the germline may develop from a single cell that has not undergone chromosome diminution. The fragmentation is followed by the addition of 2–4-kb telomeric repeats (TTAGGC). Such repeats may be added also at other chromosomal breakage region (CBR) sites. AT-rich sequences near the CBR (approximately 1/4 of the germ-line DNA, including the two types of Tas retrotransposons) are eliminated during diminution. ▶*Ascaris megalocephala*, ▶*Paramecium*, ▶telomere; Müller F, Tobler H 2000 Int J Parasitol 30:391; Redi CA et al 2001 Chromosoma 110:136; Goday C, Esteban MR 2001 Bioessays 23:242.

Chromatin Filament: Chromatin filament is a nucleosomal DNA fiber 30 nm across the diameter that appears as a beads-on-string structure during electron microscopy; the beads being the nucleosomes. The folding of the fiber may be the consequence of H1 histone-induced contraction of the internucleosomal angle as the salt concentration approaches the physiological level. Decondensation required for transcription may be the consequence of depletion

of the linker histone or acetylation of the core histone tail domain. ►nucleosome, ►histones, ►chromatin, ►lamins; Moir RD et al 2000 J Struct Biol 129:324.

C

Chromatin Modification: ►chromatin remodeling

Chromatin Remodeling: Chromatin remodeling is a change effected in the nucleosomal structure by establishing nuclease hypersensitive sites in front of active genes. In recent years several protein factors have been identified with this type of function. The first was the ATP-dependent yeast SWI/SNF (switch/*Saccharomyces* nuclear factor, 11 subunits in yeast, 8 subunits in humans) recognized by transcriptional activation. The Snf2-like subunits display helicase-like function. The NURF (nucleosome remodeling factor) and an ATP-dependent 4-subunit protein were found in *Drosophila*. Its critical subunit ISWI (imitation switch, 140-kDa; human homolog of hSNF2h) is shared by yeast. Isw2 complex represses some genes upon its recruitment by Ume6p to specific loci. Ume6 is a sequence-specific binding protein. ACF has an ISWI subunit of ATP, and also topoisomerase II activity. The RSC (remodeling *Saccharomyces* chromatin, 15 subunits) protein works on the chromatin around the centromere and is specialized probably for the regulation of the kinetochore function. The bromodomain of Gcn5/p300 co-ordinates the remodeling of nucleosomes. RSF (remodeling and spacing factor) and FACT (facilitator of chromatin transcription) mediate the initiation of transcription on chromatin template depending on ATP and other protein factors. They also facilitate elongation of the transcript through the nucleosomes. RSC can recognize acetylated nucleosomes and facilitate passage of Pol II through them supporting the view that histone modifications regulate accessibility of the coding region to Pol II (Carey M, Workman JL 2006 Mol Cell 24:481). CHD1, together with the chaperone NAP-1, assembles nucleosome arrays from DNA and histones in vitro and in vivo (Konev AY et al 2007 Science 317:1087).

A mutant form of the p53 protein was found to assume a gain-of-function switch regulating the cell cycle and causing polyploidy in the Li-Fraumeni syndrome. SWI/SNF and RSF can facilitate the expression of transcriptional repressors too. The NUR protein also has both chromatin remodeling and histone acetylation capabilities. Some of these factors participate both in the assembly of nucleosomes and in remodeling. The Swr1 chromatin remodeling protein complex facilitates the replacement of the H2A/H2B histone complex by H2AZ/H2B. The replacement recruits the Sir2, Sir3 and Sir3 silencers to the so-modified nucleosomes. As a consequence the telomeric heterochromatin is

distinguished from the adjacent euchromatin by localized silence (Mizuguchi G et al 2004 Science 303:343). Besides histone acetyltransferases and phosphorylases, methylation of lysine residue 9 near the N-end of histone 3 regulates the activity of chromatin. Methylation of Lys⁹ interferes with phosphorylation of Serine¹⁰, and may involve aberrant mitotic divisions. Phosphorylation of histone 3 (by ERK, RSK, MSK, p38) at serine 10 is linked to transcriptional activation of the DNA. Ubiquitylation, sumoylation, ADP ribosylation, deamination and proline isomerization can also affect histones (Kouzarides T 2007 Cell 128:693). Pontin (Tip49) and Reptin (tip48) are components of chromatin remodeling complexes and transcription. They interact with several proteins (TBP, β -catenin, Myc, Wnt) and are thus involved in several regulatory/developmental pathways (Etard C et al 2005 Mech Dev 122:545).

►DNase hypersensitive site, ►nucleosome, ►chromatin, ►PIC, ►histones, ►histone deacetylase, ►histone variants, ►silencer, ►heterochromatin, ►nuclear receptors, ►promoter, ►histone acetyltransferase, ►bromodomain, ►RAG1, ►CHRAC, ►BRG, ►BRM, ►SSRP, ►MSK, ►SANT, ►SNF, ►SWI, ►SAGA, ►ERK, ►RSK, ►MSK, ►p38, ►PBAF, ►PCAF, ►TAF_{II}, ►TAF_{II}230-250, ►topoisomerase, ►transcription map, ►Li-Fraumeni syndrome, ►DiGeorge syndrome, ►Williams syndrome, ►Coffin-Lowry syndrome, ►p53, ►kinetochore, ►transcription factors, ►Polycomb, ►methylation of DNA, ►ACF, ►CAF, ►Sin3, ►p300, ►GCN5; Tyler JK et al 1999 Cell 99:443; Knoepfler PS, Eisenman RN 1999 Cell 99:447; Gebuhr TC et al 2000 Genesis 26:189; Cheung P et al 2000 Cell 103:263; Cosma MP et al 2000 Cell 97:299; Nakayama T, Takami Y 2001 J Biochem 129:491; Fry CJ, Peterson CL 2001 Curr Biol 11:R185; Sassone-Corsi P 2002 Science 296:2176; Tsukiyama T 2002 Nature Rev Mol Cell Biol 3:422; Olave IA et al 2002 Annu Rev Biochem 71:755; Horn PJ, Peterson CL 2002 Science 297:1824; Pandey R et al 2002 Nucleic Acids Res 30:5063; chromatin remodeling in plants: Hsieh T-F, Fischer RL 2005 Annu Rev Plant Biol 56:327; mammalian differentiation and chromatin remodeling: de la Serna IL et al 2006 Nature Rev Genet 7:461.

Chromatin State Fixation: A hypothetical mechanism that stabilizes the function of certain genes and keeps others dormant (by heterochromatinization). ►heterochromatin

Chromatin-Negative: Cells that do not display heterochromatic Barr bodies. ►sex chromatin, ►Barr body

Chromatography: Chromatography, in various forms, partitions molecular mixtures between a stationary

(sugar, cellulose, silica gel, sepharose, hydroxyapatite) and a water base or organic liquid phase. ▶ [thin layer chromatography](#), ▶ [Rf value](#), ▶ [column chromatography](#), ▶ [high performance liquid chromatography](#), ▶ [affinity chromatography](#), ▶ [ion exchange chromatography](#)

Chromatoid Body: A perinuclear mRNA-containing cytoplasmic organelle during germ cell development; it is the processing center of RNAs. It also includes microRNA, siRNA, and proteins involved in their processing. It is very similar to nuage. ▶ [microRNA](#), ▶ [RNAi](#), ▶ [nuage](#), ▶ [piRNA](#); Kotaja N et al 2006 Proc Natl Acad Sci USA 103:2647.

Chromatophores: The pigmented cells or the pigment-rich invaginations of the cell membrane.

Chromatosome: A part of the nucleosome, obtained as an intermediate during digestion with micrococcal nuclease. It contains a core particle of a histone octamer wrapped around by about 1 and 3/4 turn of about 146 bp plus 20 on each side, held together at the entry and exit points by H1 histone. ▶ [nucleosome](#); Zlatanova J et al 1999 Crit Rev Eukaryot Gene Expr 9:245.

Chromocenter: Heterochromatin aggregates such as the common attachment point of the polytenic chromosomes in the salivary gland nuclei. ▶ [salivary gland chromosomes](#); Clark DV et al 1998 Chromosoma 107:96.

Chromodomain: A conserved domain in the family of *Polycomb* genes, and also in heterochromatin protein HP1. Chromodomains are supposed to be involved in the maintenance of chromatin structure by interacting between proteins and RNA, and repress transcription. Chromodomains may be regulators of dosage compensation in males. ▶ [chromatin](#), ▶ [dosage compensation](#), ▶ [SET](#), ▶ [heterochromatin](#), ▶ [Swi6](#), ▶ [Polycomb](#), ▶ [histones](#), ▶ [CHARGE](#); Jones DO et al 2000 BioEssays 22:124; Grewal SI, Jia S 2007 Nature Rev Genet 8:35.

Chromogranins (CGA, CGB): Inositol 1,4,5-trisphosphate-sensitive Ca^{2+} storage proteins of the secretory granules of neuroendocrine cells. They occur in the cytoplasm and in the nucleus. CGB appears to control (+ or -) the transcription of several genes, including those encoding transcription factors. ▶ [InsP³](#), ▶ [transcription factors](#); Yoo SH et al 2002 J Biol Chem 277:16011.

Chromokinesins: The proteins that hold the chromosomes on the mitotic/meiotic spindle. ▶ [NOD](#), ▶ [Xklp1](#), ▶ [spindle](#); Levesque AA, Compton DA 2001 J Cell Biol 154:1135.

Chromomere: The densely stained bead-like structures along the chromosomes at early prophase. Chromomeres represent increased coiling of the chromatin fibers (see Fig. C84). In the lampbrush chromosomes the loops seem to emanate from the chromomeres. In the salivary chromosome bands there are appositioned chromomeres of a large number of chromatids. Chromomeric structures were recognized and their constant number observed by Balbiani in 1876. In the 1920s, John Belling counted their number in the genome and assumed that chromomeres are physically identical to genes and that the 2,193 chromomeres in the lily, *Lilium pardalinum*, indicated 2,193 genes as well. The chromomeric structure of the chromosomes is useful in identifying chromosomal aberrations by light microscopy. In the human autosomes the chromomere number varies from 499 to 386. ▶ [chromosome morphology](#), ▶ [salivary gland chromosomes](#), ▶ [lampbrush chromosomes](#), ▶ [pachytene analysis](#), ▶ [gene number](#); Judd BH 1998 Genetics 150:1; Jagiello GM, Fang JS 1982 Am J Hum Genet 34:112.

Figure C84. Chromomeres as illustrated by J. Belling [1928] (University of California Publ. Bot 14:307)

Chromomethylase: Chromomethylases are enzymes of plants that methylate CpXpG chromosomal sites, especially within transposons. Histone protein (HP1) directly binds to the telomeric DNA and histone methylases methylate H3K9 and are both required for silencing telomeric sequences but telomere elongation is under the rule of H3K9 methylation. (Perrini B et al 2004 Mol Cell 15:467). Histone-3 lysine 9 (H3K9) methylase (controlled by the *Kryptonite* gene in *Arabidopsis*) and Chromomethylase-3 (CMT3) controls H3K27 positions. DNA methylation requires the simultaneous action of both of these enzymes

(Lindroth AM et al 2004 EMBO J 23:4146). ▶methylation of DNA, ▶transposon; Tompa R et al 2002 Curr Biol 12:65.

C

Chromomycin A3: Chromomycin A3 is used as a stain, specifically for GC nucleotides in the DNA.

Chromonema: Chromonema is a term that is used for the chromosomes of prokaryotes and for the smallest light-microscopically visible chromosome thread, chromatin filament, or genophore. ▶genophore, ▶Mosolov model, ▶chromosome structure, ▶chromatin filament; Nicolini C et al 1997 Mol Biol Rep 24 [4]:235.

Chromophore (dye): A chemical substance that gives color to a structure upon binding to other compounds. ▶stains, ▶fluorochromes

Chromoplasts: Plastids in which red and yellow pigments (rather than chlorophylls) predominate, as in the fruits of mature tomatoes and other plants, e.g., *Capsicum*. ▶plastids

Chromoshadow Domain: ▶heterochromatin; Lechner MS et al 2000 Mol Cell Biol 20:6449; Lomberg G et al 2006 Genome Biol 7:228; Verschure PJ et al 2005 Mol Cell Biol 25:4552.

Chromosomal Aberrations: ▶chromosomal rearrangements, ▶chromosome breakage, ▶X-ray breakage of chromosomes; Mutation Res 504, issues 1–2 (2002).

Chromosomal DNA: ▶chromatin

Chromosomal Inheritance: Chromosomal inheritance is a somewhat outdated term for inheritance of nuclear genes since frequently organellar DNA molecules are also called chromosomes.

Chromosomal Instability (CIN): CIN may occur spontaneously in cultured cells of animals and plants and its frequency depends on the age and composition of the nutrient media. Generally the frequency of the anomalies is lower in liquid media. Mitotic anomalies (nondisjunction) as well as polyploidy, aneuploidy, and rearrangements occur. One of the major contributing factors may be the lack of coordination between nuclear divisions and cell divisions. Chromosomal instabilities may be found in intact organisms as well, and are caused primarily by natural insertion and transposable elements, and also by insertions introduced by transformation. In yeast, the inactivation of Mad2 anaphase promoting protein and p53-dependent checkpoint pathway also controls chromosome instability (Burds AA et al 2005 Proc Natl Acad Sci USA 102:11296). The chromosomal complement of a cancer cell is generally unstable. The signature of chromosomal instability of particular genes is predictive of metastasis and prognosis for cancer

(Carter SL et al 2006 Nature Genet 38:1043). ▶hybrid dysgenesis, ▶RIP, ▶Roberts syndrome, ▶isochores, ▶transposable elements, ▶RIZ, ▶chromosomal rearrangements, ▶chromosomal aberrations, ▶MAD, ▶p53, ▶checkpoint, ▶cancer, ▶metastasis, ▶Nijmegen breakage syndrome, ▶Bloom syndrome, ▶Werner syndrome, ▶Fanconi anemia, ▶caffeine, Kolodner RD et al 2002 Science 297:552.

Chromosomal Interchange, Reciprocal: ▶translocation breakage syndrome, ▶Bloom syndrome

Chromosomal Mosaic: Not all the cells in the body have the same chromosomal constitution, i.e., patches of different chromosomal morphology or number co-exist. Hence the term chromosomal mosaic. ▶chimera

Chromosomal Mutation: Chromosomal mutations include mutations that involve defects detectable by the light microscope, and generally, mutations involving structural and numerical alterations of the chromosomes and mutations other than base substitutions. ▶chromosomal rearrangements, ▶chromosome breakage, ▶deficiency, ▶duplication, ▶inversion, ▶translocation

Chromosomal Passenger Complex: ▶centrosome

Chromosomal Polymorphism: Chromosomal polymorphism means that more than one type of chromosomal morphology or arrangement is present in a population.

Chromosomal Proteins: Chromosomal proteins include histones and a variety of non-histone proteins involved in the determination of the structure, replication, and transcription, as well as the regulation of these processes in eukaryotes. Protamines, instead of histones, are found in sperms. Histones are absent in a majority of fungi but eukaryotic viruses such as SV40 chromosomes have nucleosomal structure. Compared with eukaryotic chromosomes, prokaryotic chromosomes contain a lesser variety and quantity of proteins. ▶chromatin, ▶histones, ▶non-histone proteins

Chromosomal Rearrangements: Chromosomal rearrangements include (internal) deletions, (terminal) deficiencies, duplications, transpositions, inversions, and translocations (see Fig. C85). The majority of the chromosomal rearrangements are deleterious because they involve loss or altered regulations of functions (chromosomal aberrations are concomitant with several types of cancers), yet duplications and inversions play a role in evolution (see diagram). Besides neoplasias, several hereditary human diseases involve chromosomal alterations. Chromosomal rearrangements play an important role in the etiology of

C

Figure C85. Chromosomal rearrangements. Major rearrangements involving human chromosome 7. The chromosomes represented by lines above and below, chromosome 7 shown in the center. Vertical bars mark centromeres. The darker lines indicate rearrangements within chromosome 7, the lighter lines show the translocations between the chromosomes numbered and chromosome 7. (After Hillier LW et al 2003 Nature [Lond] 424:157 by permission of Dr. Richard K. Wilson)

cancer. Deletions may eliminate genes controlling important checkpoints in the cell cycle (tumor-suppressants). Inversions and translocations may result in gene fusions, and proliferative processes may be activated (oncogenes, transcription factors, transcriptional activators, etc.). If the c-MYC oncogene is inserted in the immunoglobulin heavy chain or in an immunoglobulin κ or λ gene or T cell receptor gene, the oncogene may be activated. When the ABL oncogene (9q34.1) is translocated to the breakpoint cluster (BCR) in the Philadelphia chromosome (22q), myelogenous and acute leukemia may develop as a consequence of elevated protein tyrosine kinase activity. Inversion of human chromosome 14q(11; q32) involving the T cell receptor (14q11) and the immunoglobulin heavy chain (14q32.33) results in the fusion of the variable region of the immunoglobulin and the T cell receptor (TCR α) may cause lymphoma. Translocations may facilitate protein dimerization and changes in transcription. Site-directed chromosome rearrangements can be induced by the techniques of molecular biology. The *loxP* prokaryote gene can be inserted site-specifically by recombination into two selected chromosomal positions. Then the *Cre* prokaryotic recombinase is introduced into the same embryonic mouse stem cells by a transient expression transformation procedure. Thus, translocation involving the MYC oncogene (chromosome 15) and an immunoglobulin (IgH) gene (chromosome 12) were reciprocally translocated. The selectable markers neomycin phosphotransferase (*neo*) and hypo-xanthinephosphoribosyl transferase (*Hprt*) facilitated the selective isolation of the translocations. The frequency of this type of exchange is in the 10^{-6} to 10^{-8} range. In budding yeast cells, mutations in genes RFA1, RAD27, MRE11,

XRS2, and RAD50 may increase gross chromosomal aberrations 600–5000 fold. In yeast genome-wide selection detected 10 genes that are suppressor of gross chromosomal aberrations (Smith S et al 2004 Proc Natl Acad Sci USA 101:9039). During the evolution of humans and mice, apparently one chromosomal rearrangement was fixed per Myr of evolution. Among cats, cows, sheep and pigs a far fewer (0.2/Myr) number of rearrangements took place during evolution. Among plants the rearrangement rates varied substantially from 0.15 to 0.41 per Myr to 1.1 to 1.3 per Myr. Chromosomal aberrations of larger size can be detected by light microscopic analysis of meiotic cells or sometimes the analysis of mitotic cells using old-fashioned stains (carmine or orcein) or the various banding procedures. The use of variations of the FISH technology greatly facilitates microscopic identifications. Very small chromosomes or chromosomal fragments can be studied by pulsed field gel electrophoresis. Human chromosome 2 appears to be the fusion product of two ancestral chromosome at a 2.6-Mb region of 2q21.1–2q22.2 (Hillier LW et al 2005 Nature [Lond] 434:724). Chromosomal rearrangements are restricted by the presence of Ku70-Ku80 heterodimers and by DNA replication checkpoints (Banerjee S et al 2006 Proc Natl Acad Sci USA 103:1816). ▶ chromosomal mutations, ▶ cryptic chromosomal aberration, ▶ ataxia, ▶ Bloom's syndrome, ▶ Cockayne syndrome, ▶ Fanconi anemia, ▶ Lynch syndromes, ▶ Werner syndrome, ▶ Wiskott-Aldrich syndrome, ▶ Cri du chat, ▶ Wolf-Hirschhorn, ▶ Williams syndrome, ▶ Langer-Gideon, ▶ WAGR, ▶ Prader-Willi syndrome, ▶ Smith-Magenis, ▶ Alagille syndrome, ▶ DiGeorge syndrome, ▶ Rubinstein-Taybi syndrome, ▶ Miller-Dieker syndrome, ▶ Charcot-Marie-Tooth disease, ▶ Pelizaeus-Merzbacher disease,

Chromosomal Sex Determination: In most eukaryotes, female have two X-chromosomes (XX) and males have one X and one Y chromosome (XY); birds and butterflies have heterogametic females (WZ) and homogametic males (ZZ). In some species (frogs, platyfish, housefly) both types of sex determination is known (Ogata M et al 2003 Genetics 164:613). In the monotreme platypus, an unusual mammal displaying some phenotypic characteristics similar to those of ducks and water rats, five X and five Y chromosomes form a multivalent chain in meiosis. In the male the chain includes 5 X and 5 Y, which segregate into XXXXX and YYYYY-bearing sperm. In the monotreme platypus ten chromosomes form a multivalent chain at male meiosis, adopting an alternating pattern to segregate into XXXXX-bearing and YYYYY-bearing sperm. Which, if any, of these sex chromosomes bears one or more sex-determining genes remains unknown, and the largest X chromosome (at one end of the chain) bears homology to the human X chromosome, whereas the other end of the chain the X has homology to the Z chromosome of birds, indicating an evolutionary link between mammals and birds (Grützner F et al 2004 Nature [Lond] 432:913). Multiple sex chromosomes occur as sex determination anomalies in the plant *Melandrium*. Two Y chromosomes occur in some ecotypes of *Rumex*. In the nematode *Caenorhabditis* the males have only one X-chromosome (XO) and the hermaphrodites have two (XX); similar mechanism exists also in several fishes. In wasps and bees the females and workers hatch from fertilized eggs whereas the males are the products of unfertilized eggs or hatch from eggs which lost the paternal set of chromosomes after fertilization, although in the body cells the males may double their DNA content during development. In mammals the chromosomal

constitution determines the gonads/sex but the phenotype is controlled by hormones. ►sex determination, ►sex chromosomal anomalies in humans, ►hormonal effect on sex expression, ►X-chromosome counting, ►arrhenotoky, ►thelytoky, ►deuterotoky, ►mealy bug, ►mountjack, ►monotreme, ►*Rumex hastatulus*, ►*Melandrium*; Charlesworth B 1996 Curr Biol 6:149.

Chromosomal Virulence Loci (*chv*): The majority of the virulence loci (*vir*; controlling transfer of the T-DNA of the Ti plasmid) of *Agrobacterium* are situated in the plasmid but the *chv* genes are in the main DNA (chromosome) of the bacteria. ►*Agrobacterium*, ►Ti plasmid, ►virulence genes of *Agrobacterium*; Suzuki K et al 2001 DNA Res 8:141.

Chromosome: The DNA containing nuclear structure, embedded in a protein and RNA matrix of eukaryotes. Chromosomes also refer to the DNA strings of prokaryotic nucleoids, mitochondria, and chloroplasts (sometimes also called genophores because the latter are associated with only small amounts of proteins in comparison to the eukaryotic nuclear chromosomes). The morphology (length, arm ratio, appendages [satellites], and banding pattern [natural or upon staining by special dyes]) and chromosome number are characteristic for the species in eukaryotes. The nuclear chromosomes of eukaryotes are generally linear but the organellar DNAs are circular chromosomes. Bacterial and viral chromosomes are generally circular. ►chromosome morphology, ►chromosome structure, ►satellite, ►and additional items beginning with ►chromosomal or ►chromosome

Chromosome Aberrations: Changes in chromosome numbers (polyploidy, aneuploidy, hypoploid, hyperploid) and changes in chromosomal structure (deficiency, deletion, inversion, translocation, transposition). Many chromosomal aberrations involve human disease. (See terms under separate entries, correlation of breakpoints with disease: <http://www.pdg.cnb.uam.es/UniPub/HCAD/>).

Chromosome Abnormality Database: e-mail address <mailto:simon@bioch.ox.ac.uk>.

Chromosome Addition: ►alien addition

Chromosome Arm: The portion of a chromosome on either side of the centromere (see Fig. C86). ►chromosome morphology, ►isobrachial, ►heterobrachial, ►arm ratio

Figure C86. Chromosome arm

Chromosome Assignment Test: ►somatic cell hybridization

Chromosome 5B: A gene (*Ph*) in the B genome of wheat suppresses homoeologous pairing in this allohexaploid species. In case of loss of this chromosome or its pairing controlling region, synapsis may take place among all homoeologous chromosomes and multivalents are formed. Similar regulator genes occur in other chromosomes of wheat and other allopolyploid species. ►chromosome pairing, ►synapsis, ►multivalent, ►*Triticum*, ►allopolyploid; Dworak J, Lukaszewski AJ 2000 *Chromosoma* 109:410.

Chromosome Banding: Chromosome banding visualized by various staining techniques seems to have functional significance. Broadly expressed genes generally cluster in GC isochores and in R bands and their number is low in G bands (Lercher MJ et al 2003 *Hum Mol Genet* 12:2411). ►C-banding, ►G-banding, ►Q-banding, ►R bands, ►T bands, ►isochores, ►SR motif, ►comparative chromosome painting, ►comparative genomic hybridization, ►evolution of the karyotype

Chromosome Breakage: Chromosomes may break “spontaneously” or by the effects of chemical and physical agents (ionizing radiation). The breakage may involve only one of the chromatids or both (isochromatid breaks) (see Fig. C87).

Single breaks may lead to terminal losses of chromosomes (chromosome deficiency) whereas double and multiple breaks may cause internal deletions and various rearrangements such as transposition, inversion, and translocation. Deletions require only single breaks to occur at first order kinetics, chromosomal rearrangements generally follow second or multiple order kinetics. At first order kinetics the breakage occurs in a linear proportion to the dose of the agent causing it, at second order kinetics the number of breaks are proportional to the square of the dose (exponential response), i.e., at low doses the rise of the number of breaks is slow and at higher doses the rise in the number is steeper ►kinetics

Figure C87. Chromosome breakage. The ionizing radiation traversing an elementary chromosome fiber may simultaneously inflict damage at multiple sites within 2000 basepairs hit. (After Rydberg B et al 1995 in *Radiation Damage to DNA*, p.56; Fuciarelli AF, Zimbrick JD eds., Batelle, Columbus, OH)

The electrons may directly hit the DNA or may generate reactive OH[•] radicals.

In response to DNA damage on consensus sites recognized by ATM (ataxia telangiectasia mutated) and ATR (ataxia telangiectasia Rad3-related), more than 900 regulated phosphorylation sites encompassing over 700 proteins were detected. Functional analysis of a subset of this data set indicated that this list is highly enriched for proteins involved in the DNA damage response. This set of proteins is highly interconnected and consists of a large number of protein modules and networks (Matsuoka S et al 2007 *Science* 316:1160).

Chromosomal double breaks may also be caused by the localized hits of two or more OH[•] radicals. The radical may affect only one strand at a site and a second hit may take place 10 bp away (*hybrid attack*) on the other strand of the double helix. A very low energy electron transfer may be sufficient to break the second strand; thus resulting in a double-strand break that may follow single electron absorption. When several hits are delivered at close proximity, clusters of complex damage may occur (see Boudaïffa B et al 2000 *Science* 287:1658). The final outcome is modified also by the efficiency of repair mechanisms. Cancerous growth is frequently associated with chromosome breakage although it is unknown how many cases were caused by chromosome breakage and how often this occurred only during the process of abnormal cell proliferation. Infection by adenovirus, cytomegalovirus, herpes, Epstein-Barr virus, etc., may cause human chromosomal breakage. An increased frequency of chromosome breakage and/ or deficiency of genetic repair accompanies several human diseases and or deficiency of genetic repair Fanconi's anemia, Bloom's syndrome, ataxia telangiectasia, xeroderma pigmentosum, Cockayne syndrome, and leukemia. Leukemias and solid tumors often involve chromosome breakage and concomitant gene fusion. Tumorigenesis is commonly initiated by a recombination-like event of the immunoglobulin genes or of the sequences in the T cell receptor (TCR) genes.

C

Chromosomal translocations may bring transcriptional activators, enhancers, DNA binding proteins, protein ligands, or transcription factors in the vicinity of genes resulting in the production of growth and cell cycle factors. ▶Roberts syndrome, ▶deletion, ▶inversion, ▶translocation, ▶transposition, ▶cancer, ▶chromosomal rearrangements, ▶chromosome breakage programmed, ▶environmental mutagens, ▶mutator genes, ▶DNA repair, ▶position effect, ▶cancer, ▶isochores, ▶X-ray caused chromosome breakage, ▶immunoglobulins, ▶T cell receptor, ▶transcription factors, ▶binding proteins, ▶enhancer, ▶transcriptional activators, ▶ataxia; Sánchez-García I 1997 Annu Rev Genet 31:429; Anderson RM et al 2002 Proc Natl Acad Sci USA 99:12167.

Chromosome Breakage as a Bioassay: Many mutagenic and carcinogenic agents cause chromosome breakage that is cytologically (by light microscope) detectable. Such breakage involves single chromatid lesions, double (isochromatid) breaks, deletions, transpositions, translocations, inversions, chromosome fusions, dicentric and acentric fragment formation, etc. The frequency of these alterations can be quantitated during mitotic and meiotic nuclear divisions of suitable plant (root tips, flower buds) and animal systems (cultured lymphocytes, fibroblasts, cells withdrawn from amniotic fluids during gestation, bone marrow cells, and spermatocytes). The cytological assays can also reveal aneuploidy and polyploidy, which do not involve chromosome breakage but non-disjunction may be the result of damage either to the centromere or to the spindle fibers. ▶bioassays in genetic toxicology, ▶heritable translocation assays; Chu EHY, Generoso WM (eds) 1984 Mutation, Cancer and Malformation, Plenum, New York.

Chromosome Breakage, Programmed: Programmed chromosome breakage occurs during the development of ciliated protozoa (*Tetrahymena*) and ascarid nematodes (*Ascaris megalocephala*) and converts the larger chromosomes of the germline into many smaller chromosomes of the macronucleus. In *Tetrahymena* the 5 basic chromosomes contain 50 to 200 specific breakage sites and generate fragments of about 800 kb that persist during the vegetative life. The different breakage sites in *Tetrahymena thermophila* share a 15 bp conserved tract (5'-TAAAC-CAACCTCTTT-3'). After the breakage the broken ends, 5–25 bp away, form new telomeres and lose about 25–65 bp around the breakage point. ▶*Tetrahymena*, ▶*Ascaris megalocephala*; Fan Q, Yao M-C 2000 Nucleic Acid Res 28:895.

Chromosome Breakage Syndromes: ▶fragile X syndrome, ▶Bloom syndrome, ▶Fanconi anemia, ▶ataxia, ▶trinucleotide repeats

Chromosome Bridge: ▶bridge, ▶chromatid bridge

Chromosome Coiling: The status of condensation of chromosomes (see Fig. C88). During interphase the chromosomes are almost entirely stretched out but as the cell cycle proceeds the coiling increases reaching a maximum at metaphase. The two chromatids may be twisted around each other during prophase (relational coiling). This type of coiling does not permit the coiled strands to separate entirely unless the separation begins at one end and is completed to the other end (plectonemic coiling). In case the coiling resembles pushing two spirals together, they can be separated in a single movement because they are not entangled (paranemic coiling). The coiling is not usually detectable in all cytological preparations unless specially treated (e.g., with ammonia vapor). ▶concatenate, ▶supercoiling, ▶SMC, ▶Mosolov model; Dietzel S, Belmont AS 2001 Nature Cell Biol 3:767.

Figure C88. Chromosome coiling. The *Tradescantia virginiana* photo is the courtesy of Vosa CG; from Clowes FA, Juniper BE 1968. Plant Cells. Blackwell, Oxford, UK

Chromosome Compaction: The folding and packaging of the elementary chromosome fibers into the chromosomes, visible through light microscopy. ▶chromatin

Chromosome Complement: A haploid chromosome set. ▶haploid

Chromosome Condensation: The increasingly-tight winding of chromosomal coils from interphase to metaphase. ▶chromosome coiling, ▶mitosis, ▶meiosis, ▶condensin, ▶DNA packaging, ▶packing ratio, ▶Mosolov model; Uhlmann F 2001 Curr Biol 11:R384; Pflumm MF 2002 BioEssays 24:411.

Chromosome Configuration (meiotic configuration): The manner of pairing or assembly of chromosomes during meiosis. ▶meiosis, ▶translocation, ▶inversion

Chromosome Conformation: The relative spatial disposition of the chromatin fiber. The conformation affects gene expression, interaction and genetic repair processes (Dekker J et al 2002 Science 295:1306).

Chromosome Conformation Capture (3C method): The 3C method can detect interaction between two chromosomal loci (see Fig. C89). The chromosomes can occupy a dynamic state within the nucleus and an appropriate technique can fix the conformation of two chromosomes relative to each other. At the interaction site formaldehyde can fix the pairs, endonucleases digestion can cut the area, and PCR determine the interacting nucleotide sequence. Functionally distinct AT- and GC-rich domains can display different conformations (Dekker J et al 2002 Science 295:1306). Circular chromosome conformation capture (4C) involves a circularization step that enables high-throughput screening of physical interactions between chromosomes without a preconceived idea of the interacting partners. Several of the 114 unique sequences from all autosomes were found to interact primarily with the maternally inherited *H19* imprinting control region (Zhao Z et al 2006 Nature Genet 38:1341). 4C technology (chromosome conformation capture (3C)-on-chip) allows for an unbiased genome-wide search for DNA loci that contact a given locus in the nuclear space. Active and inactive genes are engaged in many long-range intrachromosomal interactions and can also form interchromosomal contacts (Simonis M et al 2006 Nature Genet 38:1348). ▶PCR, ▶imprinting, ▶chromosome territories; review: Krueger C, Osborne CS 2006 Trends Genet 22:637.

Chromosome Contamination: ▶hybrid dysgenesis

Chromosome Core: The central axial part of the chromosome; it is well visible in lampbrush chromosomes. ▶lampbrush chromosome, ▶synaptonemal complex

Chromosome Crawling: The same as inverse PCR. ▶inverse PCR

Chromosome Crisis: Chromosome crisis occur when abnormalities in the cell lead to telomere dysfunction and to other chromosome anomalies that eventually lead to malignant transformation and cancer. ▶telomere, ▶cancer; Maser RS, DePinho RA 2002 Science 397:565.

Chromosome Dimer: A chromosome dimer is formed by recombination between two DNA rings or two ring chromosomes (see Fig. C90).

Figure C90. Chromosome dimer

Chromosome Diminution: Chromosome diminution refers to the fragmentation of the large (polycentric) meiotic chromosomes in the soma line of *Ascaris megalocephala univalens* with one pair of meiotic chromosomes and *A. bivalens* with two meiotic pairs into 52 to 72 and 62 to 144 small chromosomes in the soma, respectively. ▶macronucleus, ▶Paramecia, ▶internally eliminated sequences; Niedermaier J, Moritz KB 2000 Chromosoma 109:439.

Chromosome Doubling: Chromosome doubling can be brought about by chemical or physical agents, which block the function of the spindle fibers during meiosis or mitosis. Commonly the alkaloid colchicine is used but other agents such as acenaphthene (a petroleum product used in pesticides, industry, and plastic manufacturing), have also been employed. The purpose of chromosome doubling is the induction of polyploidy and in species hybrids to restore fertility of those hybrids which would be sterile without doubling the chromosome number because the distantly related chromosomes would not have homologs to pair with. ▶colchicine, ▶polyploid, ▶amphidiploid; Otto SP Whitton J 2000 Annu Rev Genet 34:401.

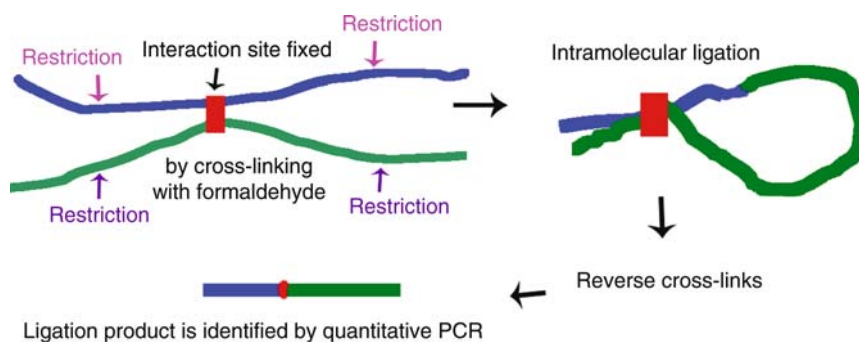

Figure C89. Chromosome conformation capture

Chromosome Drive: ► [meiotic drive](#)

Chromosome Elimination: Somatic chromosomes may be lost as a natural process during cleavage divisions in dipteran and hemipteran insects but the germline cells retain the entire and intact genome. In *Ascaridea* and some other species certain chromosomal segments may be lost as part of chromosomal differentiation during mitosis. In *Ascaris megalocephala univalens* only one pair of chromosomes is involved during meiosis and that is fragmented into several smaller chromosomes during somatic cell divisions. The macronuclei in *Paramecia* have only metabolic functions and they disintegrate after the exconjugants are formed following fertilization; only the micronuclei are retained. The macronuclei are reformed after mitoses of the diploid zygotes. Nondisjunction may also result in elimination because both the non-disjoined chromosomes pass to one pole. The gene *polymitotic* (*pol*, map location 6S-4) of maize may eliminate several or even all the chromosomes after meiosis during successive divisions because nuclear divisions do not keep up with the rapid succession of cell divisions. In the pentaploid *Rosa canina* ($2n = 35$) 7 bivalents are formed both at male and female meiosis but in the male generally all the univalents are lost whereas in the female one set of the 7 chromosomes derived from the bivalents and the univalents are retained in the basal megaspore and in the egg. Thus upon fertilization the 35 chromosome number is restored in the zygotes. Chromosome elimination occurs regularly in species with supernumerary chromosomes that have unknown function and a defective centromere. Because of the nature of the centromere, the supernumerary chromosomes commonly display nondisjunction and additional losses after fragmentation. Chromosome elimination occurs when *Hordeum bulbosum* is crossed either with *H. vulgare* or hexaploid wheat. In somatic cell hybrids of human and mouse cells, the human chromosomes are gradually eliminated unless they carry genes essential for the survival of the hybrids. ► [Hordeum bulbosum](#), ► [haploids](#), ► [cybrid](#), ► [chromosome diminution](#), ► [Ascaris megalocephala](#), ► [Paramecium](#), ► [Rosa canina](#), ► [bivalent](#), ► [univalent](#), ► [B chromosomes](#), ► [cybrid](#), ► [assignment test](#); Ruddle FH, Kucherlapati RS 1974 *Sci Am* 231[1]:36; Goday C, Esteban MR 2001 *Bioessays* 23:242.

Chromosome Engineering: Chromosome engineering generates rearrangements in the genomes, making alien additions and translocations, and facilitates homoeologous pairing and recombination, alien transfers, alien substitutions, monosomics, chromosomal rearrangement, targeting genes, etc., with the primary goal to improve the species for agronomic purposes. About 20% human pregnancies are afflicted with different kinds of major or minor

chromosomal rearrangements and genetic engineering in mice permits reconstruction of these defects (van der Weyden L, Bradley A 2006 *Annu Rev Genomics Hum Genet* 7:247). ► [individual entries for these terms](#), ► [Cre/loxP](#); Sears ER 1972 *Stadler Symp* 4:23; Higgins AW et al 1999 *Chromosoma* 108:256; Choo KH 2001 *Trends Mol Med* 7:235; Mills AA, Bradley A 2001 *Trends Genet* 17:331.

Chromosome Hopping: ► [chromosome jumping](#)

Chromosome Inheritance: Chromosome inheritance is determined by the mitotic and meiotic apparatuses. Disturbance in the normal transmission of chromosomes may cause genetic anomalies, disease, and cancer. Several proteins control the complex process. (See Dobie KW et al 2001 *Genetics* 157:1623).

Chromosome Interference: ► [interference](#)

Chromosome Jumping: Chromosome jumping is a special type of chromosome walking that takes advantage of the breakpoints of chromosomal rearrangements as guide posts and permits the cloning of the two ends of a DNA sequence without the middle section. The procedure may take advantage of existing chromosomal rearrangements or the genomic DNA may be partially digested with any restriction endonuclease or with enzymes that cut very rarely. The DNA fragments are circularized with the aid of DNA ligase and cloned in such a way that the cloning vector contains a known *E. coli* sequence between the ligation sites. The cloned product is then digested by a restriction enzyme that does not cut within the special *E. coli* sequence. Thus the fragments generated contain the *E. coli* sequence flanked by the cloned target DNA sequence that was originally far away (100–150 kb) in the chromosome. The *E. coli* sequence containing fragments are then recloned in a phage vector and the DNA is probed to a DNA library to identify the clones that contain sequences far away in the eukaryotic genome. This procedure thus facilitates the rapid movement toward the genetic cloning target. It may also be combined with chromosome walking to approach the desired gene. ► [chromosome walking](#), ► [jumping library](#); Bender W et al 1983 *J Mol Biol* 168:18.

Chromosome Knobs: The dark-stained structures in the chromosomes best recognized during pachytene stage, representing local condensation of the chromatin (see Fig. C91). Dark knobs are a characteristic feature of certain genomes within a species. The presence of knobs may affect recombination frequencies in their vicinity and knobs may be involved in preferential segregation. ► [chromosome morphology](#), ► [knob](#), ► [karyotype](#), ► [pachytene analysis](#), ► [preferential segregation](#); Ananiev EV et al 1998 *Genetics* 149:2025.

Figure C91. Chromosome knob. Pachynema of maize chromosome 9 tip, homozygous for large knob K^L . (Courtesy of Dr. Gary Kikudome)

Chromosome Landing: An approach for gene isolation from large eukaryotic genomes by first identifying linkage to close physical markers. It is a substitute for chromosome walking which is frequently impractical in these organisms. ▶chromosome walking; Tanksley SD et al 1995 Trends Genet 11:63.

Chromosome Library: A collection of individual chromosomes isolated by flow cytometric separation or pulsed field gel electrophoresis. Such a library may facilitate the manipulation of large eukaryotic genomes. ▶flow cytometry, ▶pulsed field electrophoresis; Zeng C et al 2001 Genomics 77:27.

Chromosome Maintenance Region 1 (CRM1, also called exportin 1): A karyopherin-like protein involved in nuclear import along with NES (nuclear export signal), a leucine-rich protein. CRM1 may also affect chromosome segregation. ▶karyopherin, ▶exportin, ▶importin, ▶RNA export, ▶nuclear pore; Lindsay ME et al 2001 J Cell Biol 153:1391.

Chromosome Map: ▶mapping genetic, ▶physical mapping, ▶radiation mapping

Chromosome Marker: A morphological (e.g., knob, satellite, band) or molecular (restriction enzyme recognition site) signpost on a chromosome. ▶chromosome knob, ▶satellite, ▶banding

Chromosome Mobilization: *mob*, conjugation.

Chromosome Morphology: Chromosome morphology is generally identified at metaphase and accordingly meta-, submetacentric, acro-, and telocentric chromosomes are distinguished (see Fig. C92). Furthermore, secondary constrictions and appendages (satellites)

are distinguished. The various banding techniques permit the analysis of individual chromosomes on the basis of differential staining. By the application of probes with fluorochromes chromosomes paint in different details (translocations, transpositions) and can be identified. In interphase and prophase (pachytene) some chromosomes display chromomeres, cross bands (salivary gland chromosomes, giant chromosomes), or natural knobs. The non-nuclear, prokaryotic and viral chromosomes are usually circular. ▶karyotype, ▶chromosome banding, ▶chromosome painting, ▶fluorochromes, ▶FISH, ▶PRINS, ▶pachytene analysis, ▶chromosome knobs, ▶nucleolar organizer, ▶centromere, ▶secondary constriction, ▶organelles

Chromosome Mutation: Any change (beyond the size of a nucleotide or codon) involving the structure or number of the chromosomes. ▶chromosomal aberration, ▶chromosomal rearrangement, ▶chromosome doubling, ▶point mutation, ▶codon

Chromosome Numbers: Chromosome numbers are variable among the different species and although the numbers may vary, they are important and stable taxonomic features (see Table C5). The basic number is represented by x , the gametic number by n , and the somatic number by $2n$. Thus in a diploid species like *Arabidopsis* $x = 5 = n$. In hexaploid wheat $6x = 2n$. The chromosome number may vary between males and females as a mechanism of sex determination. Also, centromeric fusion may generate one bi-armed chromosome from two telocentrics (acrocentric) or the opposite may take place. In cultured cells of mice the chromosomes may become acrocentric and double in number. The majority of bacteria have a single circular chromosome. Some other species, e.g., *Rhodobacter sphaeroides*, *Agrobacterium tumefaciens*, *Brucella melitensis*, *Vibrio cholerae* also have multiple chromosomes. Chromosome numbers of organisms often studied in genetics are shown here and additional numbers are found under the English (or scientific) name of different organisms.

Chromosome Painting: Chromosome painting is the identification of chromosomes by in situ hybridization using fluorochrome-labeled probes (see Fig. C93). With recent refinements in these techniques each human chromosome can be distinctly identified by color and various rearrangements can be detected in an unprecedented manner. ►fluorochromes, ►fluorescence microscopy, ►chromosome morphology, ►in situ hybridization, ►FISH, ►WCPP, ►USP, ►spectral karyotyping, ►telomeric probes; Fauth C, Speicher MR 2001 Cytogenet Cell Genet 93:1.

Figure C93. Chromosome painting. (Courtesy of M. Speicher)

Chromosome Pairing (synapsis): The ability of homologous (or under some circumstances, homoeologous)

eukaryotic chromosomes to associate intimately during the prophase of meiosis and form bivalents (see Fig. C94). The bivalents represent the essentially identical, homologous paternal and maternal chromosomes. In some organisms chromosomes may pair during mitoses also but this association is generally not considered as intimate as during meiosis, although in the salivary glands of *Drosophila* (and other dipterans) homologous chromosomes are tightly associated (somatic pairing). Synapsis, most commonly, begins at the termini of chromosomes at the zygotene stage and proceeds toward the centromere. By pachytene the pairing is complete and if not it is unlikely to get completed at all and some areas will remain unpaired. The pairing is genetically determined and single, specific genes may prevent pairing such as *as1* (*asynaptic*, chromosomal location 1–56 in maize). Curiously, in *as1* maize crossing over may increase. In the *phs1* mutation of maize (38 kDa protein) pairing between homologous chromosomes is replaced by synapsis between non-homologs and because of the uncoupling of Rad51 recombination is reduced. Similar genes are present in other plants too (Pawlowski WP et al 2004 Science 303:89). In hexaploid wheat the *Ph* gene suppresses homoeologous association of chromosomes but when it mutates or deletes (monosomics and nullisomics for chromosome 5B), high degree of homoeologous pairing occurs even in hybrids of related species. Some *desynaptic* genes terminate pairing precociously. In polyploids (polysomics) the homologous chromosomes may display multivalent association but at any particular point the synapsis is only between two chromosomes. In the salivary glands of trisomic flies the three chromosomes may be paired all along their length. In diptera where the X and Y chromosomes share homologous euchromatic termini, a short-duration, delayed pairing occurs (touch-and-go pairing). Synapsis is facilitated by the formation, beginning in leptotene, of the synaptonemal complex, a tripartite protein structure formed between the paired chromosomes. Synapsis provides the opportunity for the homologous chromosomes to experience crossing over and recombination. When chiasma and recombination takes place the distribution of the chromosomes at anaphase is orderly (*exchange pairing*), whereas in the absence of chiasmata (*distributive pairing*) the chance for nondisjunction increases. There are various types of pairings quite distinct from synapsis and these non-specific associations at the chromocenter of salivary gland chromosomes, association of telomeric heterochromatin in monosomes, or self-pairing in certain univalents may be observed if they possess more or less homologous sequences. ▶meiosis, ▶distributive pairing, ▶illegitimate pairing, ▶crossing over, ▶recombination, ▶somatic

pairing, ▶parasexual mechanisms, ▶pachytene analysis; Sybenga J 1999 Chromosoma 108:209.

Figure C94. Chromosome pairing. Multivalent pairing in F1 hybrid of *Triticum aestivum* (AABBDD) x *Aegilops variabilis* (C^uC^uS¹S¹) in the absence of chromosome 5B (pairing inhibitor). (Courtesy of Dr. Gordon Kimber)

C

Chromosome Partitioning: Chromosome partitioning in prokaryotes occurs after replication, when one of the two chromosomes, each, is delivered to the daughter cells. ▶mitosis, ▶DNA replication prokaryotes; Lemon KP et al 2001 Proc Natl Acad Sci USA 98:212.

Chromosome Passenger: Chromosome passengers are proteins associated with chromosomes (centromeres) during early mitosis and which, after anaphase, move to the mid-zone of the spindle. ▶centromere, ▶spindle, ▶mitosis

Chromosome Positioning: Chromosome positioning occurs in prokaryotes when the old and new (replicated) chromosomes tend to move to opposite poles of the cell. A defect in positioning may involve a condition analogous to nondisjunction in eukaryotes, i.e., the 0–2 distribution. Chromosome positions in the interphase eukaryotic nucleus are not random. In primates the gene-rich chromosomes such as human chromosome 19 tends toward the center of the nucleus, whereas the gene-poor chromosome 18 is situated at the periphery (Tanabe H et al 2002 Proc Natl Acad Sci USA 99:4424). The centromeres tend to interact with nuclear lamina at the pores. ▶anaphase; McEwen BF et al 2001 Mol Biol Cell 12:2776; Marshall WF 2002 Current Biol 12[5]: R186.

Chromosome Puffing: Chromosome puffing takes place in the polytenic chromosomes (of animals and plants) when genes are activated and begin synthesizing large amounts of RNA. When transcription is

terminated the puffs recede. Puffing may be stimulated by the administration of hormones (e.g., ecdysone in insects). See illustration at puff, ►**ecdysone**; Thummel CS 1990 Bioessays 12:561.

C

Chromosome Region Maintenance: ►CRM

Chromosome Replication: Chromosome replication numbers in human sperm prior to that produced at age A can be determined by the formula $N_A = 30 + 23(A - 15) + 5$; thus, in males aged 20, 30, 40, and 50, N_A is 150, 380, 610, and 840, respectively. Therefore it is not unexpected that the offspring of older fathers may be loaded with more new mutations. In human females the number of replications is much smaller as a function of age. Indeed the mutation of paternal genes is significantly higher in many hereditary diseases. There is an almost complete absence of mutant males in 13 X-linked traits that are lethal or sterilizing in females. This is due to the generally high male mutation rate. Affected males would have heterozygous mothers. These observations make sense if the rate of mutation in females is low. In the diseases Duchenne muscular dystrophy and neurofibromatosis, based on very large genes, the mutations are generally not of paternal origin. In these latter cases the mutations are not caused by replicational errors but by deletions and duplications. In hemophilia there is a higher male rate for point mutations and a higher female rate for deletions. ►**replication**, ►**dictyotene stage**, ►**mutation rate**, ►**muscular dystrophy**, ►**neurofibromatosis**, ►**hemophilias**; Crow JF 1999 Genetics 152:821.

Chromosome Rosette: At the prometaphase stage (lasting about 5–10 min in human cells) the chromosomes are arranged like a wheel, centromeres oriented toward the hub and the arms assuming an arrangement like spokes in a wheel (see Fig. C95). The homologs appear at opposite positions of the rosette. If the chromosomes are painted by fluorochrome labels. ►**mitosis**, ►**metaphase**, ►**FISH**; Munkel C et al 1999 J Mol Biol 285:1053.

Monocystis magna rosette

Figure C95. Chromosome rosette

Chromosome Scaffold: The structurally preserved form of the chromosome freed from histone proteins.

►**chromatin**, ►**chromosome structure**; Stack SM, Anderson LK 2001 Chromosome Res 9:175.

Chromosome Segregation: Chromosome segregation is the basis of Mendelian inheritance (mitosis and meiosis). In autopolyploids the chromosomes may segregate reductionally, e.g., at anaphase I in an autotetraploid chromosomes with A, A, A, A may move toward one pole and chromosomes with a, a, a, a toward the other. This is called reductional segregation (R). Alternatively, the distribution may be Aa, aA , and aA, Aa , or aA, Aa and Aa, Aa , (respectively) i.e., equational segregation (E) occurs. These two types of separations follow the proportion of 1R:2E. The term *chromosome segregation* is also used for cases in polyploids when genes are closely linked to the centromere and crossing over does not take place between them, in contrast to *maximal equational segregation* when one crossing over takes place between gene and centromere in each meiocyte.

Figure C96. Chromosome segregation

The segregation of the chromatids (vertical lines) is controlled by anaphase promoting complex (APC) regulated by the Aurora B kinase. If conditions are normal, the centromeres segregate equationally in mitosis (amphitelic segregation) and the two centromeres (circles) are pulled to opposite poles by the spindle fibers (arrows). This is facilitated by destroying cyclin B and securin proteins. When syntelic or monotelic movements are sensed Aurora inhibits APC at a checkpoint. Such a control assures that the daughter cells will be normal. ►**meiosis**, ►**autotetraploid**, ►**Aurora**, ►**centromere**, ►**spindle fibers**, ►**cyclin B**, ►**securin**, ►**APC**; Nasmyth K 2002 Science 297:559; chromosome and plasmid segregation: Ghosh SK et al 2006 Annu Rev Biochem 75:211.

Chromosome Set: A group of chromosomes representing once all the chromosomes of the haploid set, the genome. It is represented by x. ►**genome**, ►**haploid**

Figure C97. The image above represents a loosely packaged acrocentric human chromosome isolated from a Burkitt's lymphoma cell. The individual fibers are shown on the inset at approximately 85,000x magnification. (Photomicrograph from Lampert F, Bahr GF, and DuPraw EJ 1969 Cancer 24:367)

Chromosome Sorting: ► [flow cytometry](#)

Chromosome Stickiness: The apparent adhesion of chromosomes that tend to stay together.

Chromosome Structure: The electron-microscopic image of a chromosome reveals many more details than a light-microscopic image. The light microscope, however, shows great advantage in the study of chromosomal behavior such as chiasmata, non-disjunction, misdivision, etc., occurring during mitosis and meiosis. ► [chromatin](#), ► [nucleosomes](#), ► [Mosolov model](#); Woodcock CL, Dimitrov S 2001 Curr Opin Genet Dev 11:130.

Chromosome Substitution: Chromosome substitution can be alien substitution (see there) or inter-varietal substitution when the corresponding chromosome of another variety in polyploids replaces one chromosome of a variety where monosomic or nullisomic lines can be propagated (see Fig. C98). Thus some desirable genes can be transferred without altering the genetic background. Although E.R. Sears developed chromosome substitution primarily for hexaploid wheat plants since the 1930s, it is applicable to any other system for the localization of QTLs or other

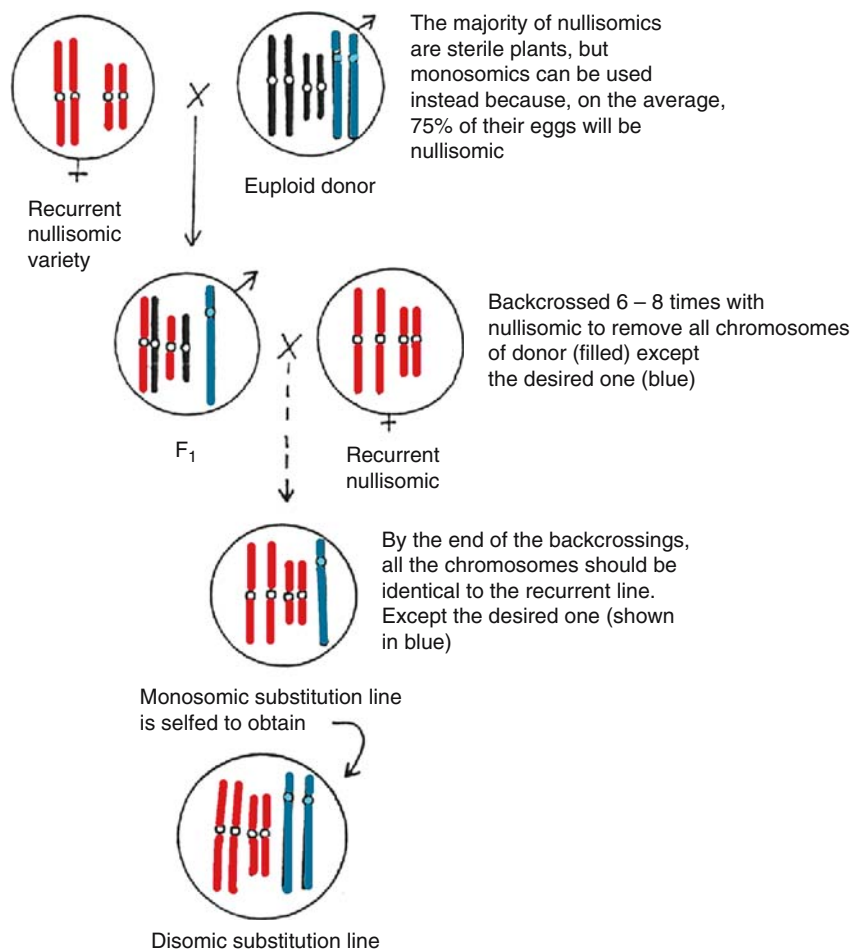

Figure C98. Chromosome substitution

genes. Complex traits can be analyzed also in mice by the use of chromosome substitution (Singer JB et al 2004 Science 304:445). ►flowchart, ►linkage in breeding, ►genetic engineering, ►QTL, ►alien substitution, ►consomic

Chromosome Telocentric: ►telocentric chromosome

Chromosome Ten Tumor Suppressors: ►PTEN

Chromosome Territories: The domains occupied by the chromosomes in the nucleus. The majority of genes prefer to occupy the surface of the territory, others loop apart and associate with nuclear bodies involved in transcription (activation or repression) (see Fig. C99). Gene-rich, early replicating chromosomal regions are generally clustered in the internal areas.

Figure C99. Chromosome territories. Human chromosome territories in false color. Each chromosome is numbered. Below: three dimensional simulation of the chromosome arrangement; prepared as specified in the Methods of the paper cited below. (From Bolzer A, Kreth G, Solovei I, Koehler D, Saracollu K et al (2005) Three-dimensional maps of all human male fibroblast nuclei and prometaphase rosettes. PLoS Biology 3(5):e157. Courtesy of Dr. Michael R. Speicher)

Whereas gene-poor, late-replicating regions seem to be located at the periphery (Tanabe H et al 2002 Mutation Res 504:37). A newer study using multiplex FISH technology applied to human fibroblast nuclei permitted three-dimensional positioning of each human chromosome (see Fig. C100). The prometaphase chromosomes provided a probabilistic, non-deterministic model of the positions as well as an assessment of the chromosomal territories in quiescent, G₀ and in cycling, S-phase cells. Small chromosomes, independently of gene density, were found closer to the center, whereas larger chromosome preferred the nuclear periphery. This arrangement was not the result of geometric constraints and it was observed in other cell types too. Gene-poor regions tended to be situated in a layer beneath the nuclear envelope whereas the gene-dense regions of the chromatin were enriched in the nuclear interior (Bolzer A et al 2005 PLoS 3[5] e157). In yeast cells, upon the mating pheromone alpha factor stimulation the myosin-like protein Mlp1 (involved in mRNA export) and the genes dependent on it tended toward the nuclear pores. This observation indicated that the chromosomal conformation and spatial arrangement were altered by developmental cues (Casolari JM et al 2005 Genes Dev 19:1188). In ultrathin cryosections of phytohemagglutinin-activated human lymphocytes painted by an improved FISH showed some intermingling of chromosomal territories. These intermingling areas contained DNA. The volume of 41% of chromosome 3 intermingled with the rest of the genome and the extent of intermingling of other chromosomes was similar. The intermingling correlated with translocation potential of the non-homologous chromosomes. Furthermore, inter-mingling facilitates interactions with transcription factories.

Figure C100. Intermingling of human chromosomes 5 and 7. (Courtesy of Branco MR & Pombo A 2006 PLoS Biol. 4(5): e138.)

Decondensed stage of the chromosomes such as in interphase and the presence active genes are favorable for intermingling. The new information provides a more meaningful view on chromosome organization and its relation to chromosome functions (Branco MR, Pombo A 2006 PLoS Biol. 4(5):e138). E.J. DuPraw published already in 1970 that the completed mount electronmicroscopic picture of human leukocytes revealed islands of chromosome fibers with numerous interconnections. ▶perichromatin fiber, ▶chromosome positioning, ▶transcriptome map, ▶nucleus, ▶FISH, ▶interchromosome domain compartment, ▶interchromosomal interactions, ▶transcription factories, ▶chromosome conformation capture; Cremer T, Cremer C 2001 Nature Rev Genet 2:292; Kosak ST, Groudine M 2004 Science 306:644; brief review: Meaburn KJ, Misteli T 2007 Nature [Lond] 445:381; regulation of transcription by territories review: Yang PK, Kuroda MI 2007 Cell 128:777; review: Fraser P, Bickmore W 2007 Nature [Lond] 447:413.

Chromosome Texture: ▶oligostickiness

Chromosome Theory: The chromosome theory was developed at the beginning of the twentieth century and stated that genetic material is contained in the

chromosomes, and the Mendelian laws are based on the mechanisms of meiosis. ▶Mendelian laws, ▶Mendelian segregation; Sutton WS 1903 Bull Biol 4:231.

Chromosome Transfer (chromosome-mediated gene transfer): ▶chromosome uptake, ▶chromosome substitution

Chromosome Uptake: (see Fig. C101)

Chromosome Walking: The mapping of the position of a DNA site or a gene by using overlapping restriction fragments(see Fig. C102). The principle involved is somewhat similar to that in classical cytogenetic mapping with overlapping deletions. It is used also for map-based isolation and then cloning of specific genes. The success of isolation of genes by this method is greatly affected by the size of the genome and even more importantly on the distance that must be “walked” from a known genomic position toward the desired gene.

Some means must also be found for determining the function of the gene so its identity can be verified. In large eukaryotic genomes, the procedure is facilitated if physical maps are already available. ▶cosmid vectors, ▶YAC vectors, ▶chromosome

Figure C101. Chromosome walking

C

Chromosome uptake

- The transferred segment may be 17 to 1000 kbp and microscopically invisible (microtransgenome)
- Microscopically visible segments (macrotransgenomes) constitute about 15% of the transformants
- Integration is generally not by homology, rather by random events like translocations
- Transferred genes are expressed, frequently at higher intensity because of larger copy number
- Both partially degraded and more or less intact fragments become stable after integration

Figure C102. Chromosome uptake

jumping, ►map based cloning, ►chromosome landing, ►position effect; Bender W et al 1983 J Mol Biol 168:17; Kneidinger B et al 2001 Bio-techniques 30:248; diagram.

Chromosome-Specific Cell Line: The cells of species (A) are heavily irradiated and are fused with normal (unirradiated) cultured cells (B). Cells are then selected that contain only one chromosome of the A line and allowed to hybridize genes (DNA sequences) to this cell so that on the basis of binding to the critical chromosome, physical mapping can be achieved like in the use of radiation hybrids. Also, flow cytometer-sorted chromosomes or chromosome fragments can be mapped by the use of polymerase chain reaction

(PCR) and fluorescent staining. ►radiation hybrid, ►polymerase chain reaction, ►flow cytometer, ►addition line, ►alien addition, ►chromosome substitution; VanDevanter DR et al 1994 Proc Natl Acad Sci USA 91:5858.

Chromosomin: A non-histone protein of the chromatin. ►chromatin

Chronic Granulomatous Disease (CGD): A complex disease based on the inability of the phagocytizing neutrophils to destroy infectious microbes due to defects in delivering sufficient levels of oxygen to the neutrophil membranes. Laboratory diagnosis is generally based on the failure of the phagocytes to reduce nitroblue tetrazolium. Prenatal diagnosis

exists for males and carriers. The afflicted persons are liable to infections. The human gene was localized to Xp21, and it has apparently a defect in the cytochrome b system, probably most commonly in the β subunit (CYBB), whereas the autosomal form (human chromosome 16q24) is defective in the α subunit (CYBA). In some variants other functions may also be involved. (►immunodeficiency, ►cytochromes, ►neutrophil, ►phagocytosis). (See McBride OW, Peterson JL 1980 Annu Rev Genet 14:321).

Chronic Lymphocytic Leukemia (CLL): ►leukemia

Chronic Radiation: Radiation dose(s) delivered continuously without interruptions. ►fractionated dose

Chronic Wasting Disease (CWD): A prion disease-like encephalopathy of (~4%) wild deer and (~1%) of elk in the American North-West. Its transmission and symptoms are similar to other encephalopathies although the epidemiological information is still limited. It may pose a danger to cattle, eaters of venison, and to taxidermists. Infectious prions present in the saliva, blood, urine, and feces of the sick animals are a source of transmission (Mathiason CK et al 2006 Science 314:133). ►encephalopathies, ►prion; Angers RC et al 2006 Science 311:1117.

Chronological Aging: The length in time of the lifespan. ►aging, ►replicative aging, ►lifespan, ►longevity

Chronology of Genetics: ►genetics chronology of

CHUK: A synonym of I κ B- α kinase. ►I κ B

Chrysanthemum (*C. indicum*): Herbaceous perennial ornamental; 2n = 20, 45–30.

Churg-Strauss Vasciculitis: A deficiency of the C1-INH complement component resulting in allergic inflammation of the vessels system. ►complement

chv: Chromosomal virulence loci in *Agrobacterium*. ►virulence genes of *Agrobacterium*

Chylomicron: The transporters of lipoproteins ingested or synthesized in the small intestines. ►hyperlipoproteinemia, ►Anderson disease, ►Marinesco-Sjögren syndrome

Chymases: Chymases are similar to chymotrypsin and hydrolyze peptide bonds near the carboxyl end of hydrophobic amino acids. They are regulated by IL-15 (Orinska Z et al 2007 Nature Med13:927). ►chymotrypsin, ►IL-15

Chymotrypsins: Proteases (M_r 25 K) cleaving near aromatic amino acids, non-polar groups, ester bonds. They are targeted by nerve gas (DFP).

Ci (Curie): A measure of radioactivity; 1 Ci = 3.7×10^{10} disintegrations/sec. ►radioactivity, ►isotopes, ►radioactive label

cl: A phage λ repressor. ►lambda phage

CIA: ASF1.

CIBD (chronic inflammatory bowel disease): The prevalence of CIBD in the western world is 2×10^{-3} . ►Crohn disease

CIBEX (Center for Information Biology Gene Expression Database) <http://cibex.nig.ac.jp/>.

CIC (chloride ion channel): The CIC controls the excitability of skeletal muscles and blood pressure, acidifies endosomal compartments, and regulates GABA responses. ►endosome, ►GABA, ►ion channels

CID (collision-induced dissociation): CID is a fragmentation of molecules, e.g., peptides at particular bonds and sheds information on the peptide sequence analyzed by mass spectrometry in proteomics. ►mass spectrometer, ►MALDI/TOF/MS, ►neutral-loss scan; Wells JM, McLuckey SA 2005 Methods Enzymol 402:148.

CID (centromere identifier): A nucleosome assembly complex that localizes the CenH3, centromere-specific histone, a variant of the H3 histone, into the centromere. ►histones, ►histone variants

CIGAR: The CGGAAR (R = purine) enhancer motif of Herpes simplex virus. ►TAT-GARAT, ►Herpes

Cigarette Smoke: Cigarette smoke contains dozens of various combustion products including the most potent carcinogens and mutagens, e.g., benzo(a) pyrene (about 20–40 ng/cigarette) responsible for the majority of lung cancer cells, which carry mutations in the p53 tumor suppressor gene, mainly G→T transversions, at codons 157, 248, and 273. The codon 157 hot spot is absent from other types of cancers. These hot spots are the sites of adduct formation by benzo(a) pyrene diol epoxide and guanine-N². Gene expression arrays are suitable for the determination of the genes permanently or transiently affected by the expression of bronchial cells (Spira A et al 2004 Proc Natl Acad Sci USA 101:10143). ►p53, ►cancer, ►hot spot, ►benzo(a) pyrene, ►transversion; Izzotti A et al 2001 Mutation Res 494:97.

CIITA (class II transactivator): An apparently non-DNA-binding modulator of the synthesis of class II MHC molecules. When it binds GTP it moves to the cell nucleus where it interacts with the complex RFX. RFX is bound to MHC II gene promoters. CIITA transcription uses four promoters. Promoter 1 specifically

controls its expression in dendritic cells, Promoter 3 is essential in B and T lymphocytes, and Promoter 4 is activated by interferon- γ . CIITA is also a global co-activator of the human leukocyte antigen-D (HLA-D) genes and it also regulates import through the nuclear pore. ▶MHC, ▶HLA, ▶RFX, ▶dendritic cell, ▶interferon, ▶nuclear pores, ▶transactivator; Wiszniewski W et al 2001 J Immunol 167:1787.

Cilia (singular cilium): Cilia, the hair-like structures formed from microtubules, are extensions of the basal bodies. They are used for locomotion (swimming) in watery media or on viscous films by a vibratory or lashing movement (see Fig. C103). Cilia are involved also in sensory reception and signaling through intra-flagellar transport. The Joubert syndrome, Meckel syndrome, Alström syndrome, Bardet-Biedl syndrome, Kartagener Syndrome, Polycystic Kidney Disease, and Nephronophthisis may show defects in cilia and in the anchoring basal bodies. ▶axoneme, ▶microtubule, ▶flagellum, ▶dynein, ▶kinesin, ▶basal body, ▶named syndromes; Scholey JM, Anderson KV 2006 Cell 125:439; < 1,200 non-redundant human proteins: <http://www.ciliaproteome.org/>.

Figure C103. Ciliary function

Ciliary Dyskinesia, Primary: In primary ciliary dyskinesia, the basic defect is in the axonemal heavy chain dynein at 7p21. Half of those afflicted by Kartagener's syndrome show the same mutation. ▶Kartagener syndrome

Ciliary Neurotrophic Factor (CNTF, human chromosome 11q12.2): Glial cells release CNTF to repair damaged neurons. CNTF is also involved in the general differentiation of nerve cells (gliogenesis)

from multipotential precursor cells. Its 41-kDa receptor, CNTFR, is encoded at 9p13. CNTF specifically stimulates also the JAK-STAT signal transduction pathway leading to cell fate determination. CNTF deficiency is not involved in any known human disease although CNTF may show beneficial effects in amyotrophic lateral sclerosis. It has some effects like leptin. ▶neuron, ▶neurogenesis, ▶signal transduction, ▶APRF, ▶nerve growth factor, ▶amyotrophic lateral sclerosis, ▶leptin, ▶obesity; Linker RA et al 2002 Nature Med 8:620.

Ciliates: ▶Oxytricha

CIMP (CpG island methylator phenotype): CIMP activates neoplasias by interfering with the expression of tumor suppressor genes. ▶CpG island, ▶methylation of DNA, ▶tumor suppressor genes

CIN: chromosome instability factors. ▶chromosomal instability

Cin: An invertase. ▶invertases, ▶Cin4

Cin4: non-viral retroposons, hybrid dysgenesis I – R.

Ciona intestinalis (Ascidian): A chordate evolutionarily ancestral to vertebrates. It has ~16,000 protein-coding genes in its genome (2n = 16) draft. (See Dehal P et al 2002 Science 298:2157; Satoh N 2003 Nature Rev Genet. 4:285; tunicate database: <http://dbtgr.hgc.jp/>).

CIP (calf intestinal alkaline phosphatase): CIP is used for the removal of 5' phosphate from nucleic acids and nucleotides, and is a general inhibitor of CDKs. ▶CDK, ▶KIP

CIP: ▶p21, ▶p/CIP

Ciprofloxacin: Ciprofloxacin is a fluoroquinolone antibiotic that inhibits bacterial DNA gyrase and topoisomerase IV cleavage and resealing, and thus, DNA replication. It is used effectively against anthrax. The same family of drugs (under different trade names) is used against other bacteria too. ▶antibiotics, ▶gyrase, ▶topoisomerase, ▶antibiotic resistance, ▶anthrax

Figure C104. Ciprofloxacin

CIR: The cardiac inwardly rectifying ion channel. ▶ion channels, ▶I_{KAch}

Circadian Rhythm (circadian clock): The circadian rhythm has a daily (24 h) periodicity; the term is derived from the Latin *circa diem* [around the day]. Such periodicity (rhythm) may occur in plants in opening and closing flowers and in translocation of metabolites, or may affect in various ways in animals daily behavioral and metabolic patterns such as, sleep, social activities, etc. The transcriptional coactivator PGC-1 α integrates the mammalian circadian clock with energy metabolism (Liu C et al 2007 Nature [Lond] 447:477). The circadian rhythm usually independent of temperature. In *Arabidopsis*, nearly 500 genes are affected by the daily rhythm. A clock-controlled promoter sequence (AAAATATCT) repeats many times in most cycling genes. In *Arabidopsis* mutants, when the clock periods matched the environmental light cycles, plants produced more chlorophyll, fixed more carbon, grew faster, and survived more successfully, indicating the biological advantage of the circadian rhythm (Dodd AN et al 2005 Science 309:630).

In *Drosophila*, the *per* (period) mutation shows, however, a dimerization domain PAS that is subject to temperature effects. The *per* genes encode Thr-Gly repeats in 14, 17, 20, and 23 dipeptide lengths in the various ecological races of different *Drosophila* species. The 17 and 20 alleles are predominant in Mediterranean regions and the northern regions of Europe, respectively. In animals the control spot for the circadian periodicity resides in the suprachiasmatic nucleus of the hypothalamus in the brain. Injecting glutamate, methyl-D-aspartate, or nitric oxide into the brain produces the same effect as light does in controlling periodicity. Intracellular Ca²⁺-ryanodine channels play a regulatory role. Circadian rhythm is involved in olfactory responses too. Some prokaryotes also display this rhythm but *Saccharomyces* and *Schizosaccharomyces* eukaryotes apparently lack it. The molecular mechanism of the circadian oscillations seems complex but it appears that it is dependent on activation of the E-box and transcription of genes *Per* and *Time* by the genes *Clock-MOP3* complex. Clock is a histone acetyltransferase (Doi M et al 2006 Cell 125:497). After the mRNAs are translated, the protein may eventually feedback inhibits *Clock* and the daily oscillations come to a full circle. The expression of *vrille* is a requisite for *Clock*. In *Drosophila*, the gene *Doubletime* product (DBT) that destabilizes *Per* in the evening has been identified. DBT plays this role until sufficient quantity of *Tim* (Timeless) accumulates and protects *Per* from DBT. The *Neurospora* clock gene (frequency, *FRQ*) regulates rhythmically its own expression by the transcriptional activator, White collar Complex (*WCC*), through cyclically modulating phosphorylation. Dephosphorylation and

activation of *WCC* require protein phosphatase 2A (PP2A). Hypophosphorylated *WCC* binds to the clock box of *FRQ* promoter. Hyperphosphorylated *WCC* binding is compromised even when *FRQ* is depleted (Schafmeier T et al 2005 Cell 122:235). The *Doubletime* homolog of Syrian hamster (*TAU*) encodes a casein kinase1 epsilon (CK1 ϵ) protein. Then *Per* and *Tim* pass to the nucleus and cause their feedback inhibition. By the morning, these two gene-products fade away and *Clock* and other proteins will turn on again *Per* and *Tim*. *Drosophila* controls the circadian functions by five major genes. Similar systems based on homologous genes and proteins operate in other animals. Under the conditions of 24-h nights or 24-h daylight in the arctic regions, the diurnal rhythm of polar animals is temporarily suspended (van Oort BEH et al 2005 Nature [Lond] 438:1095). The circadian light receptor in mammals resides in the eyes and the pineal gland and the signals are chemically transmitted to the organs (deep in the body) that are not accessible to light. In plants, the control is slightly different. In the transparent body of *Drosophila* or zebrafish, internal organs also have light oscillators. A common circadian rhythm disorder is the *jet lag*, based on maladjustment to longer-than-5 h time zone differences, especially while traveling from the west to the east. Jet lag is an F-box protein with leucine-rich repeats and promotes the degradation of Timeless (Koh K et al 2006 Science 312:1809). Evidence is accumulating for the role of PDF (pigment-dispersing factor, a neuropeptide) in the control of genetic clock genes. An analog of the *Clock* gene (*NPA2*) expressed in the forebrain of mammals is regulated by the redox state of NAD cofactors. The human gene (Advanced sleep-phase syndrome, FASPS) homologous to *Per2/CKI* of *Drosophila* has been mapped 2q37.3. It involves a serine→glycine substitution at site 662 in the casein kinase-I- ϵ gene ((Tooh KL et al 2001 Science 291:1040). Its mutation controls early sleeping and early awakening. A human threonine → alanine substitution at site 44 in the CKI δ protein in transgenic *Drosophila* was seen to cause increased circadian period, whereas in mice (similarly to humans) it showed a shorter circadian period, indicating different regulation in insects and mammals (Xu Y et al 2005 Nature [Lond] 434:640). Clock mutants of mice have diminished diurnal feeding rhythm and become hyperphagic and obese (Turek FW et al 2005 Science 308:1043). Knocked-out *CLOCK* in mouse indicates that this gene is not necessary for full circadian function (DeBruyne JP et al 2006 Neuron 50:465). ▶*per* mutation in *Drosophila*, ▶endogenous rhythm, ▶hypothalamus, ▶nitric oxide, ▶clock genes, ▶brain human, ▶E box, ▶F-box, ▶ryanodine, ▶rhodopsin, ▶cryptochrome,

Circle: A geometric figure with circumference = $2\pi r$; area = $r^2\pi$, where r = radius and $\pi \cong 3.14159$.
►geometric solids

Circular Dichroism: The difference between the molar absorptivities for left-handed and right-handed polarized light as observed in chiral molecules (enantiomorphs). Circular dichroism detects Z DNA structures and the interaction of drugs and carcinogens/mutagens with the DNA. ►enantiomorph, ►chirality, ►Z DNA

Circular DNA: Covalently closed ring-shaped DNA such as the genetic material of bacteria, eukaryotic organelles, and the majority of the plasmids (see Fig. C105).

Figure C105. Circular DNA

Circularization: Circularization is the phenomenon of forming a circle, like in plasmids; unwanted circularization of DNA can be prevented by directional cloning or treatment with bacterial phosphatase to remove terminal phosphates needed for joining DNA ends. ►directional cloning

Circumcision: Circumcision in the *male* involves the removal of the foreskin (prepuce) from the distal end of the penis of infants. It is thought to reduce the

chance of sexually transmitted disease. Recent results from studies in Africa indicate substantial reduction (50–60%) of AIDS infection in circumcised males (Newell ML, Bärnighausen T 2007 Lancet 369:617). However, this procedure should not be considered a preventive measure against AIDS, at the risk of not observing other safety rules. In the *female*, circumcision is a barbaric procedure practiced in some underdeveloped regions of the world and is considered ethically unacceptable (see Fig. C106). At the least, it involves the surgical removal of the clitoris but in more drastic forms the labia minora are also removed. ►clitoris, ►vagina

Figure C106. Female external genitalia

Circumnutation: A movement of plants around their axis, as in the case of tendrils (see Fig. C107).
►tendrils

Figure C107. Circumnutation

Cirrhosis of the Liver: Liver cirrhosis includes mainly autosomal recessive diseases characterized by fibrous structure of the liver. It may be precipitated by various environmental factors such as copper toxicity, alcoholism, and antitrypsin deficiency. Hepatitis C virus infection is a causal agent and may affect as many as 170 million persons in a year causing 3000.000 annual deaths. It may occur as a component of other syndromes. The quantitative gene locus HC, encoding complement factor 5, has a causal role in fibrogenesis in mouse and humans (Hillebrandt S et al 2005 Nature Genet 37:835). Cirrhotic liver loses its ability to regenerate normal cells, apparently because of diminished telomerase activity. Childhood cirrhosis characterized by cholestasis, was localized to 16q22 (Chagnon P et al 2002 Am J Hum Genet 71:1443). The telomerase gene, carried by adenoviral

vector, was found to improve cirrhosis in telomerase deficient mice. ►Wilson's disease, ►galactosemia, ►transaldolase deficiency, ►antitrypsin, ►alcoholism, ►autoimmune diseases, ►complement, ►cholestasis, ►cholic acid, ►adenovirus, ►gene therapy; Friedman SL 2000 J Biol Chem 275:2247; Iredale JP 2007 J Clin Invest 117:539.

CIS (CISH, cytokin-inducible-SH2-containing protein, 3p21.3): CISH contains 222 amino acids and binds to tyrosine-phosphorylated IL-3 and erythropoietin receptors. It may be a part of the system turning off cytokine signaling. Its deletions are frequent in lung and kidney tumors. ►cytokines; ►IL-3; ►erythropoietin; ►SH2 domain; ►SOCS-box; ►JAB; ►SSI-1; Uchida K et al 1997 Cytogenet Cell Genet 78:209.

Cis Arrangement: CIS arrangement occurs when two genes (or two different mutant sites) of a locus are within the same chromosome strand, e.g., *a b*. ►trans arrangement, ►cis-trans test

Cis Preference: The protein products of the L1 retrotransposons usually (not necessarily) bind to the encoding RNA. ►LINE

Cis-Acting Element: The Cis-acting element must be located in the same DNA strand as its target to act upon it during transcription. Genes that are conserved across species will also display conservation at the level of their transcriptional regulation and this will be reflected in the organization of cis-elements mediating this regulation. Using a computational approach, clusters of transcription factor binding sites that are absolutely conserved in order and in spacing across human, rat, and mouse genomes were identified. These regions are called (PRIs), pattern-defined regulatory islands (Cheung TH et al 2007 Proc Natl Acad Sci USA 104:10116). ►trans-acting element, ►cis-regulatory modules, ►LCR, predictor of cis-regulatory elements: <http://bibiserv.techfak.uni-bielefeld.de/jpredictor/>; transcription factor annotation tool on chromatin immunoprecipitation arrays: <http://ceas.cbi.pku.edu.cn/>; binding site detection tool for longer regulatory modules: <http://stubb.rockefeller.edu/>; cis-regulatory elements in *Arabidopsis*: <http://www.athamap.de/>; coregulated by cis elements in *Arabidopsis*: <http://www.atted.bio.titech.ac.jp>.

Cis-Dominant: Dominance affecting only alleles in *cis* position but not those in *trans*. ►cis arrangement

Cis-Golgi: The side of the Golgi apparatus where molecules enter the complex. ►Golgi apparatus, ►trans-Golgi network

Cis-Immunity: The property of transposons to prevent integration of another element within the boundary of the insertion element. ►self-immunity, ►transposon

Cis-Morphism: The variation in low-copy repeats within the same chromosome strand. ►transmorphism

Cisplatin (cis-diamminedichloroplatinum, $\text{PtCl}_2(\text{NH}_3)_2$, cis-DDP): Cisplatin is a DNA cross-linking agent and an (90%) effective anticancer drug with some specificity for testicular tumors. It inhibits DNA and RNA polymerases and avoids nucleotide excision repair. High-mobility group proteins are attracted to the DNA distorted by cis-DDP and may mediate anti-tumor activity. The clinical response to cisplatin is influenced by cell-to-cell communications via gap junctions. The signal is produced by the kinase function of Ku70, Ku80 and the DNA-dependent protein kinase complex (Jensen R, Glazer PM 2004 Proc Natl Acad Sci USA 101:6134). It may cause kidney, neural and hearing damage. Cisplatin resistance may eventually develop by several different mechanisms. The rapamycin derivative RAD001 (everolimus) increases the likelihood of apoptosis in the presence of the wild type p53 protein by inhibition of the translation of p21 mediated through TOR (Beuwink I et al 2005 Cell 120:747). A GeneChip array was found to identify variations in human cell populations of different ethnicity ranging from 27% to 29%, to 45% due to 8, 2, and 16 quantitative trait loci, respectively (Huang RS et al 2007 Amer. J. Hum. Genet. 81:427). ►cancer therapy, ►high-mobility group of proteins, ►rapamycin, ►p53, ►p21, ►TOR, ►Ku70, ►DNA-PK, ►melanoma, ►GeneChip; Lippert B (ed) 1999 Cisplatin: Chemistry and Biochemistry of a Leading Anticancer Drug. Helvetica Chimica Acta Vlg; Zürich Ch; Jung Y et al 2001 J Biol Chem 276:43589; Wei M et al 2003 J Biol Chem 278:1769; Reedijk J 2003 Proc Natl Acad Sci USA 100:3611.

Figure C108. Cisplatin

Cis-Regulatory Modules (CRMs): CRMs are modular units of a few hundred base pairs in the DNA and mediate the multiple binding of transcription factors. They play important roles in the development and tissue-specific expression of genes. ►tissue specificity; Berman BP et al 2002 Proc Natl Acad Sci USA 99:757.

CISS Hybridization (chromosome in situ suppression): Before DNA probes are applied to chromosomes for in situ hybridization, the chromosomes are treated with DNA to block the non-target sequences so that these do not interfere with annealing of the specific labeled probes. ▶ *in situ hybridization*, ▶ *probe*; Sadler MT et al 2000 Genome 43:1081.

CIS-SYN Dimer: CIS-SYN dimer is a mutagenic cyclobutane UV photoproduct (see Fig. C109). DNA polymerase η apparently can replicate through such dimers and insert new nucleotides despite the distorted structure (Washington MT et al 2003 Proc Natl Acad Sci USA 100:12093) but the fidelity of the replication is diminished (McCulloch SD et al 2004 Nature [Lond] 428:97). ▶ *cyclobutane*, ▶ *UV photoproducts*, ▶ *DNA polymerases* [Pol η], ▶ *translesion*; McCullough AK et al 1998 J Biol Chem 273:13136; Park H et al 2002 Proc Natl Acad Sci USA 99:15965; Johnson RE et al 2005 Proc Natl Acad Sci USA 102:12359.

Figure C109. Cis-Syn dimer

Cis-Trans Test: A procedure for determining allelism. If two independent *recessive* mutations are made heterozygous in a diploid (or by using an F' plasmid in bacteria), are located in the opposite strands (in trans position), $\frac{m_1}{+} \frac{+}{m_2}$ and fail to complement each other (i.e., the phenotype is mutant), then the two mutations are allelic (occupy the same cistron). When, however, the two recessive mutations are both in the same DNA strand (in cis $\frac{+}{m_1} \frac{+}{m_2}$ position) and are made heterozygous (or merozygous in prokaryotes) they are expected to be complementary, i.e., non-mutant in phenotype, because the strand containing the two non-mutant sites permits the transcription of a wild type (un-interrupted) mRNA in the heterozygote. Molecular geneticists involved in physical DNA mapping use the term allele for any physical variation that is inherited by a Mendelian fashion and occupies the same chromosomal locus. ▶ *allele*, ▶ *allelism test*, ▶ *cistron*, ▶ *SSNC*, ▶ *pseudalleles*; Lewis EB 1951 Cold Spring Harbor Symp Quant Biol 16:159.

Cisterna: A membrane-enclosed space that frequently contains fluid.

Cistron: A segment of the DNA coding for one polypeptide chain or determining the base sequence in one tRNA or one rRNA subunit. Mutant sites within a cistron generally do not fully complement, i.e., the heterozygotes are not wild type, although, in rare cases weak allelic complementation may be observed. ▶ *allelic complementation*, ▶ *cis-trans test*; Benzer S 1957 p. 70. In: McElroy WD, Glass B (eds) The Chemical Basis of Heredity. Johns Hopkins University Press, Baltimore.

Cis-Vection: Cis-vection is a position effect, operational only when the genetic elements are syntenic, e.g., the promoter, some DNA binding protein elements (UAS) and structural gene. (▶ *position effect*; ▶ *syteny*; ▶ *operon*; ▶ *pseudoalleles*; ▶ *cis-acting element*; UAS; Lewis EB 1950 Advances Genet 3:73).

Citation Index: A publication of the Institute of Scientific Information (ISI, <http://www.isinet.com/isi/>) listing the number of times a particular journal paper has been cited in the scientific literature by first author. ▶ *impact factor*

Citric Acid Cycle: ▶ *Krebs-Szentgyörgyi cycle*

Citron: A RHO-regulated protein kinase mediating myosin-based contractility of the spindle fibers during cytokinesis. Its overproduction may lead to multinucleate cells. ▶ *spindle fibers*, ▶ *cytokinesis*, ▶ *myosin*, ▶ *RHO*, ▶ *PDZ*; Madaule P et al 2000 Microsc Res Tech 49:123.

Citrullinemia (ASS): ASS is a family of chromosome 9q34 (CTLN1) and 7q21.3 (CTLN2) recessive defects in the enzyme argininosuccinase. Normally citrulline is converted, via aspartate, into argininosuccinate. If the latter cannot be cleaved, citrulline and ammonia accumulate and as a consequence there may occur incontinence, insomnia, sweating, vomiting, diarrhea, convulsions, psychotic anomalies, and even periods of coma. The disease has an early onset and may proceed progressively into adulthood; rarely is the onset during adult life. Craving for high arginine food (legumes) and avoidance of low arginine food and sweets are noticeable symptoms. According to hybridization by a DNA probe, the ASS genes may be present in 10 copies per human genome scattered over several chromosomes. The multiple copies are presumably pseudogenes. ▶ *arginine*, ▶ *urea cycle*, ▶ *argininemia*, ▶ *amino acid metabolism*, ▶ *pseudogene*, ▶ *urea cycle*

Citrullinuria: Same as citrullinemia.

Citrus (*Citrus* spp): The taxonomy is unclear but several species are known, $x = 9$ and diploid as well as

tetraploid forms exist among lemons, oranges, mandarin, lime, grapefruit, etc.

Civilization: ►humanized antibody

CJD: ►Creutzfeldt-Jakob disease

CJM: A cell junction molecule. ►gap junction

CKB (casein kinase genes): The product of CKB genes is required for the completion of anaphase. (►cell cycle; McKay RM et al 2001 Dev Biol 235:378).

CKI: An inhibitor of the CDK-cyclin complex. ►CDK, ►FAR

C-Kinase: A protein phosphorylase activated by Ca^{2+} and diacylglycerol. (See Hartness ME et al 2001 Eur J Neurosci 13:925).

CKR: A chemokine receptor. ►chemokines, ►acquired immunodeficiency, ►CCR

CKS1: Cks1 is a subunit of cyclin-dependent kinases (CDKs) and is an essential cofactor in the ubiquitination of p27 CDK inhibitor by SCF. Cks2 controls the transition from metaphase I to anaphase during mammalian meiosis. ►meiosis, ►CDK, ►SCF, ►ubiquitination; Harper JW 2001 Curr Biol 11: R431; Spruck CH et al 2003 Science 300:647.

Clade: A group of distinct families/subfamilies descended from a common ancestral taxonomic entity by an evolutionary split.

Cladistic: Cladistic links and nodes show representation of descent in the manner of a dendrogram, i.e., in the divergence of taxonomic groups. ►dendrogram, ►evolutionary tree, ►parsimony, ►character index, ►homoplasy, ►stratocladistics

Cladogenesis: An evolutionary change involving branching of lineage of descent. ►anagenesis

Cladogram: ►evolutionary tree, ►character index

Claforan: ►cefotaxim antibiotic

Clam (bivalve): There are about 7,000 species of bivalves, including clams, oysters, mussels, and scallops (see Fig. C110). Most clams inhabit seas and oceans but some occur in lakes. Not all clams have byssus (an anchoring organ) but the majority can float and move. Some bivalves feed on dinoflagellates, which can produce a very powerful neurotoxin (saxitoxin, paralytic shellfish poison, PST) (see Fig. C111). The softshell clam (*Mya arenaria*) can acquire resistance to PST by mutation from glutamic acid to glutamine or to aspartic acid in the α subunit of the voltage-gated ion channel. Alteration at a single amino acid site may reduce by 1000-fold the binding of saxitoxin and selectively assure the survival of the clam but it also greatly

increases the toxicity of clams for human consumption. ►ion channels; Bricelj VM et al 2005 Nature [Lond] 434:763.

Figure C110. Clam

Figure C111. Saxitoxin

Clamp-Loader: A conformation of some proteins capable of assisting ring-shaped DNA polymerase processivity factors to be placed in the DNA. It is generally a component of the eukaryotic DNA polymerase holoenzyme. It is essential for DNA replication, repair, and recombination in prokaryotes and eukaryotes. In its absence mutation rate may increase probably by an impaired mismatch repair system. ►processivity, ►DNA polymerase, ►DNA repair, ►replication, ►replication machine, ►sliding clamp; for structure: Bowman GD et al 2004 Nature [Lond] 429:724; Ellison V, Stillman B 2001 Cell 106:655; Jeruzalmi D et al 2002 Curr Opin Struct Biol 12:217; Johnson AS, O'Donnell M 2005 Annu Rev Biochem 74:283.

Claspin: A protein required for strong ATR activation of Chk1 phosphorylation during the cell cycle. Claspin is an adaptor protein required for Chk1 activation and it becomes degraded at the onset of mitosis. The degradation is triggered by its interaction with, and

ubiquitylation by, the SCF·TrCP ubiquitin ligase. This interaction required the activity of the Plk1 kinase and the integrity of a β TrCP recognition motif (phosphodegron) in the N terminus of Claspin (Mailand N et al 2006 Mol Cell 23:307). ▶ATR, ▶ATRIP, ▶Chk1, ▶cell cycle, ▶SCF, ▶phosphodegron; Kumagai A et al 2004 J Biol Chem 279:49599.

Class I Genes (eukaryotic): Class I genes are transcribed by RNA polymerase I; these include 5.8S, 18S and the 28S ribosomal RNAs. ▶pol I eukaryotic

Class II Genes: Class II genes are transcribed by eukaryotic RNA polymerase II; these include mRNA and snRNA (except U6 RNA). They carry in the mRNA transcript a 7-methyl guanine cap (with the exception of the picornaviruses), and a 2,2,7-trimethyl guanine in the U RNAs. In lower eukaryotes, a 75 to 125-residues-long- and in vertebrates, a 200 to 300 residues-long poly-A tail is added posttranscriptionally. Histone mRNAs and U RNAs have no poly A tails. Some mRNAs include N6-methylated adenine, while U RNAs have modified uracils. They are regulated by cis- and trans-acting elements. The cap is associated with a cap-binding protein, the capping enzyme. ▶pol II, ▶eukaryotic, ▶transcription, ▶transcription factors, ▶transcription termination in eukaryotes, ▶transcription unit, ▶capping enzyme, ▶polyA mRNA, ▶U RNA, ▶cis-acting, ▶trans-acting

Class III Genes: The class III genes of eukaryotes are transcribed by RNA polymerase III; they include 5S ribosomal RNA and some small cytoplasmic RNAs. ▶pol III eukaryotic

Class Switching: Class switching is the change in expression of immunoglobulin (antibody) heavy chain genes during cellular differentiation of an antibody-producing lymphocyte by changing the production from one immunoglobulin heavy chain to another, e.g., the IgM constant region in one gene is replaced by the constant region of another class of immunoglobulin such as IgG, IgA or IgE. The efficiency of class switching is correlated with the length of the switch region, which is several kb long (Zarrin AA et al 2005 Proc Natl Acad Sci USA 102:2466). ▶immunoglobulins, ▶AID, ▶antibody gene switching, ▶hyper-IgM syndrome; Stavnezer J 2000 Curr Top Microbiol Immunol 245:127; Kinoshita K, Honjo T 2001 Nature Rev Mol Cell Biol 2:493; Petersen S et al 2001 Nature [Lond] 414:660.

Classical Genetics: Studies functions based on phenotype and genotype of the genetic material serve the primary guidance to the understanding of the mechanisms involved, in contrast to reversed genetics where the analysis begins with molecules. ▶reversed genetics

Classical Hemophilia: ▶hemophilia

Classification: The sorting out of phenotypes (or genotypes) by groups. It may be difficult in case of continuous variation or when the penetrance or expressivity is low. (▶expressivity, ▶penetrance).

Classification and Regression Tree (CART): A multivariate analysis for future classification.

Clastogen: Any agent that can cause chromosomal breakage directly, or indirectly by affecting DNA replication. Clastogenic agents may be ionizing radiation, bleomycin, hydroxyurea, maleic hydrazide, etc. ▶chromosome breakage

Clathrin: Clathrins are 192-kDa triskelion proteins that in cooperation with smaller (~35 kDa) polypeptides form the polyhedral coat on the surface of the coated vesicles involved in intracellular transport between cellular organelles. Before fusing with the target, the vesicle coats are stripped with the assistance of chaperones (hsp70) and another cofactor, auxilin. Clathrin is also required during the mitotic spindle function. (Royle SJ et al 2005 Nature [Lond] 434:1152). ▶adaptin, ▶triskelion, ▶auxilin, ▶cargo receptors, ▶endocytosis, ▶coatamer, ▶chaperone, ▶lysosomes; Kirchhausen T 2000 Annu Rev Biochem 69:699; Ford MGJ et al 2002 Nature [Lond] 419:361.

Claudin-11 (3q26.2-q26.3): An oligodendrocyte transmembrane protein controlling a paracellular barrier of tight junctions required for normal spermatogenesis and nerve conduction. Mutation in Claudin-16 (3q27) may involve hypercalciuria, hypomagnesemia, and chronic renal failure (Müller D et al 2003 Am J Hum Genet 73:1293). Claudin-5 (22q11.2) deletions lead to a transmembrane defect and velocardiofacial syndrome. Claudin-1 is implicated in a late step of the Hepatitis C virus entry procedure (Evans MJ et al 2007 Nature [Lond] 446:801). ▶tight junction, ▶velocardiofacial syndrome, ▶hepatitis; Gow A et al 1999 Cell 99:649.

Claw-Foot (Roussy-Levy hereditary areflexic [no reflexes] dysplasia): An autosomal dominant anomaly usually involving paternal transmission. It bears resemblance to the Charcot-Marie-Tooth disease but is accompanied by hand tremors. ▶Charcot-Marie-Tooth disease

Clavulanate: A product of streptomycetes is suicide substrate for β -lactamase; it enhances the effect of amoxicillin and is an effective weapon for circumventing some antibiotic resistance (see Fig. C112). ▶amoxicillin, ▶ β -lactamase, ▶antibiotics

Figure C112. Clavulanate

Claw-like Fingers and Toes (curved nail of fourth toe): A rare, apparently autosomal recessive nail deformity of the fourth (and fifth) toes and fingers.

CLB: A mitotic cyclin protein. CLB6 activates only the early origins of replication of the chromosome whereas CLB 5 activates both early and late replicational origins. To prevent polyteny or polyploidy a complex of CLB–Cdc28 prevents an additional cycle of replication when one is completed. ▶cyclin, ▶CDK, ▶DNA replication during the cell cycle, ▶DNA replication eukaryotes

CIB Method: The *CIB* method detects new sex-linked lethal mutations among the grandsons of *Drosophila* males on the basis of altered male: female ratios (*C* is an inversion, eliminating cross-over chromosomes, *l* is a lethal gene, and *B* stands for *Bar eye* [narrow]). If a new recessive lethal mutation (*m*) occurred in the X-chromosome of the grandfather, either the grandson receiving this, or the *CIB* chromosome will die (see Fig. C113). In F₂ the males carrying either the *CIB* or the mutant X-chromosome will die; without the new mutation (*m*) the female: male ratio is

2:1. In case of a new lethal mutation no grandsons may survive; in case the expressivity of the new lethal gene is reduced, some males may survive. ▶*Basc*, ▶autosomal dominant, ▶autosomal recessive mutation; Muller HJ 1928 Genetics 13:279.

C

CLC: The chloride/proton antiporter family of proteins of the chloride ion channels. ▶CIC, ▶antiporter; Picollo A, Pusch M 2005 Nature [Lond] 436:420.

Cleanroom: A laboratory or manufacturing facility where the biological or chemical material is relatively safe from contamination and aseptic conditions can be maintained during use and in between use. Generally 4 grade levels are distinguished by government regulations on the basis of the maximum floating particle size (0.5 μm to 5 μm) and number per m³, flowhood circulation, etc. The institutional safety officer should be able to provide up-to-date information.

Cleavage Furrow: The cleavage furrow is an early embryonal division (that gives rise to the blastomeres) by which the larger fertilized egg breaks up into several smaller cells without growth. In general, the furrow splits cells, organelles, and macromolecules into two. The cleavage furrow is formed by an actomyosin structure of the *contractile ring*. ▶actomyosin; Glotzer M 2001 Annu Rev Cell Dev Biol 17:351.

Cleavage Nucleus: The nucleus of the dividing egg.

Figure C113. CIB method

C

Cleavage Stimulation Factors: Cleavage stimulation factors mediate the polyadenylation of the majority of mRNAs. CstF is a heterotrimeric protein of 77, 64 and 50-kDa subunits and recognizes the G + U-rich element downstream of the RNA transcript. CstF-64 binds to the RNA. CstF-77 (a homolog of suppressor of forked in *Drosophila*) bridges the 64 and 50 subunits and interacts with the AAUAAA polyadenylation signal-binding factor CPSF (cleavage-polyadenylation specificity factor). CstF-50 contains WD-40 repeats and interacts with the largest subunit carboxy-terminal domain of RNA polymerase II. ▶polyadenylation signal, ▶WD-40, ▶BARD-1, ▶forked, ▶polyadenylation signal; Gross S, Moore C 2001 Proc Natl Acad Sci USA 98:6080.

Cleft Lip: ▶harelip

Cleft Palate: An oral fissure frequently associated with harelip (lip fissure). Its incidence in the general population is about 4 to 20/10,000. Its recurrence risk in sibs of an affected individual are about 2% or more, in monozygotic twins the risk is 50%. Actually, these developmental anomalies may be parts of autosomal or X-linked dominant or autosomal recessive syndromes and some trisomies. Human chromosomal regions 2q32, 4p16-p13, and 4q31-q35 may be associated with the disorder. In mouse, deficiency of the $\beta 3$ subunit of the A type γ -aminobutyric acid receptor results in a cleft palate. In mouse, mutation in the LIM domain of a homeobox gene *Lhx8* appears to be critical for the determination of the cleft palate. Glycogen synthase kinase 3 β deficiency can result in midline defects (cleft palate, incomplete fusion of the ribs) in mice and its replacement at critical stages of development during gestation may rescue the condition (Liu KJ et al 2007 Nature [Lond] 446:79). In humans the condition is associated with variation in the epidermal growth factor level. The CLPEDI (cleft lip/ectodermal dysplasia) gene encoding nectin-1 (PRR1) was assigned to 11q23. Nectin is a cell adhesion protein and the principal receptor for α -herpesvirus; its mutation may convey resistance to these viruses. Cleft palate with ankyloglossia (adherent tongue) has been located to human chromosome Xq21 and occurs due to mutation in the T-box transcription factor TBX22. ▶recurrence risk, ▶sib, ▶trisomy, ▶neural crest, ▶Van der Woude syndrome, ▶GABA, ▶CATCH, ▶harelip, ▶GSK3, ▶EGF, ▶homeobox, ▶LIM, ▶herpes; Braybrook C et al 2001 Nature Genet. 29:179.

Cleidocranial Dysostosis (syn. cleidocranial dysplasia, 6p21, CCD): Autosomal dominant and recessive mutations may lead to deficiency of closure of the skull sutures, supernumerary teeth, chest, shoulder, hip and finger anomalies, short stature, etc. Autosomal

dominant forms may also show reduced jaw size, absence of thumbs or toes, and loss of distal digital bones. A mutation in mouse chromosome 6 may involve the CBFA-1 (core binding factor) gene (apparently homologous with CCD) encoding or regulating osteocalcin, a protein that controls osteoblast formation. This molecule may function as a transcription factor for bone forming genes. The term CCD is now used for the human central core disease of the muscles in humans due to mutation in the ryanodine receptor (RYR1, 19q13.1). ▶stature in humans, ▶osteogenesis imperfecta, ▶dysostosis, ▶pseudospondylosis, ▶central core disease

Cleistogamy: The shedding of pollen before the flowers open, thus resulting in self-fertilization in plants. ▶autogamy, ▶protandry, ▶protogyny

Cleistothecium: A closed, spherical fruiting body of ascomycetes such as in *Aspergillus* and powdery mildew fungus (see Fig. C114). The asci containing the spores are released after the rupture of the wall of the fruiting body. ▶perithecium, ▶gymnothecium, ▶ascogonium

Figure C114. Cleistothecium

CLIA (Clinical Laboratory Improvement Amendments): A US government organization that oversees the laboratory procedures for clinical testing of genetically determined diseases.

Cline: A gradual change in the distribution of genotypes or phenotypes within a large population caused by the environment, population density, or other factors. ▶aclinal

Clinical Genetics: clinical genetics deals with practical genetic problems encountered during patient care. ▶empirical risk, ▶medical genetics, ▶human genetics, ▶genetic counseling, ▶counseling genetic, ▶informed consent, ▶bioethics; <http://bioinfo.weizmann.ac.il/cards/index.html>.

Clinical Laboratory Tests: see <http://www.genetests.org>.

Clinical Tests for Heterozygosity: Many genes fail to reveal their anomalous alleles by simple visual observation. Some of these are detectable by enzyme

or serological assays in biopsies, by amniocentesis, and cell cultures. These tests may not be able to identify with certainty the genetic constitution of all samples because the same function may be affected by different gene loci. Some mutant alleles can be identified by RFLP or PCR analysis. ▶ [carrier](#), ▶ [PCR](#)

Clinical Trial Phases: Clinical trial phases, applicable also to gene therapy, are conducted in three steps. (I) the first trial with a few humans, expected to provide information on safety/maximal dose, timing, and body reaction. (II) More individuals are tested for safety as well as efficacy. (III) large-scale experimental treatment is expected to reveal efficacy compared with alternative methods of treatments and side effects. Rarely, the phase I clinical trials may result in injury to some volunteers (Wood AJJ et al 2006 New England J Med 354:1869). ▶ [informed consent](#), ▶ [experiments](#)

Clinodactyly, Congenital: Crooked finger(s); may be observed in several syndromes of genetic malformations involving bones.

CLIP (class II-associated invariant-chain complex protein): ▶ [major histocompatibility complex](#)

CLIPS (chaperone-linked protein synthesis): In eukaryotes, some chaperones assist in folding of the nascent proteins while others are destined either to restore distressed proteins, or assist in their disposal. ▶ [chaperone](#)

ClIP: ▶ [sister chromatid cohesion](#)

Clipboard: The clipboard of a computer is a storage area of the memory system from where information can be transferred to different documents created in the computer.

Clitoris: An oval body 7 to 13 cm long (homologous to the male penis) in the inner side of the cleft between the opening of the urethra and the vagina of female mammals. Its expansion results in relaxation following sexual excitement (climax, orgasm) without ejaculation. ▶ [circumcision](#), ▶ [penis](#)

CLN: Cyclin genes regulating cell division. ▶ [cyclin](#), ▶ [CDK](#)

Cloaca: Cloaca, in lower vertebrates, is the joint passageway of urinary and fecal discharge. In mammals it is the terminus of the hindgut before its differentiation into rectum, bladder, and genital primordia. ▶ [bladder exstrophy](#)

Clock Genes: Clock genes affect the biological clock such as the diurnal rhythm and endogenous rhythm or aging. ▶ [circadian rhythm](#), ▶ [endogenous rhythm](#), ▶ [aging](#); Lakin-Thomas PL 2000 Trends Genet 16:135.

Clonal Analysis: The study of pattern formation (genetic mosaics) as a consequence of mutation, deletion, recombination, and nondisjunction. Such an analysis permits tracing the event to its origin, estimation of the number of cell divisions that have taken place since the event, the number of cells in the primordium involved, etc. Usually, the availability of appropriate genetic markers is a requisite for such an analysis. Cell autonomous genes are particularly useful for clonal analysis because genes of neighboring cells do not affect their expression. Heterozygotes for recessive color markers are frequently used because the loss or mutation of the dominant allele will result in the formation of recessive sector(s) and pseudodominance. An unstable (ring) X-chromosome in *Drosophila* may lead to the formation of gynandromorphs. Nondisjunction or somatic recombination may lead to the formation of twin spots (sectors). In *Drosophila*, developmental compartments of polyclonal origin may be revealed on the basis of the structures and organs affected simultaneously or consequently. Mutations formed in the last three divisions of the wing imaginal disk involve changes in cuticular elements e.g., hairs and wing veins. The presence of sectors also reveals that a gene is cell autonomous and also whether its expression is modified by the product of other genes. Extracts of wild type lymph, mRNA, or protein injected into mutants may correct genetic defects in a localized form according to a gradient or in a particular pattern, depending on the nature of the function of the corresponding mutant allele being a specific transcription factor, a transmembrane protein, or a signal receptor, among others. DNA labeled by fluorochromes and hybridized in the tissues may identify the regions of mRNA distribution of a particular gene. The function of particular genes in regulation of others can be detected by immunostaining of particular loci with specific antibodies. ▶ [morphogenesis](#), ▶ [cell lineage](#), ▶ [fate map](#), ▶ [fluorochromes](#), ▶ [probe](#), ▶ [immunostaining](#), ▶ [luciferase](#); GUS; Steffensen DM 1968 Am J Bot 55:354; Hotta Y, Benzer S 1972 Nature [Lond] 240:527; Duchmann R et al 2001 Clin Exp Immunol 123:315.

Clonal Interference: The competition between beneficial mutations in asexual lineages within populations.

Clonal Restriction: In clonal restriction, proliferating cells are propagated only within the pre-ordained pattern of differentiation. ▶ [clonal analysis](#), ▶ [cell lineages](#)

Clonal Selection: Clonal selection involves selection and propagation of certain types of cells in a tissue. Specificity for certain antigens exists in the lymphocytes before exposure to antigens. A few antibody

C

producing lymphocytes, which are committed to the production of a specific antibody, are selected for clonal proliferation and stimulated for the synthesis of that specific antibody when infected by the pertinent antigen. Immunity may thus build up. The B-lymphocytes with lesser selective value are eliminated by apoptosis. Clonal selection may also favor certain cell types and lineages during carcinogenesis. New evidence indicates that some B-lymphocytes can produce two functional immunoglobulins Gerdes T, Wabl M 2004 *Nature Immunol.* 5:1282). ►immune system, ►lymphocyte, ►antibody, ►immunoglobulins, ►B cell, ►apoptosis, ►memory immunological, ►receptor editing; Meffre E et al 2000 *Nature Immunol.* 1:379; Silverstein AM 2002 *Nature Immunol* 3:793.

Clone: The progeny of asexual reproduction or molecular cloning yielding identical products. ►asexual reproduction, ►cloning, ►molecular cloning, ►cloning vectors, ►nuclear transplantation; McLaren A 2000 *Science* 288:1775.

Clone Validation: Clone validation in large-scale genome sequencing terminology indicates that the clones accurately represent the genome. ►DNA sequencing, ►genome projects

CloneConvert: A computer program that converts a file into the "miniset.dat" format for individual Map-Search Probes. (See Rudd KE et al 1991 *Nucleic Acids Res* 19:637).

Clone-based Map: The genomic DNA is incompletely digested by restriction endonuclease to about 150 kbp pieces and propagated by BAC vectors. Subsequently, the clones are completely digested by restriction enzymes to generate a collection of smaller fragments. The fragments are then aligned by chromosome walking and finally sequenced repeatedly to obtain an accurate order of the nucleotides. This is one of the basic principles used for sequencing larger genomes. ►BAC, ►restriction enzyme, ►chromosome walking

Clonidine: An α -2-adrenoreceptor agonist. At low concentrations it decreases presynaptic firing of noradrenergic cells. Its antagonist is idazoxan. ►synapse, ►adrenergic receptor, ►agonist

Cloning: Asexual reproduction in eukaryotes or replication of DNA (genes) with aid of plasmid vectors in appropriate host cells (*molecular cloning*). *Reproductive cloning*, i.e., generating embryo from human stem cells is prohibited in most countries for ethical reasons. *Therapeutic cloning*, i.e., generating human tissues for medical purposes seems to be favored by biologists and medical researchers. ►clone, ►cloning vectors, ►DNA library, ►plasmids, ►DNA,

►expression cloning, ►nuclear transplantation, ►transplantation of organelles, ►therapeutic cloning, ►stem cells

Cloning Animals and Humans: Cloning is technically feasible by the use of the procedures of nuclear transplantation. However, because of technical problems the cloning of higher animals cannot be used as a routine procedure for propagation. Currently 15% or more of the cloned mammalian embryos suffer from chromosomal or metabolic defects. In cloning embryos, trophoctoderm and placental defect may frequently cause developmental failures.

Based on less-than-well informed ethical considerations, there is a rather widespread opposition to this type of research (reproductive cloning). Naturally, almost any technology can potentially be abused, but most of the condemning arguments against cloning are weak on biological grounds. Before the application of cloning or any other medical technology, sensible guidelines need to be formulated. Politically motivated banning of research may deprive society of expanding its repertory for remedying human disease. In 1997 (*Science* 278:2130) the gene for antihemophilic factor IX was introduced into sheep by nuclear transplantation, opening a new avenue to cure hemophilia B (Christmas disease). Many dread the ethical consequences of cloning humans. Others fear of the biological consequences. Unfortunately the ethical criteria are rather subjectively and ill defined. The biological consequences of poor technologies are real. It must be also considered that using somatic donor nuclei the risks of undesirable combination of homozygous deleterious genes can be avoided if the nuclei are taken from adults who have already withstood the test of being disease- or malformation-free. The potential risk of inbreeding should be and can be managed. In human cloning, distinction must be made between cloning cells for therapeutic purposes and cloning as a means of reproducing intact organisms. Consumption of animal products obtained through cloning (nuclear transfer) thus far (2007) has not revealed any difference from consumption of animal products obtained from conventionally bred herds (Yang X et al 2007 *Nature Biotechnol* 25:77). ►nuclear transplantation, ►hemophilia, ►bioethics, ►therapeutic cloning, ►embryo research, ►stem cells, ►trophoctoderm; Solter D 2000 *Nature Revs Genet* 1:199; Jaenisch R, Wilmut J 2001 *Science* 291:2552; Lanza RP et al 2002 *Science* 294:1893; O'Mathúana DP 2002 *EMBO Rep* 3:502; commercial and regulatory issues with animal cloning: Suk J et al 2007 *Nature Biotechnol* 25:47.

Cloning Bias: The deviation from randomness in the representation of fragments in a DNA library. The

bias may be caused by rearrangement of direct repeats in *Rec⁺* bacterial strains, (but can be avoided by *recA* hosts). Palindromic sequences may become unstable in some λ phage and plasmid vectors (can be avoided by the use of *recB* and/or *recC* and *shcB* strains of *E. coli*, base modification of the DNA, host restriction enzymes, etc.). ▶DNA library, ▶restriction enzyme, ▶cloning vectors

Cloning Sites: Recognition sequences for restriction enzymes within genetic vectors or other recipients where passenger DNA can be inserted. ▶restriction enzymes, ▶vectors, ▶passenger DNA

Cloning Strategy: The plan that permits the identification of the cloned copy either by a suitable probe (DNA, RNA or antibody) or one through a positional cloning or PCR based procedure. ▶probe, ▶PCR, ▶positional cloning, ▶gene isolation

Cloning Vectors: Cloning vectors are generally plasmid, phage, or eukaryotic virus-derived linear or circular DNA capable of reproduction (most commonly in bacteria or yeast) and producing (in large numbers) molecular clones of the DNA inserted into them. Cloning vectors must have replicator mechanisms (replication drive unit) for self-propagation, multiple cloning sites (single or few recognition sites for several restriction enzymes), selectable markers (for verifying the success of molecular recombination and uncontaminated maintenance), regulatory elements for their copy number in the host (generally smaller plasmids can be present in larger number of copies), mechanisms for equal partition among the daughter cells, and genetic stability to prevent rearrangement by host enzymes. Often, it is desirable to propagate in more than one host cell (shuttle vectors). Some cloning vectors are used only for propagation of DNA, others permit expression of the genes carried, and yet others may be useful in isolating functional elements of the hosts (promoters, enhancers) by virtue of in vivo gene fusion. ▶lambda vectors, ▶cosmids, ▶phagemids, ▶YAC, ▶BAC, ▶PAC, ▶SV40, ▶retroviral vectors, ▶agrobacterial vectors, ▶plasmids, ▶ColEI, ▶shuttle vector

Cloning Vehicles: Cells suitable to propagate the cloning vectors, e.g., *E. coli*, yeast, *Agrobacterium*, etc. ▶cloning vectors

Clonogenic Test: In a clonogenic test, isolated cancer cells seeded onto culture plates are exposed to radiation or other anti-cancer treatments, and incubated for about two weeks. Solid tumor cells in this assay die only when they divide, e.g., due to chromosome breakage. This fact indicates that mechanical injury to the chromosomes rather than apoptosis caused the demise of the cells as an evidence

of failure forming clones. Such an assay may reveal some information about the prospects of treatment of a particular cancer by different agents. Microvascular damage and apoptosis caused by radiation may be critical for the reduction of tumor growth because of the disruption of angiogenesis (Garcia-Barros M et al 2003 Science 300:1155). ▶cancer, ▶cancer therapy, ▶angiogenesis, ▶apoptosis

Clonote: The product of nuclear transplantation when an enucleated egg is combined with an isolated nucleus from a somatic cell. The term is coined from the analogy of a zygote that is the product of the natural fertilization of an egg by a sperm. Production of a clonote would be, in all essential ways, reproductive cloning. A clonote could also be exploited for stem cell research but it appears inadvisable to use it for human reproduction on both ethical and biological grounds. ▶in vitro fertilization, ▶nuclear transplantation, ▶stem cells; McHugh PR 2004 New England J Med 351:209.

Closed Promoter Complex: In a closed promoter complex, the transcriptase attached to the target promoter cannot start transcription because the DNA strands are not separated. ▶open promoter complex, ▶pol prokaryotic RNA polymerase

Closed Reading Frame: Chain termination (nonsense) codons block the translation of a closed reading frame.

Closed-Loop Model of Translation: In a closed-loop model of translation, the mRNA supposed to be translated is visualized as a molecule circularized by the 5'—3' ends. Support comes from the observation that the poly(A) tail promotes translation; electron microscopy has also been known to reveal RNA circles. The circularization is mediated by trans-acting protein factors such as eIF4G, eIF4F, polyA-binding proteins. ▶polyA tail, ▶eIF4G, ▶eIF4F; Jacobson A 1996 p. 85. In: Hershey JWB et al (eds) Translational Control. Cold Spring Harbor Lab. Press, Cold Spring Harbor, New York; Sachs A 2000 p. 447. In: Sonnenberg N et al (eds) Translational control of gene expression. Cold Spring Harbor Lab. Press, Cold Spring Harbor, New York.

Clostridium botulinum: An anaerobic bacterium, which produces botulinum toxin ($LD_{50} \cong 0.2$ ng/kg body weight). ▶biological weapons

Clostridium difficile: A bacterium that produces cytotoxins A and B responsible for antibiotic-induced diarrhea and pseudomembranous colitis in hospital settings. (See Reineke J et al 2007 Nature [Lond] 446:415).

C

Clostridium perfringens: Flesh-eating Gram-positive bacterium that encodes several toxins, particularly serious is the one, which destroys muscles. Its genome of 3,031,430 bp comprises 2,660 protein-coding and 10 rRNA genes. ▶tetany, ▶host-resistance genes; Shimizu T et al 2002 Proc Natl Acad Sci USA 99:996.

Closure of Mapping: Approaching completion, when two-genome-size DNAs had been mapped, the use of random clones is very inefficient; therefore, non-random clones are used. ▶physical map

Clotting Factor: ▶antihemophilic factor

Cloverleaf: The cloverleaf is a representation of the tRNA in which, the single strand stem (amino acid arm) loop is akin to the stem, and the D (dihydrouracil), AC (anticodon), and T (thymine) loops like the three leaflets of a leaf of a clover plant (see Fig. C115). ▶tRNA

Figure C115. tRNA cloverleaf

Clovers (*Trifolium* spp): Clovers include about 250 species. The most prominent representatives are: white clover (*T. repens*, $2n = 32$), the fragrant alsike (*T. hybridum*, $2n = 16$), strawberry (*T. fragiferum*, $2n = 16$), red clover (*T. pratense*, $2n = 14$), crimson clover (*T. incarnatum*, $2n = 14$), and the subterranean clover (*T. subterraneum*, $2n = 16$).

Clp (*ClpX*): *ClpX* includes different prokaryotic proteins from the Hsp100 family, and are involved in chaperone or protease activities (see Fig. C116). The size of the different molecules may vary substantially. They include inducible and non-inducible forms and are distributed widely among eukaryotes and prokaryotes. *Clp* proteins also occur in chloroplasts and in the “plastids” of *Plasmodia*. The budding yeast Hsp104 *Clp* protein and the *E. coli* *ClpB* are intramolecular chaperones, and as such do not depend on ATP, but *ClpA* and *ClpX* are chaperones and ATP-dependent proteases. *Clp*-dependent proteolysis may protect against degradation of unmodified bacterial DNA by type I restriction endonucleases. ▶protease, ▶proteasome, ▶chaperone, ▶Hsp, ▶Plasmodium, ▶chloroplasts, ▶protein repair, ▶AAA proteins; Neuwald AF et al 1999 Genome Res 9:27; Kenniston JA et al 2005 Proc Natl Acad Sci USA 102:1390.

Figure C116. ClpA degradation

CLR4: ▶Suv39

Clubfoot (talipes): A hereditary malformation of the foot with a prevalence of below 0.1% and with a recurrence risk among the sibs of an afflicted child at about 4% (see Fig. C117). Thus, it appears to be under the control of more than one gene and depends on substantial environmental influences because even monozygotic twins may not be both afflicted. In New Zealand based and Polynesian populations, the occurrence of clubfoot appears to be controlled by a single dominant gene with 0.33 penetrance, and the gene frequency is predicted to be 0.009 (Chapman C et al 2000 J Med Genet 37:680). Various forms have been classified and only one is shown on the photo. ▶limb defects, ▶arthrogryposis

Figure C117. Clubfoot of an infant. (Courtesy of the CDC Public Health Image Library)

CLUSTAL W (improving the sensitivity of progressive multiple sequence alignment through sequence weighting, position-specific gap penalties and weight matrix choice): A freely available computer program published in one of the ten most cited papers during 2000. The multiple sequence alignment program (MAFFT-5) has been improved over CLUSTAL

(Katoh K et al 2005 Nucleic Acids Res. 33:511). (See Thompson JD et al 1994 Nucleic Acids Res 22:4673, ITERALIGN, <http://www.ebi.ac.uk/clustalw>).

Cluster Analysis: The cluster analysis monitors simultaneously the expression patterns, based on DNA arrays, of thousands of genes at various stages of development or in response to any particular environmental influence. The method utilizes mathematical cluster analysis suitable for classification of multidimensional complex data. The GENECLUSTER computer program can perform calculations and assists in the interpretation of the biological meaning of the information collected. Alternatively, the differential expression of particular genes involved in similar functions can also be tested statistically. ▶microarray hybridization, ▶DNA chips, ▶support vector machine, ▶maps self-organizing, ▶GSEA, ▶regression; Tamayo P et al 1999 Proc Natl Acad Sci USA 96:2907; Eisen MB et al 1998 Proc Natl Acad Sci USA 95:14863; Miki R et al 2001 Proc Natl Acad Sci USA 98: 2199; Thomas JG et al 2001 Genome Res 11:1227; Harris RA et al 2002 Proteomics 2:212; Ramoni MF et al 2002 Proc Natl Acad Sci USA 99:9121; hierarchical clustering of proteins: <http://www.protonet.cs.huji.ac.il>; cross-species clustering analysis of microarray data: <http://biocomp.bioen.uiuc.edu/oscar>.

Cluster Homology Regions (CHR): CHR are homologous DNA sequences located in different chromosomes and probably are the results of gene duplication. In some cases, the coded protein is specialized to tissue- or organelle-specific functions or its function has changed, i.e., it has assumed a new function. ▶clustering of genes, ▶duplication, ▶evolution and duplication; Nagai K 2001 Gene 270:161.

Cluster of Differentiation (CD): CD are a very large number of specific surface glycoprotein antigens that identify particular differentiated cells (leukocytes), microbes, cancer cells, etc. and can be used for diagnosis, prognosis, and in therapeutic intervention. (See Woolfson A et al 2006 Pharmacogenomics 7:759).

Clusterin (complement lysis inhibitor, CLI): CLI is an evolutionarily highly conserved 75–80 kDA heterodimeric glycoprotein, encoded in human chromosome 8p21. Isoform 1 is repressed by androgens, whereas isoform 2 is upregulated by androgens through direct interaction with the first intron (Cochrane DR et al 2007 J Biol Chem 282:2278). Along with vitronectin, it prevents the attack of the C5b-9 complex upon the cell membrane. It also regulates lipoprotein metabolism, neuroendocrine

functions, and germ cell differentiation and is involved as well, in the development of inflammatory diseases such as Alzheimer's disease and Niemann-Pick disease. Its level may be elevated in some neurological disorders. ▶complement, ▶vitronectin, ▶Alzheimer's disease, ▶Niemann-Pick disease; Bailey RW et al 2001 Biochemistry 40:11828; Jones SE, Jomary C 2002 Int J Biochem & Cell Biol 34:427.

Clustering, Hierarchical: ▶cluster analysis

Clustering of Genes: Bacteriophage genes exist in a linear order of morphogenesis; several bacterial genes are clustered in the exact order of the biosynthetic pathway (tryptophan operon), others are located only within a group but not in strict biosynthetic order (histidine operon) and are under coordinated regulation. In the lower eukaryotes (fungi), some histidine genes and chorismic acid genes are in groups, although, they are not transcribed into a polycistronic RNA. The vertebrate homeotic genes of the HOX families are in functional groups and may be regulated by shared global enhancers. The ribosomal and tRNA genes are in a linear array in prokaryotes and eukaryotes and are processed after transcription into individual molecules. The histone genes in *Drosophila* and sea urchin are located in the same region but separated by spacers. Some of the antibody genes in mammals are clustered in gene families and are repeated many times. Some highly expressed mammalian housekeeping genes are clustered (Lercher MJ et al 2002 Nature Genet 31:180). The clusters are generally preceded by motifs, which facilitate the recruiting of transcription factors required by regulated expression of gene clusters (Conlon EM et al 2003 Proc Natl Acad Sci USA 100:3339). Essential genes may be clustered and recombination within the clusters seems to show low incidence (Pál C, Hurst LD 2003 Nature Genet 33:392). Some genes of the nematode *Caenorhabditis* are even polycistronic. Some (e.g., ribosomal) chloroplast genes are clustered according to the pattern of their prokaryotic ancestors. Some chromosomal clustering of chloroplast and mitochondrial genes in plants might have been favored by the advantage of proximity in expression (Alexeyenko A et al 2006 Trends Genet. 22:589). In mice, genes involved in spermatogenesis are not distributed at random in the genome, e.g., 10/25 spermatogonia-specific genes are located in the X chromosome and three in the Y chromosome. Of the 36 genes found to be involved in sperm production, only 23 are scattered among the 18 autosomes. In five eukaryotes (yeast, humans, *Caenorhabditis*, *Arabidopsis*, and *Drosophila*) 98 to 30% of the analyzed metabolic

C

pathways are controlled by clustered genes. Only seven of the 69 pathways studied in these organisms were clustered in all five (Lee JM, Sonnhammer EL 2003 Genome Res 13:875). The clustered paralogous genes of higher eukaryotes are the consequences of duplications in the chromosomes that occurred during evolution. ▶operon, ▶coordinate regulation, ▶polycistronic mRNA, ▶His operon, ▶chorismate, ▶histones, ▶spacer DNA, ▶tRNA, ▶rRNA, ▶homeotic genes, ▶synexpression, ▶attenuator region; [for the tryptophan operon diagram]; ▶HLA, ▶RIDGE; Wicker N et al 2002 Nucleic Acids Res 30:3992; Boutanaev AM et al 2002 Nature [Lond] 420:666; Sproul D et al 2005 Nature Rev Genet 6:775.

Clustering of Phenotypes: Clustering of phenotypes may be caused by exposure to similar environmental effects. Epidemiological factors such as carcinogens in the environment and viral infections may precipitate the expression of phenotypes in an unusual distribution.

Clustering of Recombinants: Clustering of recombinants may be found in the progeny or in the gametes if recombination in the germline (mitotic recombination) preceded meiosis. The reality of clustering may need statistical verification by using the formula, (Tanaka MM et al 1997 Genetics 147:1769) where u_i = numbers in category u of brood i , k = total number of broods, $U = \sum u_i$ = total counts in category u , n_i = total number of progeny in brood i , and $N = \sum n_i$ = the total number of progeny in the set of data. ▶mitotic crossing over, ▶brood

$$V_W = \frac{1}{N} \sum_i^k \left[\frac{u_i^2}{n_i} - \frac{U^2}{N} \right]$$

Clusters of Differentiation: Antigens associated with distinct processes of differentiation are immunologically detectable. ▶CD proteins

Clutch: A cluster of eggs laid by a bird.

c.m. or c.M.: centi Morgan = 1% recombination; 1 map unit. ▶mapping genetic, ▶recombination

C-Meiosis: C-meiosis is meiosis arrested because colchicine is poisoning the spindle fibers. ▶meiosis, ▶colchicine

cMG1: A protein related to TIS11 (a 67 amino acid region is 72% identical), which responds to epidermal growth factor and cycloheximide.

CFI (cell-mediated immunity): ▶immunity

C-Mitosis: C-mitosis is mitosis in which, the poisonous effects of colchicine block mitotic anaphase, and consequently the cell and its progeny may become

polyploid (see Fig. C118). Endo-replication may take place and the two-chromatid chromosomes may sometimes be detected in juxtaposition. ▶C-meiosis, ▶colchicine, ▶partial karyotype at left

Figure C118. C-mitosis. (after W.V. Brown, 1972 Textbook of Cytogenetics, Mosby, St. Louis)

CMR (comprehensive microbial resource): Annotation of the sequenced microbial genomes; total of 250 bacteria, archaea and viruses. (See <http://cmr.tigr.org/tigr-scripts/CMR/CMrHomePage.cgi>).

CMRF35H (17q24): An inhibitory immune receptor on leukocytes.

cms: Cytoplasmically determined male sterility. ▶cytoplasmic male sterility

CMT: CMT refers to the monkey cell line expressing SV40 T antigen. ▶SV40

CMV: Cytomegalovirus, hCMV: human cytomegalovirus. ▶cytomegalovirus

Cne1, CneX: The yeast homologs of calnexin. ▶calnexin

CNE: Conserved non-coding element. ▶non-coding DNA

CNF (cytotoxic necrotizing factor): CNF inhibits GTPase activity and thus contributes to the activation of RHO (p21). CNF is a virulence factor of *E. coli* bacteria. ▶RHO, ▶p21, Thomas W et al 2001 Infect Immun 69:6839.

CNK (connector enhancer of KSR): CNK is a multi-domain protein involved in RAS signaling.

CNK^{N-term} enhances RAS signals, whereas CNK^{C-term} interferes with signaling when overexpressed. ▶KSR, ▶RAS; Anselmo AN et al 2002 J Biol Chem 277:5940.

cNMP Cyclase (cyclic nucleotide monophosphate cyclase): cNMP cyclase is involved in the biosynthesis of cAMP and cGMP. ▶cAMP, ▶cGMP; McCue LA et al 2000 Genome Res 10:204.

CNS: The central nervous system. ► [brain human](#)

CNS (conserved non-coding sequences): ► [non-coding sequences](#)

CNTF (ciliary neurotrophic factor): ► [APRF](#), ► [neurotrophins](#), ► [ciliary neurotrophic factor](#)

C-Oncogenes: Cellular oncogenes. ► [v-oncogenes](#)

Co⁶⁰: ► [isotopes](#)

CO₂ Sensitivity: CO₂ sensitivity in some strains of *Drosophila* is manifested as paralysis and death after being anesthetized with the gas. The condition is caused by infection with rhabdovirus sigma. This RNA virus resembles the vesicular stomatitis virus (VSV) of horses (an acute febrile [fever causing] infection of the tongues, mouth membranes, and lips) and some fish viruses (PFR, SVC) that can also elicit carbon dioxide sensitivity in *Drosophila*. The fly virus, however, cannot infect vertebrates. In the non-stabilized state, only the *Drosophila* females transmit the virus. In the stabilized state the transmission by eggs is 100%; the virus is also transmitted by the sperm, although, in the latter stabilized infection does not ensue. The *ref* mutants (in chromosomes X, 2, 3) are refractory to this type of infection. The ability to detect CO₂ helps blood-feeding insects (e.g., *Anopheles* mosquitos) to locate hosts by olfactory sensory neurons situated in their maxillary appendages (mouth palps). In *Drosophila*, two homologous chemosensory receptors are present in the sensory organs of the antennae (Jones WD et al 2007 Nature [Lond]: 445:86). ► [Rhabdoviridae](#), ► [Drosophila](#); L'Héritier P 1948 Heredity 2:325.

CoA: ► [acetyl coenzyme A](#)

Coacervate: The term coacervate refers to the colloidal aggregate of organic compounds. These compounds have probably played a role in organic evolution. ► [prebiotic evolution](#); Jensen SA et al 2000 J Biol Chem 275:29449.

Co-activator (AF, activator function): In addition to TBP, TAF, and general transcription factors, co-activator molecules are required for activation of gene transcription. Co-activators seem to acetylate histones, whereas histone deacetylases appear to be transcriptional co-repressors. ► [TBP](#), ► [TAF](#), ► [transcription factors](#), ► [TATA box](#), ► [high mobility group of proteins \[HMG\]](#), ► [transactivator](#), ► [nuclear receptor](#), ► [chromatin remodeling](#); Näär AM et al 2001 Annu Rev Biochem 70:475; Spiegelman BM 2004 Cell 119:157.

Co-adapted Genes: Co-adapted genes represent genotypes capable of expression of a satisfactory (fit) phenotype. (► [fitness](#), ► [outbreeding depression](#);

Dobzhansky T, Pavlovsky O 1958 Proc Natl Acad Sci USA 44:622).

Coagulation Factors: ► [antihemophilic factors](#)

Coalescence: The point or node of an evolutionary tree where two lineages merge (diverge) at a time or at any other scale. ► [evolutionary tree](#), ► [MRCA](#), estimation of coalescence times: Meligkotsiodou L, Fearnhead P 2005 Genetics 171:2073.

Coalescent: Coalescent is a statistical parameter of the genealogical information of genetic data. It is an approximation from a random sample of genes in a population with “constant size” over many generations without selection and recombination within the chromosomal sequences considered. The analysis should reveal the number of generations that the chosen entities have undergone since they were separated from the common ancestor. The analysis thus reveals the *most recent common ancestor* (MRCA) on what the genetic samples coalescing. The coalescent represents the dynamic (demographic) history of the populations. Genetic drift may be a confounding factor. ► [F_{ST}](#), ► [\[δμ\]²](#), ► [mutation age of](#), ► [drift genetic](#); Donnelly P, Tavaré S 1995 Annu Rev Genet 29:401; Rosenberg NA, Nordborg M 2002 Nature Rev Genet 3:380.

Coancestral: Coancestral gene(s) are identical by descent in two individuals, e.g., uncle and niece, first cousins, etc. ► [coefficient of coancestry](#), ► [consanguinity](#), ► [inbreeding coefficient](#)

Coarctation of the Aorta: The coarctation of the aorta is an apparently autosomal polygenic narrowing of the blood vessels leading to congenital heart failures. ► [cardiovascular disease](#), ► [heart disease](#), ► [supravalvular aortic stenosis](#)

Coassortment: ► [macronucleus](#)

Coat Color: ► [pigmentation of animals](#), ► [fur color](#). (see Fig. C119)

Figure C119. Coat color. (Courtesy of Dr. Paul Szauter, <http://www.informatics.jax.org/mgihome/other/citation.shtml>)

Coat Protein: The protein(s) of the viral capsid and some membrane surfaces. ▶capsid, ▶capsomer, ▶uncoating

C

Coated Pits: Coated pits are generated on the surface of coated vesicles by invagination and pinching off. Thereby, they facilitate transport by losing the coat and fusing with other intracellular vesicles (lysosomes). ▶lysosomes, ▶dynamitin

Coated Vesicles: Clathrin-coated vesicles. ▶clathrin

Coatomer (coat-protomer): A coatomer is the large protein complex on the surface of vesicles (Golgi), mediating non-selective transport within cells. Its assembly requires ATP. After the transfer of the cargo, the coatomer is still retained and docks with another membrane. ▶clathrin, ▶COP transport vesicles; Sullivan BM et al 2000 Mol Biol Cell 11:3155.

cob: *apocytochrome b* gene in the mitochondrion (yeast) may exist both without introns and with introns (called boxes). Its exons code for the apocytochrome 1 protein, whereas the box 3 introns code for a “maturase” protein that excises the introns from the long form gene. A box 7-coded protein splices the exons of the adjacent cytochrome oxidase (*oxi3*) gene. For the stability of the cob Mrna, the nuclear gene product Cbp1 must interact with a CCG sequence in the 5' untranslated region. ▶cytochromes, ▶mtDNA

Cobalamin (cyanocobalamin): The vitamin B12, a coenzyme for methylmalonyl CoA mutase; it has therapeutic use in anemia and acidosis. Cobalamin is a cofactor also of homocysteine metabolism and branched-chain amino acid and odd-chain fatty acid catabolism. Hyperhomocysteinemia is observed in some cardiovascular and psychiatric diseases and cancer (Lerner-Ellis JP et al 2006 Nature Genet 38:93). Plants do not contain cobalamin, and a strictly vegetarian diet as well as the autoimmune diseases of the elderly may show deficiencies (Croft MT et al 2005 Nature [Lond] 438:90). ▶transcobalamin, ▶transcobalamin deficiency, ▶vitamin B12 defects

cob-box Genes: encode mitochondrial cytochrome oxydase with introns. The intron boxes may have independent functions in processing the apocytochrome transcripts. ▶mtDNA

Cobra-Fish (combined binary ratio-FISH): In the Cobra-Fish process, human chromosomes are painted in 24 colors by using four fluorophores. Three fluorophores (fluorescein, lissamine, and cy5) are used pair-wise for ratio labeling of a set of 12 chromosome-painting probes. The second set of 12 probes is labeled the same way but exposed also to a fourth

fluorophore (diethylaminocoumarin). See Tanke HJ et al 1999 Eur J Hum Genet 7:2; ▶combinatorial labeling, ▶FISH, ▶fluorescein, ▶coumarine, ▶Cy, ▶fluorophore

Cobratoxin: The major protein toxin in cobra venom. It blocks irreversibly, nicotinic receptors and cholinergic transmission at the neuromuscular junctions. ▶toxins

Coca (*Erythroxylon coca*): A source of cocaine; 2n = 2x = 24. ▶cocaine

Co-Carcinogens: Co-carcinogens, such as phorbol esters, may not be carcinogenic alone but may act as tumor promoters. ▶phorbol esters, ▶carcinogens

Cocaine (3-benzoyloxy)-8methyl-8-azabicyclo[3.2.1]octane-2-carboxylic acid methyl ester): Cocaine is a topical anesthetic and a euphoriant. It is an addictive drug obtained either from *Erythroxylon* plants or produced by chemical synthesis. Cocaine-dependence and intense craving may return even after prolonged abstinence. The priming of the relapse seems to be mediated by the D₂-like receptor agonists of the dopamine system, whereas the D₁-like receptor agonists prevent cocaine-seeking behavior. The effect of cocaine seems to be the blocking of the dopamine transporter protein. In cocaine addiction, a specific serotonin receptor may be involved. Continued use of cocaine increase cAMP activity and PKA in the brain. Escalating cocaine use in rats causes structural reorganization of the lower hypothalamus and the changes are supposed to drive an increased craving for the drug (Ahmed SH et al 2005 Proc Natl Acad Sci USA 102:11533). Excessive expression of CREB in the rat brain nucleus accumbens (site in the brain that responds through rewarding actions to opiates) decreases the craving for cocaine and actually promotes aversion to it. Excessive expression of a dominant negative CREB mutation intensifies the cocaine reward. Blocking the opioid receptors by dynorphin may antagonize the CREB effect. Cocaine immunoconjugates may block substantially the effects of the drug. A computationally redesigned butyrylcholinesterase mutation may substantially accelerate the hydrolysis of cocaine and thus may have medical use (Pan Y et al 2005 Proc Natl Acad Sci USA 102:16656). ▶dopamine, ▶agonist, ▶serotonin, ▶dynorphin, ▶CREB, ▶PKA, ▶opiate, ▶cAMP, ▶alkaloids; Yarmolaieva O et al 2001 J Neurosci 21:7474.

Coccus: A small (~1 > μm) spherical bacterium.

Co-Chaperone: A co-chaperone assists in the function of a major chaperone, e.g., DnaJ for Hsp70 in *E. coli*. ▶chaperone, ▶Hsp70, ▶DnaJ, ▶CbpA, ▶heat-shock proteins

Co-Chaperonin: GroES in bacteria assists protein folding by GroEL chaperonin. Similar is the function of the bacteriophage encoded Gp31 protein, which can assist GroES or can substitute for it. ►[chaperonin](#)

Cochlea: A snail shell-like structure in the inner ear essential for normal hearing.

Cochliomya hominivorax (screwworm): A tropical and subtropical fly, an obligatory parasite of warm-blooded animals (see Fig. [C120](#)). Its infestation causes myiasis (weight loss and sometimes death). It punctures the skin (hide) of animals and thus leads to a multimillion-dollar annual loss to animal breeders. It is also a pest for humans. For its biological control, the mass release of genetically sterile (irradiated) males has been proven effective. ►[genetic sterilization](#), ►[myiasis](#), image from Insects; USDA Yearbook 1952 Stefferud A (ed), by permission.

Figure C120. *Cochliomya hominivorax*

Cockayne Syndrome (CS): CS is characterized by very short stature, precocious aging, deafness, eye degeneration, mental retardation, and sensitivity to sunlight. The condition seems to be associated with a DNA repair defect but unlike other DNA repair problems (ataxia telangiectasia, xeroderma pigmentosum, Bloom syndrome, Fanconi anemia) it does not involve increased proclivity to cancer. Some of the mutations (TAM) seem to be associated with the transcription-coupled nucleotide exchange repair of oxidative damage. It may be controlled by non-allelic autosomal recessive loci. CSA was assigned to human chromosome 5, CSB has been located to human chromosome 10q11 (and it functions as transcript elongation protein). CSB protein is a member of the SWI2/SNF2 family with roles in DNA repair and transcription. The purified recombinant CSB and the major human apurinic/apyrimidinic (AP) endonuclease, APE1, physically and functionally interact and under normal conditions protect against base excision repair (Wong H-K et al 2007 Nucleic Acids Res 35:4103). CSD is located in chromosome 19 and CSG in chromosome 13. Yeast has homologous genes *RAD2* and *RAD26*. All CS loci are involved in nucleotide exchange repair, base-excision repair, or in transcription-coupled repair. Complete inactivation of nucleotide exchange repair

in *Csbn/m/Xpa*^{-/-} (Cockayne syndrome/xeroderma pigmentosum) mutants of mice causes a phenotype that reliably mimics the human progeroid CS syndrome. Newborn *Csbn/m/Xpa*^{-/-} mice display attenuated growth, progressive neurological dysfunction, retinal degeneration, cachexia, and kyphosis and die before weaning. Mouse liver transcriptome analysis and several physiological endpoints reveal systemic suppression of the growth hormone/insulin-like growth factor 1 (GH/IGF1) somatotroph axis and oxidative metabolism, increased antioxidant responses, and hypoglycemia along with hepatic glycogen and fat accumulation (van der Pluijm P et al 2007 PloS Biol 5[1]e2). ►[DNA repair](#), ►[chromosome breakage](#), ►[light-sensitivity diseases](#), ►[ultraviolet-sensitivity syndrome](#), ►[DNA repair](#), ►[xeroderma pigmentosum](#), ►[trichothiodystrophy](#), ►[transcription factors \[TFIIH\]](#), ►[transcript elongation](#), ►[cerebro-oculo-facio-skeletal syndrome](#), ►[cachexia](#), ►[kyphosis](#), ►[somatotroph](#); Le Page F et al 2000 Cell 101:159; Lee S-K et al 2002 Cell 109:823; Licht CL et al 2003 Am J Hum Genet 73:1217; the paper by Le Page F et al on oxoguanine repair and transcription has been retracted; Le Page F et al 2005 Cell 123:711.

Cockroach: *Blattella germanica*, 2n = 23 male, 24 female 2n = 24.

This common pest of warehouses and homes is a source of allergic diseases and is a vector of pathogens (see Fig. [C121](#)). Its sex pheromone (blattellaquinone) is gentisyl quinone isovalerate, and its discovery may facilitate the control of cockroaches by luring the insects to improved traps (Nojima S et al 2005 Science 307:1104) (see Fig. [C122](#)).

Cocoa: ►[cacao](#)

C

Coconut (*Cocos nucifera*): The coconut ($2n = 2x = 32$) is a source of copra (endosperm), is used as food, and its oils are processed for margarine, etc. Before synthetic plant hormones became available commercially, coconut milk would be used in plant tissue cultures.

Co-Conversion: In co-conversion, two neighboring sites are simultaneously involved in gene conversion. (► [gene conversion](#))

Co-Cultivation: Co-cultivation refers to permitting plant cell proliferation on agar plates in the presence of *Agrobacterial* suspension (equipped with a vector plasmid) for a period of about one and a half to two days. During this period the T-DNA is transferred to the plant cells. Then the bacteria are stopped or killed by an appropriate antibiotic (e.g., cefotaxim or carbenicillin) and the transformed cells are selectively grown further on a medium to which, they are expected to be resistant. ► [transformation genetic](#), ► [vectors](#), ► [carbenicillin](#), ► [cefotaxim](#), ► [antibiotics](#)

Co-Deletion Analysis: Genes situated very closely to each other are jointly lost more frequently than those separated by a larger distance and this fact permits the construction of deletion maps. ► [deletion mapping](#)

Code, Comma-Free: In the 1950s, before the genetic code was experimentally identified, various speculations suggested that the code needs some marks to avoid ambiguity. Eventually, it was agreed that punctuation marks were unnecessary because the triplet codons could otherwise be read flawlessly. Actually, frame-shift mutations may alter the meaning of the text yet there are no signals between triplets. The nucleotide sequence needs only initiator codons and stop codons and some larger genes have additional demarcations by exons and introns. All nucleotide sequences are commaless ► [frame shift](#), ► [intron](#), ► [exon](#), ► [insulator](#); Crick FHC et al 1957 Proc Natl Acad Sci USA 43:416.

Code, Genetic: The genetic code specifies in adjacent nucleotide triplets (commaless code) each amino acid in the polypeptide chain. The triplets are generally called *codons* and are represented in mRNA nucleotides. The sequence of amino acids is determined by those codon sequences in the mRNA that are recognized by the anticodons in the tRNAs. The genetic code is redundant because some amino acids have up to 6 codons. The redundancy is also called *degeneracy* because several codons are degenerated (reduced) to the meaning of one amino acid. The code is *almost universal* from prokaryotes to eukaryotes, i.e., identical codons are used for the same amino acids across taxonomic boundaries. Exceptions to these rules exist in some mycobacteria, ciliates, and

mitochondrial DNAs. The 4 regular nucleotides in all possible combinations of 4 (4^3) generate 64 triplets from which 61 are *sense codons*, i.e., specify amino acids and 3 are *nonsense codons* (stop codons) because at their position in the mRNA the translation into protein stops and the polypeptide chain is terminated. In the customary codon table, the triplets are arranged into 16 families (► [see table of genetic code](#)) where the first two nucleotides may be sufficient for specifications although all 3 must be present. In higher organisms usually only one of the DNA strands is transcribed into mRNA codons; in prokaryotes both strands may be coding but in opposite orientation (always 5' to 3'). Although individual codons are *not overlapping*, the genes may be read, however, in overlapping registers ► [overlapping genes](#). This facilitates a better use of the relatively miniscule amount of DNA for a greater variety of functions in some bacteriophages. The *usage* of the redundant codons may vary from gene to gene ► [codon usage](#). Some suppressor mutations in DNA may alter the anticodons of the tRNAs, and the meaning of the stop or other codons may be altered, although, the mRNA codons remain the same. Changes in the codons require mutation in the DNA. Synthetic non-triplet codons may also be translated. ► [genetic code](#), ► [codon](#), ► [amino acid symbols in proteins sequences](#), ► [RNA editing](#)

Coden: Abbreviation of literature references as given by the Periodical Tables of the Chemical Abstracts Service.

Coding Capacity: The coding capacity of an organism or organelle is determined by the number and length of its open reading frames. ► [open reading frame](#)

Coding Dictionary: ► [code genetic](#), ► [genetic code](#)

Coding Joints: The junctures of the VDJ segments of the immunoglobulin and T cell receptor genes. ► [immunoglobulins](#), ► [TCR](#)

Coding Sequence (coding region): The coding sequence is transcribed into a functional RNA. The term coding has been used in two different ways. Some authors consider coding sequence only that part of the DNA that has the potential to be transcribed into RNA, which in turn may be translated into protein. In a somewhat broader sense, the transcription itself may be described as coding for RNA. The semantic problem is aggravated by the fact that some RNAs alone or in association with protein perform enzyme activity as ribozymes. ► [transcript](#); ► [RNA polymerase](#), ► [non-coding sequence](#), ► [ribozyme](#), ► [RNA editing](#), ► [open reading frame](#)

Coding Strand: The coding strand is the DNA strand, which has the same base sequence as the functional

RNA within the cell, except that in DNA thymine occurs at the place of uracil. The terminology has some ambiguity because in certain cases both strands of the DNA may be transcribed into RNA. Also, in some older papers coding strand is defined as the DNA strand, which is transcribed. Larger scale sequencing of *Drosophila* genome does not indicate much difference in the transcription of the two strands of the DNA (121:108) and in the areas crowded by genes the direction of transcription seems to alternate although in general it appears to be random. There is a possibility that transcripts of both strands of a DNA tract are combined for the translation of a particular protein. ▶anticoding strand, ▶antisense RNA, ▶sense strand, ▶template; Labrador M et al 2001 Nature [Lond] 409:1000.

CODIS (Combined DNA Index System): CODIS is a forensic database of biological evidence collected at crime scenes by the Federal Bureau of Investigation for the purpose of comparing DNA profiles local, state, and national, by participating organizations. It includes the Offender Index of individuals committing rape and other violent crime and felonies. As of October 2007 NDIS (National DNA Index) included a total of 5,265,258 profiles, forensic profiles of 194,785 and Convicted Offender profile of 5,070,473. The FBI also provides free information for procedures and standards over the Internet. ▶forensic genetics, <http://www.fbi.gov/hq/lab/codis/>.

Codominance: In codominance, both alleles at a locus are simultaneously expressed in the heterozygote (see Fig. C123). At the phenotypic level, observed without in depth analysis, codominance is not very common. At the protein level (using electrophoresis or serological tests) the majority of the heterozygotes (H) display the products of both alleles (that of P₁ and P₂) at a locus. ▶dominance

Figure C123. Codominance

Codon (a nucleotide triplet): 61 triplets specify the 20 natural amino acids, with 1 to 6 codons for each; and 3 codons (nonsense codons) signal the termination of the polypeptide chain. tRNAs can recognize synthetic 4-base codon with 4-base anticodons and unnatural amino acids can be incorporated into proteins. Similarly, 5-base codon can also be translated with tRNA with synthetic 5-base anticodons. Actually, in an *E. coli* mutant a GUGUG codon was translated

into valine by a 3-base-anticodon tRNA^{Val}. These unusual constructs are useful for studying the mechanisms of frame shift mutations and the effect of non-natural amino acids on protein function. ▶code genetic, ▶genetic code, ▶protein synthesis, ▶anticodon; Jukes TH 1978 Adv Enzymol 47:375; Hohsaka T et al 2001 Nucleic Acids Res 29:3646.

Codon Adaptation Index (CAI): The CAI measures the relative usage of each codon by particular genes and the codon usage by organisms. ▶codon usage; Sharp PM, Li WH 1987 Nucleic Acids Res 15:1281.

Codon Bias: ▶codon usage

Codon Choice: ▶codon usage

Codon Family (synonymous codons): A group of codons encoding the same amino acid. E.g., CGU, CGC, CGA, CGG, AGA, and AGG all code for arginine. ▶genetic code

Codon Preference: ▶codon usage

Codon Recognition: ▶protein synthesis, ▶aminoacyl tRNA, ▶anticodon

Codon Usage: Synonymous codons may not be selected at random but their usage varies from gene to gene, e.g., in the MS2 RNA phage the UAC codon for tyrosine is used 3 times as frequently as the UAU codon. In the δ -chain of human hemoglobin (146 amino acid residues), the CUU codon for leucine and the GUA codon for valine were not used at all but the CUG and GUG codons were relied on 12 and 13 times, respectively. In plants, the CUG codon for leucine was used on the average in 9%, whereas the CUU codons were employed in 27–28%, and the AAG lysine codon was used almost twice as frequently as the AAA codon. Similar variations occur in the use of other codons in the majority of organisms and genes. Nucleotides following the codons (N₁ context) generally affect codon usage in the sequenced eukaryotes (Fedorov A et al 2002 Nucleic Acids Res 30:1192). Codon usage may vary in different tissues of the same organism (Plotkin JB et al 2004 Proc Natl Acad Sci USA 101:12588). The most highly expressed genes tend to use codons corresponding to the major tRNAs, whereas the less frequently expressed genes rely mainly on rarer tRNAs. The highly expressed genes containing A and T chose for 3rd position C and if the first two bases are G and C, the third is preferentially T. TAA stops the translation of highly expressed genes and TAG and TGA nonsense signals block those of lower expression. The rate and accuracy of the translation is lowered by substitution of rare codons into the Mrna, and this may result also in frameshifts, skipping, or termination. The codon usage in eukaryotes may also vary in the different isochores. Gene

C

length and higher recombination frequency may also increase codon bias. Highly expressed genes may show higher codon bias and lower synonymous substitutions than genes with low level of expression. The optimally chosen codons are recognized by the most common tRNAs. There is, however, a bias also in tRNA usage. In humans, the highly used CUG^{Leu} codon has only 6 cognate tRNAs genes, whereas for the relatively rare UGU and UGC cysteine codons 30 tRNA genes are available. The nature of the second codon in the open reading frame may affect the efficiency of translation. ▶code genetic, ▶genetic code, ▶amino acids, ▶Grantham's rule, ▶antisense DNA, ▶sense DNA, ▶isochore, ▶amelioration of genes, ▶coding strand, ▶codon adaptation indexes, ▶translational selection; codon usage in bacteria: Sharp; PM et al 2005 Nucleic Acids Res 33:1141; McVean GAT, Vieira J 2001 Genetics 157:245; Dunn KA et al 2001 Genetics 157:295; Sato T et al 2001 J Biochem 129:851; <http://www.kazusa.or.jp/codon/>; <http://pbil.univ-lyon1.fr/pbil.html>; codon usage bias across genomes: <http://www.sysbiology.org/CodonO/>.

Co-eIF-2A: Similar to eIF-2C.

Coefficient of Coancestry (kinship, consanguinity): The coefficient of coancestry indicates the probability that one allele, derived from the same common ancestor, is identical by descent in two individuals (see Fig. C124). All diploid individuals have two alleles (paternal and maternal) at a locus and each parent has 50% chance for transmitting one or the other of these alleles to the offspring. Thus an allele of a grandmother has 0.5 chance to be transmitted to her daughter or son and that individual again has 0.5 chance for being transmitting to the grandchildren. Thus the probability that two first cousins would have the same allele of the grandmother is 0.5^4 . The degree of consanguinity varies a great deal in different cultures and within ethnic groups.

Figure C124. The coefficient of consanguinity can be derived from the pedigrees. The solid line paths through which a particular allele is transmitted are numbered

Overall in Europe, by the middle of this century, consanguinity remained below 1% (with rare exceptions).

In North, Central, and South America the frequency of consanguineous marriages was generally higher. In Asia it was significantly higher, especially in Southern India and Pakistan where in some areas the majority of the marriages were consanguineous. Similar situation existed in many African regions. Increased urbanization and expanding education result in reduction of inbreeding in human populations. ▶inbreeding, ▶inbreeding coefficient, ▶relatedness degree, ▶genetic load, ▶lethal equivalent, ▶incest

Coefficient of Coincidence: The coefficient of coincidence was designed by H.J. Muller in 1916 for estimating interference on the basis of dividing the number of double crossovers *observed* by the number of double crossovers *expected* by the probability of single crossover frequencies. In case the two crossing over events are independent, the coefficient of coincidence is 1 and there is no interference. Genes far apart generally have higher coincidence than those closely linked. An example for computation is the size of the testcross progeny is 3,000 individuals. Frequencies of single-recombinant individuals are 0.0687 and 0.2973. Thus expected frequency of double recombinants is $0.0687 \times 0.2973 \approx 0.0204$. Hence the expected number of double recombinants is $0.0204 \times 3,000 = 61.2$. The number of double recombinants observed was 50. Hence the coefficient of coincidence is $50/61.2 \approx 0.817$. (Note that coincidence must be computed from integers and not from fractions). The *positive interference* in the example shown here is $1 - 0.817 = +0.183$. In case of *negative interference* the actually observed double recombinants exceed the expectations based on single events. Thus, e.g., if the observed number of double recombinants would be 300 and the expected number 50, then the coincidence is 6, and hence the interference would be $1 - 6 = -5$. In some cases *high negative interference* has been observed which may be as high as -100 or more. Recent investigations indicate that coincidence is not related to the physical distance of genes (base pair or micrometers) but rather to the genetic distance expressed in map units. Accordingly, the coefficient of coincidence as a function of map distances for separated intervals can be calculated by the Foss equation (Genetics 133:681):

$$S_4 = (m + 1)e^{-y} \sum_{i=0}^{\infty} \frac{y^{m(m+1)i}}{[m + (m + 1)i]!}$$

where m = fixed number recombinational events resolved without crossing over between neighboring crossover events resolved with crossover, y = mean number of events ($y = 2[m + 1]x$) per tetrad that can result in gene conversion disregarding accompanying crossovers in a test intervals, and S_4 = coefficient of coincidence for separated intervals,

x = map distance in Morgan units (mean number of events resolved per tetrad in a given interval).

►interference, ►gene conversion, ►tetrad analysis, ►map unit; Zhao H et al 1995 Genetics 139:1045; Chase M, Doermann AH 1958 Genetics 43:332.

Coefficient of Consanguinity: ►coefficient of coancestry

Coefficient of Crossing Over: A term coined by Calvin Bridges (1937), stating the relation of the physical length relative to map distance. Bridges found in *Drosophila* that 1 map unit corresponded to 4.2 μ m length of the salivary gland chromosomes (see Fig. C125).

Today, the genetic length of chromosomes can be expressed in nucleotide numbers. Estimates among organisms may vary greatly depending on the amount of the DNA and the resolution of the genetic markers. In *Arabidopsis*, 1 map unit is about 140 kb, whereas in maize it is about 240,000 kb. These ratios become important in map-based isolation and cloning of genes. Until a genome is completely sequenced, the stated estimates may not be accurate. Another problem with the estimation of the coefficient of crossing over is the variation in genetic recombination frequencies among different lines of the same organisms. ►mapping genetic, ►mapping function, ►physical mapping, ►map based cloning, ►gene number, ►recombination hot spots, ►bands of polytenic chromosomes, illustration.

Coefficient of Inbreeding: ►F, ►inbreeding

Coefficient of Kinship: ►coefficient of coancestry

Coefficient of Selection: ►selection coefficient and fitness

Coefficient of Variation: C = standard deviation/arithmetic mean. ►standard deviation, ►mean

Coelocanth: (*Latimeria chalumnae*): The “living fossil” fish, survivor of the ancient fish appearing during

evolution about 350 million years ago. It has a large tail fin and side fins resembling limbs. Its body contains only cartilage, except in its head and at the base of the fins (see Fig. C126).

Figure C126. *Latimeria chalumnae*

Coelom: The inner cavity of the embryo. In mammals, there are two such cavities: the chest and the abdomen. (see Fig. C127)

Figure C127. Coelom

Coelomocytes: Scavenger cells, which continuously and nonspecifically endocytose fluids of the body cavity of *Caenorhabditis*. ►endocytosis; Fares H, Greenwald I 2001 Genetics 159:123.

Coenobium: A colony of unicellular organisms enclosed by a single membrane.

Figure C125. The distal end of the X-chromosome of *Drosophila*. (After Bridges CB 1935 J Heredity 26:69)

C

Coenocyte: A multinucleate protoplast or cell aggregate without separation by walls.

Coenospecies: Coenospecies have common phylogenetic origin yet they differentiated (in the overlapping area) into different forms (ecological species), which may have among them only a limited exchange of genes (See Turesson G 1922 *Hereditas* 3:211).

Coenzyme: A cofactor required for normal activity of enzymes; many coenzymes are vitamins. Coenzyme A (acetyl coenzyme A) transfers acyl groups within cells.

Co-Evolution: The evolution of two populations is concomitant because they have some mutual relationship, e.g., host and parasites, predators and preys, or two gene loci evolve as a unit. Interacting proteins may also display co-evolution (Fraser HB et al 2004 *Proc Natl Acad Sci USA* 101:9033). ▶ [selection types](#), ▶ [frequency-dependent selection](#), ▶ [high-dose/refuge strategy](#), ▶ [networks](#), ▶ [quorum sensing](#), ▶ [Red Queen hypothesis](#), ▶ [gene-for-gene](#), ▶ [introgression](#), ▶ [trophophoresis](#); Bergelson J et al 2001 *Annu Rev Genet* 35:469; Wade MJ 2007 *Nature Rev Genet* 8:185.

Cofactor: An inorganic or organic substance required for enzyme activity. ▶ [enzymes](#)

Coffee (*Coffea* spp): Coffee has about 90 species with $x = 11$ and the plants are either diploid or tetraploid. Mutants of *Coffea arabica* have been found with defect in caffeine synthase and accumulation of theobromine. These mutants are promising for the development of high quality flavor without significant caffeine content (Silvarolla MB et al 2004 *Nature [Lond]* 429:826). Surprisingly, coffee and tomato share a common gene repertoire (Lin C et al 2005 *Theor Appl Genet* 112:114). ▶ [caffeine](#), ▶ [tomato](#)

Coffin-Lowry Syndrome (CLS): CLS is a Xp22.3-p22.1 dominant condition that shows mental retardation, face anomalies, tapered fingers, and lysosomal storage defects. The MAPK/RSK signaling pathway is responsible for the expression of the Rsk-2 ribosomal S6 kinase that is affected in this anomaly by aberrant splicing. Rsk-2 is required for histone H3 phosphorylation activated by the epidermal growth factor (EGF). Deficiency of the ATF4 transcription factor leads to osteoblast defects involved in bone anomalies of CLS. ▶ [mental retardation](#), ▶ [head/face/brain defects](#), ▶ [lysosomal storage diseases](#), ▶ [MAPK](#), ▶ [RSK](#), ▶ [EGF](#), ▶ [osteoblast](#), ▶ [ATF2](#), ▶ [chromatin remodeling](#), ▶ [bromodomain](#); Zeniut M et al 2004 *Nucleic Acids Res* 32:1214.

Coffin-Siris Syndrome (fifth digit syndrome): The Coffin-Siris syndrome does not have clear criteria but generally its symptoms include mental retardation, broad nose, tapered fingers, sometimes the distal digits missing, poor nail development, and hypertrichosis on the body but hypotrichosis on the scalp. It is probably autosomal dominant with low penetrance although autosomal recessivity has also been claimed. ▶ [hypertrichosis](#), ▶ [Coffin-Lowry syndrome](#), ▶ [patella aplasia-hypoplasia](#)

Cofilin (actin depolymerizing factor, ADF): Cofilin is a small (M_r 15–20K) actin- and phosphatidylinositol-binding protein mediating the rapid turnover of actin in the cytoskeleton. Its phosphorylation by LIM kinase is activated by ROCK. Cofilin and Arp2/3 mediate barbed end formation involved in cell motility. ▶ [actin](#), ▶ [phosphoinositides](#), ▶ [cytoskeleton](#), ▶ [LIM kinase](#), ▶ [ROCK](#), ▶ [Williams syndrome](#); Bamburg JR et al 1999 *Trends Cell Biol* 9:364; Pfannstiel J et al 2001 *J Biol Chem* 276:49476; Ichetovkin I et al 2002 *Curr Biol* 12:79.

COG (cluster of orthologous groups): Genes that have common ancestry and related function. They may also be members of paralogous groups of genes. ▶ [orthologous](#), ▶ [paralogous](#); Tatusov RL et al 2001 *Nucleic acids Res* 29:22; includes also eukaryotes: Tatusov RL et al 2003 *BMC Bioinformatics* 4:41; <http://www.ncbi.nlm.nih.gov/COG/>.

COGENT (complete genome tracking): Database of fully sequenced genomes. It links genome sequences to other resources (Janssen P et al 2003 *Bioinformatics* 19:1451).

Cognate: Cognate molecules have the ability to recognize a particular molecule, like ligand and receptor, enzyme and substrate. ▶ [ligand](#), ▶ [receptor](#), ▶ [substrate](#)

Cognate tRNAs: Cognate tRNAs are recognized by an aminoacyl synthetase. ▶ [aminoacylation](#)

Cognitive Abilities: The major components of cognitive abilities include verbal and spatial abilities, memory, speed of perception, and reasoning. These components may have subcategories such as verbal comprehension, verbal fluency, vocabulary, etc. ▶ [behavior genetics](#), ▶ [human intelligence](#)

Cohen & Boyer Patents: US # 4.237.224 and 4.468.464 were obtained by Stanford University on the construction of cloning plasmid chimeras (pSC101), and for the products commercially produced with their aid. Users must thus pay reasonable royalties for these key procedures. The fact of patenting became the subject of a controversy because of its unusual nature, but it called to the attention of academic

institutions the benefits to be derived from the commercial exploitation of the results of scientific discoveries. ►patent

Cohen Syndrome: A highly complex autosomal recessive anomaly (psychomotor retardation, prominent incisors, high nasal bridge, eye defects, mental retardation, hypothyroidism, etc.) with suggested chromosomal locations 15q11, 5q33, 7p, 8q22. The 8q22 locus (COH1) encodes a protein of 4,022 amino acids with a presumed role in intracellular protein transport (Kolehmainen J et al 2003 Am J Hum Genet 72:1359). ►eye diseases, ►mental retardation

Cohesin: Cohesin is an at least four-protein (Smc1, Smc3, Scc1, Scc3) complex regulating in combination with other four proteins, including APC, the cohesion of sister chromatids primarily during interphase after the replication of DNA. The complex of Scc2 and Scc4 mediates the association of cohesin with chromosomes (Gillespie PJ, Hirano T 2004 Current Biol 14:1598). Cohesin (Scc1/Rad21) is removed by separase before the onset of anaphase and cytokinesis. Rad21-cohesin requires a special heterochromatin protein, Swi6, for the association at centromeres but not for that along the chromosome arms. Cohesin is required for double-break repair of DNA (Ström L et al 2004 Mol Cell 16:1003). Another cohesin function is mediated at the telomeres by tankyrase 1 (Dyrek JN, Smith S 2004 Science 304:97). *REC8* cohesin null mice display germ cell failure and sterility and meiotic recombination is aborted but recombination between sister-chromatids is promoted (Xu H et al 2005 Developmental Cell 8:949). Phosphorylation of Rec8 and recombination promote step-wise loss of cohesins against shugoshin and facilitate in meiosis II segregation (Brar GA et al 2006 Nature [Lond] 441:532). In *Schizosaccharomyces pombe*, cohesin proteins also mediate double-strand breaks during meiotic recombination (Ellermeier C, Smith GR 2005 Proc Natl Acad Sci USA 102:10952). Single-strand DNA breaks induce post-replicative repair (Ström L et al 2007 Science 317:242). DNA double-strand breaks can trigger genome-wide cohesion and acetyltransferase activity through factor Eco1/Ctf7 for preserving integrity of the genome (Ünal E et al 2007 Science 317:245). ►sister chromatid cohesion, ►ORC, ►meiosis I, ►condensin, ►CTF, ►adherin, ►securin, ►heterochromatin, ►cytokinesis, ►mitosis, ►shugoshin, ►tankyrase, ►monopolin, ►Scc1, ►APC, ►double-strand break, ►Rec8, ►De Lange syndrome; Tanaka T et al 1999 Cell 98:847; Nasmyth K et al 2000 Science 288:1379; Bernard P et al 2001 Science 294:2539; Kirsten A et al 2003 Nature Rev Genet 4:520; Marston AL et al 2004 Science 3003:1367.

Cohesion-Tension Theory: The cohesion-tension theory interprets the movements of sap through vessel system of plants. ►transpiration, ►guttation; Steudle E 2001 Annu Rev Plant Physiol Plant Mol Biol 52:847.

Cohesive Ends: Two DNA molecules have base complementarity ends that can anneal. (see Fig. C128)

Figure C128. Cohesive ends

Cohort: In population studies, the term cohort is used to designate a particular group of individuals with common characteristics (age, treatment, ethnicity, education, taxonomic group, disease, etc.).

Coil: The tract of the unstructured backbone of the protein.

Coiled Body (CB, Cajal body): The coiled bodies are intranuclear elements (1–10 per nucleus) attached to the surface of the nucleolus. CB are formed from 0.15 to 1.5 μm tangled threads of snRNA and proteins. They are formed during G₁ phase of the cell cycle but disassemble during mitosis. ►nucleus, ►nucleolus, ►gemini of coiled bodies, ►coilin, ►snRNA, ►Cajal body; Gall JG 2000 Annu Rev Cell Dev Biol 16:273.

Coiled Coil: Two α helices of polypeptides wound around each other. Dodecanucleotide d (ATATATA-TATAT) coiled coil structure of DNA with single stranded two-base overhangs has also been determined by single-crystal X-ray crystallography (see Fig. C129). ► α -helix; mechanism of coiled coil formation: Steinmetz MO et al 2007 Proc Natl Acad Sci USA 104:7062, DNA model is by Campos JL et al 2005 Proc Natl Acad Sci USA 102:3663; courtesy of J.A. Subirana.

Figure C129. Coiled coil of DNA

Coilin: A 80 kDa protein in the nuclear coiled body (Cajal body), involved in processing of nucleolar and extranucleolar RNA. (Cajal body; Raska I et al 1991 Exp Cell Res 195:27).

Coincidence: ►coefficient of coincidence

C

Co-Inducer: A co-inducer is a chemical substance required, in addition to the inducer substrate, to activate the gene, e.g., in the arabinose operon besides the P protein, cAMP is also required for turning on the genes. ▶ *Arabinose operon*, ▶ *Lac operon*, ▶ *co-activator*

Cointegrate Vector: The cointegrate vector of *Agrobacterium* is a plant transformation vector containing both the T-DNA and the virulence genes in a single circular molecule. These vectors are usually free of oncogenes and carry both bacterially and plant-selected markers besides some engineered genes. ▶ *Ti plasmid*, ▶ *binary vector*, ▶ *selectable marker*

Cointegration: In cointegration, two circular plasmids combine, without loss, into a double size plasmid (see Fig. C130). Also, a circular donor plasmid carrying a transposable element fuses with a recipient circular plasmid and at each point of juncture there will be a copy of the transposable element.

This process requires the breakage of the phosphodiester bond and the duplication of the target site and the insertion element. This is replicative transposition.

The cointegrate includes the two plasmids and the two transposable elements. Upon resolution of the cointegrate, two plasmids are produced, each carrying a transposable element. ▶ *plasmid*, ▶ *transposable element*, diagram; Clewell DB 1975 Proc Natl Acad Sci USA 72:1720.

Coisogenic: A coisogenic organism has identical genes with another strain, except at a single locus. ▶ *isogenic*, ▶ *congenic*, ▶ *inbred*, ▶ *substrain*, ▶ *subline*

Coitus: Sexual intercourse.

Col: ▶ *colicin*

Colcemid (demecolcine, *N*-deacetyl-*N*-methylcolchicine): A synthetic colchicine. ▶ *colchicines*, ▶ *demecolcine*

Colchicine: An alkaloid produced by (*Colchicum autumnale* and other liliaceous plants) (see Fig. C131). Its tropolone ring specifically and strongly binds and disassembles microtubules of the mitotic spindle. Thus, the nuclear divisions are arrested in mitosis and cells skip at least one division resulting in doubling (or multiplying) of the chromosome number (polyploidization). It is particularly useful for doubling the chromosome number of interspecific and intergeneric hybrids, thereby making the otherwise sterile individuals fertile by securing a pair for all chromosomes. Colchicine alleviates some of the symptoms of gout, a mammalian disease caused by uric acid overproduction. Colchicine is synthesized from phenylalanine and tyrosine. The LDLo oral dose for humans is 5 mg/kg and therefore it is a dangerous substance, absorbed also through the skin (see Fig. C132). ▶ *chromosome doubling*, ▶ *autotetraploid*, ▶ *allotetraploid*, ▶ *colcemid*, ▶ *demecolcine*, ▶ *gout*, ▶ *c mitosis*, ▶ *microtubule*, ▶ *alkaloids*; Eigsti OJ, Dustin P Jr 1955 Colchicine. Iowa State College Press, Ames, Iowa; Ravelli RBG et al 2004 Nature [Lond] 428:198.

Figure C130. Cointegration

Figure C131. Colchicine

Figure C132. *Colchicum autumnale*.

Cold Hypersensitivity: Autosomal dominant genes may be responsible for the development of urticaria (allergy-like rash), joint discomfort, and fever after exposure to cold. It may be associated with amyloidosis (accumulation of fibrillar proteins) in various tissues. Amyloid nephropathy may be fatal. Familial cold urticaria (FCU) and the Muckle-Wells syndrome encode a protein with a pyrin domain and leucine-rich repeat at human chromosome 1q44. The Muckle-Wells syndrome has similar symptoms (rash, conjunctivitis, pain in the joints, and fever) but the symptoms are not elicited by cold. ▶[amyloidosis](#), ▶[hyperthermia](#), ▶[temperature-sensitive mutation](#), ▶[cold-regulated genes](#), ▶[urticaria familial cold](#), ▶[asthma](#), ▶[Muckle-Wells syndrome](#); Hoffman HM et al 2001 *Nature Genet* 29:301.

Cold-Induced Sweating (19p12): Cold-induced sweating includes a rare autosomal recessive disorder and several associated anomalies. The afflicted suffer from profuse sweating in some parts of the body at temperature of 7 to 18 °C. A two-base deletion was observed in the cytokine receptor-like factor 1. ▶[cytokine](#); Knappskog PM et al 2003 *Am J Hum Genet* 72:375.

Cold-Regulated Genes (COR): COR are required for acclimation to low temperature. Some plant mutants may become very sensitive to cool conditions. An *Arabidopsis* mutant was killed after a few days of exposure to 18 °C. The chilling may cause electrolyte leakage and changes in the synthesis of sterol esters. Cold acclimation is frequently based on microsomal

stearoyl coenzyme A desaturase activity. The unsaturated phosphoglycerides restore fluidity of cold-rigidified cell membranes. The COR genes are regulated by the binding of the CBF transcriptional activator to the CRT/DRE (C-repeat/drought responsive) element. Excessive expression of HOS1 (osmotically responsive gene) in transgenic *Arabidopsis* reduces the expression of CBF (C repeat binding factor) genes and decreases tolerance to freezing. HOS1 is a ubiquitin E3 ligase that mediates the degradation of ICE1 transcription factor (Dong C-H et al 2006 *Proc Natl Acad Sci USA* 103:8281). ▶[cold hypersensitivity](#), ▶[thermotolerance](#), ▶[anti-freeze proteins](#), ▶[glycerophospholipid](#), ▶[ubiquitin](#), ▶[fatty acids](#); CBF; Lee H et al 2001 *Genes Dev* 15:912; Karlson D et al 2002 *J Biol Chem* 277:35248; cold-adapted enzymes: Siddiqui KS, Cavicchioli R 2006 *Annu Rev Biochem* 75:403.

Cold-Shock Proteins: Cold-shock proteins are produced in response to an abrupt change to a lower temperature. At low temperatures, *E. coli* cold-shock proteins are anti-terminators of transcription and enhancers of translation. It appears that a wheat nucleic acid binding protein, similar to that in bacteria, is an RNA chaperone (Nakaminami K et al 2006 *Proc Natl Acad Sci USA* 103:10122). In mammals uncoupling proteins (UCP1, UCP2) transmit a proton electrochemical gradient across the inner membrane of the mitochondria resulting in generation of heat rather than ATP. A plant protein homolog (StUCP) appears to have a similar function. ▶[heat-shock proteins](#), ▶[uncoupling agent](#), ▶[Hsc66](#); Phadtare S et al 1999 *Curr Opin Microbiol* 2:175; Somerville J 1999 *Bioessays* 21:319; Manival X et al 2001 *Nucleic Acids Res* 29:2223, <http://www.chemie.uni-marburg.de/~csdbase/>.

Cold Resistance: In plants, a member (CBF3) of the centromere binding protein family transcription factor mediates cold tolerance. ICE1 inducer of CBF regulates this protein. ICE1 is a MYC-like basic helix-loop-helix (bHLH) transcriptional activator. In plants, the mitogen activated protein kinase (MKK2) regulates cold and salt stress (Teige M et al 2004 *Mol Cell* 15:141). ▶[antifreeze proteins](#), ▶[DNA binding proteins](#), ▶[MKK](#); Chinnusamy V et al 2003 *Genes Dev* 17:1043.

Cold Sensitive: A cold-sensitive mutant fails to grow normally at a lower temperature although it may behave entirely normally at a higher temperature. The TRP (transient receptor potential) family ion channels mediate thermosensation. ▶[temperature-sensitive mutants](#), ▶[cold hypersensitivity](#); McKemy DD et al 2002 *Nature [Lond]* 416:52.

Cold Spots: Chromosomal areas in which, mutation, recombination, or insertion are rare. ▶ [hot spot](#)

ColE1 Replicon: The colE1 replicon is similar in nature to pMB1. The replicon produces 15–20 copies per cell and does not require a plasmid-encoded function for replication for which, it uses DNA polymerase I and III, DNA-dependent RNA polymerase, and the long-living products of the bacterial genes *dnaB*, *dnaC*, *dnaD*, and *dnaZ*. When cell replication ceases in the presence of protein synthesis inhibitors (chloramphenicol, spectinomycin), this replicon can produce 2,000 to 3,000 plasmid copies per cell. The majority of modern bacterial vectors utilize this replicon. The name is derived from natural plasmids coding for colicine production. The 4.2 megadalton plasmid is non-conjugative. ▶ [colicins](#), ▶ [plasmids](#) [several entries], ▶ [cloning vectors](#), ▶ [phagemids](#), ▶ [replicon](#); Mruk I et al 2001 Plasmid 46:128.

Coleoptile: The membrane-like first leaf in monocotyledones enclosing succeeding leaves at the stage of germination (see Fig. C133). ▶ [embryogenesis in plants](#)

Figure C133. Coleoptile

Coleorhiza: An envelope of the root-tip of germinating grasses.

Coleus blumei: A leafy, shade-tolerant ornamental plant; $2n = 24$.

Colicinogenic Bacteria: Killer strains producing colicins (bacterial toxins)

Colicins: Produced by killer *E. coli* and *Shigella sonnei* bacteria, colicins are genetically (plasmid) controlled bacterial toxins that kill sensitive bacteria even at very low concentrations. Colicins require binding to the extracellular receptor (BtuB, vitamin B₁₂ receptor) of the target cells. Then Ton or Tol proteins mediate the translocation to the periplasm, followed either by voltage-gated depolarization of the inner cell membrane and/or nuclease action on ribosomes or the DNA. Colicin E1 and colicin K inhibit active transport, colicin E2 may contribute to the degradation of DNA, and colicin E3, E4, and E6 interfere with protein synthesis of the sensitive bacteria by attacking the 16S rRNAs at the 49th base from the 3' end and removing a small fragment from their

3' terminus. E5 colicin splits tRNAs of Tyr, His, Asp, and Asn, which contain the Q (queuine [a deazapurine]) at the wobble site of the anticodon. Colicin E5 bacteria harboring Col plasmids are immune to the lethal effects of colicins and this property is used to select Col-transformed bacterial cells. Each cell may normally carry about 20 copies of these plasmids. Colicin resistance mutations occur at appreciable frequencies in bacterial populations. The ColE1 plasmid has a molecular size of about 4.2 MDa and is non-conjugative. The ColE1 plasmid replicon has been used for the construction of genetic vectors and has been engineered into cosmids and other plasmids. ▶ [ColE1](#), ▶ [killer strains](#), ▶ [queuine](#), ▶ [deazanucleotides](#), ▶ [ion channels](#), ▶ [rock-paper-scissors model](#); Riley MA 1998 Annu Rev Genet 32:255; Stroud RM et al 1998 Curr Opin Struct Biol 8:525; Lazdunski CJ et al 1998 J Bacteriol 180:4993; Smajs D, Weinstock GM 2001 J Bacteriol 183:3949; colicin import mechanisms: Housden NG et al 2005 Proc Natl Acad Sci USA 102:13849.

Coliform: Enteric, gram-negative bacteria, related to *E. coli* (see Fig. C134). ▶ [E. coli](#)

Figure C134. Coliform

Collinear: ▶ [collinear](#)

Coliphage: A bacteriophage, infectious for *E. coli* bacterium.

Collaborative Tagging: Web users are exposed to a resource and freely associate tags with it. Their interaction with the system also exposes them to tags previously entered by themselves and by other users. The aggregated activity of users leads to an emergent categorization of resources in terms of tags shared by a community. Tagging is designed to organize and share diverse online resources such as bookmarks, digital photographs, academic papers, music, and more (Cattuto C et al 2007 Proc Natl Acad Sci USA 104:1461).

Collagen: A fibrous protein built mainly from hydrophobic amino acids (35% Gly, 11% Ala, 21% Pro and hydroxyproline). It forms a left handed helix with three residues per turn, made up of repeated units with glycine at every third position. The collagens form triple helices from three polypeptide chains and play

structural roles in the cell (see Fig. C135). The 38-kbp chicken collagen gene (similar to the gene in humans and in mice) has 52 introns and short exons (54 to 108 bp) built of tandem repeats of nine bases. There are roughly nine types of collagens, encoded by about 17 gene loci in humans. This protein is the major component of the cuticle, tendons, and the cartilage. Synthetic collagen triple helices, longer than the natural ones, can be produced and have applicational potential (Kotch FW, Raines RT et al 2006 Proc Natl Acad Sci USA 103:3028). Some collagen diseases can be detected by prenatal analysis. In *Caenorhabditis*, about 150 collagen genes determine cuticle organization. Several mammalian diseases are based on defects in the collagen. ▶osteogenesis imperfecta, ▶osteoarthritis, ▶Ehlers-Danlos syndrome, ▶Alport syndrome, ▶Marfan syndrome, ▶Stickler disease, ▶Kniest dysplasia, ▶spondyloepiphyseal dysplasia, ▶achondrogenesis, ▶hypochondrogenesis, ▶epiphyseal dysplasia multiple, ▶chondrodysplasia, ▶muscular dystrophy, ▶Weissenbacher-Zweymüller syndrome, ▶aneurism aortic, ▶epidermolysis, ▶spondyloepiphyseal dysplasia, ▶dermatoparaxis of cattle, ▶metastasis, ▶porencephaly; Nimni ME (ed) 1988 Collagen. CRC Press, Boca Raton, Florida.

Figure C135. Collagen

Collagenases: Collagenases are cell surface metalloproteinases involved in remodeling the cellular matrix, and thus shape cells and facilitate cell migration. ▶collagen, ▶metalloproteinases; Saffarian S et al 2004 Science 306:108.

Collapsin: A member of the protein family of semaphorin; it seems to be inhibitory to axon outgrowth. ▶semaphorin, ▶CRMP-62, ▶axon, ▶neurogenesis; Liu BP, Strittmatter SM 2001 Curr Opin Cell Biol 13:619.

Collapsing Data: Collapsing data is used in some instances to reduce information into certain categories in order to facilitate statistical handling (See Hahn LW et al 2003 Bioinformatics 19:376).

Collateral: An accessory.

Collateral Relatives: Animals in a breeding program that have one or more common ancestors but are not direct descendants of these ancestors.

Collectins: Broad-spectrum, complement-like antimicrobial glycoproteins in mammals. They may assist in the removal of apoptotic bodies and may control inflammation. ▶complement, ▶apoptosis, ▶inflammation; Ohtani K et al 2001 J Biol Chem 276: 44222.

Collenchyma: Found in the stems of plants, collenchyma are parenchymal cells that fit together closely; they have thickened walls especially at the corners (see Fig. C136).

Figure C136. Collenchyma

Colletotrichum circinans: A fungal parasite producing “smudge” on sensitive onions. Generally white onions are susceptible because they lack the gene for the synthesis of parahydroxy acid that inhibits the parasite. Red onions have the *W* allele, which conveys resistance. Some varieties of onions have an *I* (inhibitor) allele that prevents the expression of *W*; thus in the F_2 of the double heterozygote there are 13 white susceptible and three red and resistant segregants.

Collie Eye: An eye anomaly occurring very frequently among collie dogs. It is detectable only by ophthalmoscope, yet often impairs the dog’s vision.

Collinearity (colinearity): Collinearity occurs when amino acid sequences in the polypeptide correspond to the codon sequences in nucleic acids, the 5' end of the mRNA matching with the NH₂ end of the polypeptide chain. Some *Drosophila* genes, e.g., within the *ANTC* (*Antennapedia* complex, chromosome 3-47.5) appear the same sequence in the map as the morphogenetic function they control (*lab*, *Pb*, *Dfd*, *Scr*, *Antp*). Similar collinearity has been shown in the *BXC* (*Bithorax* complex) *Ultrabithorax* segment. (Collinearity is spelled with two *ls* because derived from the Latin *cum* + *linearis* [*collineo*]). In the homeotic complexes generally there is another “position effect”; the products of the relatively posterior acting genes appear to be more abundant than that of the anterior ones. Recent information indicates that collinearity is not completely valid for some/most parts of the genome because the same genetic elements are used differently in different contexts of genes and form an interleaved or modular genomic architecture (Kapranov P et al 2007 Nature Rev Genet: 413). ▶*Lac* operon, ▶lambda phage, ▶morphogenesis in *Drosophila*, ▶homeotic genes; Yanofsky C, Horn V 1972 Biol Chem 247:4494.

Collinsia (Scrophulariaceae): ca. 20 plant species $2n = 2x = 14$; used in cytogenetic studies.

Collision between Replication and Transcription in Prokaryotes: ►leading strand, ►gene distribution

Collochores: Short heterochromatic sequences in the chromosomes supposed to be involved in chromosome association, especially in the absence of chiasmata, e.g., in the X–Y bivalents. In these cases, 240 base pair intergenic spacers of the rDNA repeats mediate disjunction (McKee BD et al 1992 Genetics 94:625). ►heterochromatin; Virkki N 1989 Hereditas 110:101.

Collodion: An alcohol and ether solution of pyroxylin (mainly nitrocellulose), used in microtechnical preparations and as a skin protector veterinary procedure.

Collodion Fetus: A variable form of ichthyosis (collodion like) present before and after birth that may or may not heal during later development. Eye defects may be part of the syndrome. Two genes at chromosome 14q11 (defect in keratinocyte transglutaminase, TGM1) and at 2q33-q35 may be involved. ►ichthyosis

Colloid: Colloids are particles with diameters ranging from 0.1 to 0.001 μm , and can exist in fine suspensions (in gas, liquid or solids) or emulsions (in water).

Colobidae (Old World primates, langurs): *Nasalis larvatus* $2n = 48$; *Presbytis cristatus* $2n = 44$; *Presbytis entellus* $2n = 44$; *Presbytis obscurus* $2n = 44$; *Pygathrix nemaeus* $2n = 44$. ►primates

Coloboma: Coloboma appears as a missing or defective sector involving the iris, retina, or the optic nerve (see Fig. C137). It may be associated with brachydactyly, abnormal movements, and retardation. Autosomal dominant or recessive genes may control it but X-linkage has also been suggested for some forms. ►eye diseases, ►cat eye syndrome, ►brachydactyly

Figure C137. Coloboma of the iris. (From Bergsma D (ed) 1973 Birth Defects Atlas and Compendium. By permission of the National March of Dimes Foundation)

Colon Cancer: ►colorectal cancer

Colonization: The evolutionary factor of settling outside the original habitat. ►gene flow

Colony: A group of microbial cells grown at the same spot. They may have originated from a single cell or from several. The shape of the colony for a certain bacterial strain may vary according to the nutrient content and diffusion, the movement and reproduction of the bacteria, and local cell communication. Colony characteristics are used as a criterion for classification.

Colony Hybridization: Colony hybridization involves, first, the cutting up with appropriate restriction endonucleases, of isolated DNA into fragments. A library of the fragments is then established by cloning the fragments with the aid of a cloning vector (e.g. cosmid, YAC, etc.). The bacteria, presumably each carrying the DNA fragments in a chimeric plasmid, are seeded at low density on agar plates so each colony would be separate. After the colonies are formed a replica plate is established from the master plate by pressing over it a membrane filter. After denaturation of the DNA on the nitrocellulose filter, it is hybridized with a labeled DNA or RNA probe. After washing off the unbound probe, the filter is autoradiographed and the colonies containing the desired molecules of DNA are identified. Since the position of the colonies corresponding to the black dots on the photographic film (dot blot) can be identified, the bacteria containing the vector with that specific DNA can be further propagated (see Fig. C138). In the reverse dot blot, the labeled DNA or RNA (the probe) is immobilized on the hybridization filter and the cloning vector is annealed to it. ►cloning vectors, ►cosmids, ►plaque lift, ►cosmid, ►YAC, ►denaturation, ►probe, ►autoradiography, ►DNA library, ►replica plating; Grunstein M, Hogness DS 1975 Proc Natl Acad Sci USA 72:3961.

Figure C138. Colony hybridization

Colony Lift: A colony lift is basically similar to a plaque lift. A nylon or nitrocellulose membrane is layered over a growing colony of cells. The colonies stick to the membrane and can be used as a dot blot, and

specific mutants can be identified in the dots with the aid of DNA hybridization.

Colony Stimulating Factor (CSF-1): A cytokine protein activating RAS p21 protein by increasing the proportion of GTP-bound molecules. CSF2 is encoded within the IL-3 gene cluster. ▶CSFR, ▶M-CSF, ▶RAS, ▶IL-3; McMahon KA et al 2001 Biochem J 258[pt2]:431.

Color Blindness: Color blindness exists in different forms. Complete or nearly complete light sensing color blindness (monochromatism or achromatopsia) has prevalence in the 10^{-5} range and it may not involve any alteration in the retina (achromatopsia 1: human chromosome 14, achromatopsia 2: 2q11, achromatopsia 3: 8q21-q22). Adjacent chromosomal areas frequently modulate the X-linked recessive gene. One form of achromatopsia (autosomal recessive) involves also light sensitivity and the affected individuals are bothered by light but have better than average vision under dim conditions (day blindness). Complete achromatopsia involves defects in the retinal cones and, in molecular terms, the α subunit of the cone photoreceptor of a cyclic guanine monophosphate-gated cation channel. This gene (CNGA3 is at human chromosome 2q11. The X-linked incomplete *congenital stationary night blindness* gene CSNB2 encodes at Xp11.23 a retina-specific Ca^{2+} channel α_1 subunit of 48 exons with 1966 amino residues. The complete form of this anomaly was mapped to Xp11.4. Partial color blindness (green color blindness, *deuteranopia*) is also a Xq28-linked recessive and may affect 8% of the males of Western European descent. A cluster of genes that may recombine and undergo gene conversion, explaining the variations and the high frequency of this condition, encodes the green color vision. The red color blindness (*protanopia*) appears to be determined by two X-chromosomal recessive loci (Xq28) with a frequency of 0.08 in males. Another type of color blindness that involves loss of blue and yellow sensors but retains those for red and green (*tritanopia*) may exist in X-linked recessive or autosomal dominant forms (7q31.3-q32). This condition may occur at a very high frequency of 0.02 in some populations, whereas in others it may be lesser by an order of magnitude, or even lower. The blue cone pigment gene displays high homology to that of rhodopsin and substantial homology with the red and green pigments. In the latter form, the rhodopsin receptor may be defective. The great chemist John Dalton suffered from “daltonism” or deuteranopia. ▶hemeralopia, ▶nyctalopia, ▶rhodopsin, ▶eye diseases, ▶color vision, ▶deuteranomaly, ▶ion channels; Neitz J et al 1999 Nature Neurosci 2:884; Crognale MA et al 1999 Vision Res 39:707.

Color Vision: In the human X-chromosome, there is an array of middle (2–7) to long-wavelength (2–4)-sensitive visual pigments. Humans with normal color vision typically have a single long-wavelength gene and two or three middle-wavelength sensitivity genes. The multiple copies probably arose due to unequal recombination and those with more copies may be able to better the differences in hues. Unlike humans, pigeons perceive also ultraviolet light. ▶color blindness, ▶rhodopsin, ▶opsin, ▶unequal crossing over; Yokoyama S, Radwimmer FB 2001 Genetics 158:1697; Yokoyama S 2002 Gene 300:69; Solomon SG et al 2007 Nature Rev Neurosci 8:276.

Colorectal Cancer: Colorectal cancer may be controlled by a large number of genes involved in the “cancer family” syndrome. In many cases, the mismatch repair genes have mutated compared to Gardner syndrome where the APC tumor suppressor is mutant. In colorectal cancer, 40% of the mutations involve the PI(3)K pathway (Parsons DW et al 2005 Nature [Lond] 436:792). Genetic instabilities causing this type of cancer can be dominant involving changes in chromosome number, or if recessive, concerned with microsatellite instabilities. In cancer cells, the telomeres are frequently reduced resulting in anaphase bridges and instability. This may be followed by multipolar mitoses, although multipolarity rarely contributes to clonal cell lines in colorectal cancer (Stewénus Y et al 2005 Proc Natl Acad Sci USA 102:5541).

The common most types of cancers caused are adenocarcinoma of the colon and endometrial (inner mucous membrane) cancer of the uterus; but other types such as breast, ovarian, and brain tumors, as well as leukemia, etc. may be under similar controls (Lynch type I). EphrinB receptors block colorectal cancer progression (Batlle E et al 2005 Nature [Lond] 435:1126). About 75% of the carcinomas show deletions of the short arm of human chromosome 17. This chromosomal segment may be responsible for the transition from the benign to the malignant states of the carcinomas. Nonpolyposis colorectal carcinoma causes 3.8 to 5.5% of the colorectal cases, whereas adenomatous carcinoma contributes to 0.2% and ulcerative colitis to 0.6%. About 1/3 of the alterations involve the RAS oncogene (KIS = Kirsten murine sarcoma oncogen, 12p12.1). Deletions also involve human chromosomes 22, 5, 6, 12q, 15, 17, and 18. The human chromosome 18q21 locus encodes a TGF β -regulated serine/threonine kinase receptor, MADR2. Chromosome 18q24.21 also harbors a susceptibility factor (Tomlinson A et al 2007 Nature Genet 39:984). DCC (deleted in colorectal cancer) is based on a defect in a netrin

C

receptor. Netrin is a human homolog of the *Caenorhabditis* gene products UNC-6 and UNC-40 involved in the guidance of neuronal axons (Forcet C et al 2002 Nature [Lond] 417:443). These findings indicate that besides the activation of the major oncogen, it is necessary to inactivate several tumor suppressors. UV light-induced cyclobutane pyrimidine dimers are more readily removed from the transcribed strand of the DNA than from the other (the non-transcribed strand). This is called transcription-coupled repair. Such a repair system seems to be defective in several types of colorectal cancers. About 50% of the Western populations develop this type of cancer by age 70 and 10% of the cases become malignant. An estimated 15% of the cases have a strong dominant hereditary component. NO-ASA (2-[acetyloxy]benzoic acid 4-[nitrooxymethyl]phenylester) is a nitric oxide donating aspirin and appears to inhibit colon cancer hundreds of times more effectively than does aspirin alone by promoting apoptosis (Gao J et al 2005 Proc Natl Acad Sci USA 102:17207). 15-Hydroxyprostaglandin dehydrogenase degrades prostaglandin in normal colon mucosa but it is lost in colon cancer. Knockout of the hydroxylase increases colon tumors in mice 7.6 fold (Myung S-J et al 2006 Proc Natl Acad Sci USA 103:12098). Higher expression of Na^+ /monocarboxylate transporter (SMCT) gene (SLC5A8) is favorable for the prognosis of colorectal cancer (Paroder V et al 2006 Proc Natl Acad Sci USA 103:7270). The location and type of tumor-infiltrating lymphocytes in colorectal and other cancers may predict survival potentials (Galon J et al 2006 Science 313:1960). ▶Gardner syndrome, ▶polyposis, ▶RAS, ▶cancer, ▶p53, ▶p16, ▶DNA repair, ▶hereditary nonpolyposis colorectal cancer, ▶adenomatous polyposis, ▶FAP, ▶PIK, ▶mismatch repair, ▶cyclobutane ring, ▶neuron, ▶Lynch cancer families, ▶PRL-3, ▶mitochondrial genetics, ▶mitochondrial disease in humans, ▶evolutionary clock, ▶RIZ, ▶PMS, ▶plantibody, ▶prostaglandin, ▶CD133; Abdel-Rahman WM et al 2001 Proc Natl Acad Sci USA 98:2538.

Color-Less Testa: Mutations leading to the color-less testa occur in different plant species. These recessive mutations display delayed inheritance because the seed coat is maternal tissue, but in F_3 usually about 1/4 of the individuals uniformly have the recessive seed-coat color. ▶testa, ▶delayed inheritance

Colton (Co): A relatively rare blood type encoded apparently in human chromosome 7. ▶blood groups

Column Chromatography (adsorption chromatography): The separation of (organic) mixtures on sugar, resin, sephadex, silica gel, or other columns established in

glass tubes and eluting the components stepwise with the help of different solvents or solvent mixtures. The eluates collected by fraction collectors can be monitored by spectrophotometry in the samples. ▶chromatography, ▶sephadex, ▶spectrophotometry

Comb: A comb-like device to make wells in the electrophoresis gel (see Fig. C139).

Gel bed comb

Figure C139. Comb

Comb Traits: The comb traits of poultry are determined by two allele pairs and the interaction of their gene products specifies 4 comb types. *RRPP* and *RrPp*: walnut, *RRpp*: rose, *rrPP*: pea, and *rrpp*: single comb in the proportion of 9:3:3:1. ▶Mendelian segregation, ▶epistasis, ▶walnut comb

Combed DNA Color Bar Coding: The combed DNA color bar coding is a technique for the rapid detection of deletions in the DNA. An appropriate genetic sample is stretched out on a treated glass surface and analyzed with fluorescent probes to detect structural changes. (See Gad S et al 2001 Genes Chromosomes Cancer 31:75).

Combination: In a combination generating from n number of individuals, all possible sets contain only x numbers in each set. Mathematically: $= \frac{n!}{x!(n-x)!} : \left(\frac{n}{x}\right)$ ▶binomial distribution, ▶permutation, ▶variation

Combinatorial Chemistry: A method aiming to generate permutations of small molecular building blocks with the goal of finding the most effective pharmaceuticals. This process is then combined with bioassays to find agonists and antagonists of the biochemical process to discover new, effective drugs. The completion of the genome sequencing projects and the developing information on molecular structure facilitate the drug discovery process. ▶agonist, ▶antagonist, ▶chemical genetics, ▶parallel synthesis, ▶chemogenomics, ▶pharmaceuticals, ▶high-throughput analysis, ▶high-content screening; Lehn J-M, Eliseev AV 2001 Science 291:2331; Bhattacharyya S 2001 Curr Med Chem 8:1383, <http://www.combichemistry.com/>.

Combinatorial Diversification: Combinatorial diversification refers to the phenomenon in which, large number of various immunoglobulin genes may enter

into different combinations and generate an enormous array of antibody molecules. ►immunoglobulins, ►antibody, ►junctional diversification, ►affinity maturation, ►somatic hypermutation

Combinatorial Gene Control: The transcription of genes is regulated by the cooperative action of general and specific transcription proteins. It is not known how many such proteins exist but their number can be much smaller than the number of genes, yet they can assure a high degree of specificity. If we just assume that there are a total number (n) of 20 different inducible transcription factors (certainly an underestimated figure) and each gene requires 5 (x), the total number of specificities could be

$$\binom{n}{x} = \frac{n!}{x![n-x]!} = \frac{20!}{5!(15)!} = 15,504.$$

Or if there were 27 inducible transcription factors and 5 were to be used by each gene, the number of specificities $\binom{n}{x} = \frac{27!}{5!22!} = 80,730$ would be enough to regulate all the estimated human genes (ca. 25,000 to 40,000 or according to the latest estimate of about 25,000). ►regulation of gene activity, ►gene number; Darimont BD et al 1998 Genes Dev 12:3343.

Combinatorial Labeling: A cytogenetic method of chromosome analysis using simultaneously more than one fluorochrome-conjugated nucleotide. The number of useful combinations is $2^N - 1$. ►FISH, ►chromosome painting, ►fluorochromes, ►ratio labeling

Combinatorial Library: Antibody heavy and light chain cDNAs are amplified separately by PCR, then ligated and cloned in vectors. Thus a random combinatorial array of constructs is generated. *E. coli* cells infected with the vectors produce both antibody chains. But only the heavy chain contains the variable region, the first constant domain, and the Fab region (see antibody diagram). This protein binds to the antigen but lacks the effector domain. The library can be screened by a radioactively labeled antigen and after washing off the unbound radioactivity, the sought antigen-antibody can be spotted on the plate by the radioactivity fixed. This method permits a very efficient selection among millions of types of antibodies, a selection that appears a thousand fold more efficient than the monoclonal method. The method is further improved upon by using filamentous phages (M13) that display antibodies on their surface. Screening can be done in liquid media and subjected to adsorption chromatographic purification. This procedure is also called epitope screening. ►epitope, ►antibody, ►antigen, ►filamentous phage, ►phage display, ►monoclonal antibody,

►chromatography; Pelletier J, Sidhu S 2001 Curr Opin Biotechnol 12:340; Pinilla C et al 2001 Cancer Res 61:5153.

Combing: ►molecular combing

Combining Ability: A term used in quantitative genetics and animal and plant breeding. *General combining* indicates that a particular stock has better than average performance in any hybrid combinations. *Specific combining ability* indicates a better than average performance only in certain hybrids. From (n) lines $\frac{n(n-1)}{2}$ single crosses and $\frac{[n-1][n-2][n-3]}{8}$ double crosses are possible. ►heterosis, ►hybrid vigor, ►double cross; Henderson CR 1952 In: Gowen J (ed) Heterosis. Iowa State College Press, Ames, Iowa.

Combretastatin: (see Fig. C140). ►angiogenesis

Figure C140. Combretastatin

ComEA: is a membrane-bound double-stranded DNA binding protein in prokaryotes and promotes transformation. Before uptake of DNA one of the strand is degraded. In Gram-negative bacteria, however, the dsDNA passes through the outer membrane with the assistance of secretin.

Comet Assay: The comet assay detects chromosomal lesions by exposing alkaline treated (pH 13) cells to electrophoresis and examining microscopically the comet shape of the destabilized nucleus suffered chromosome breakage by the mutagenic agent. The tail (length of the comet) and the head (diameter) ratios are evaluated (see Fig. C141).

Figure 141. Comet assay

Comm (*commisureless*): *Drosophila* gene counteracts the effects of *Robo*. ►axon, ►Robo

Commaless Code: In 1961, Francis Crick and coworkers (Nature [Lond] 192:1227) predicted the triplet nature of the genetic code from mutation experiments and they concluded that the code is degenerate, not overlapping, and the triplets follow each other in a linear order without interrupted commas. Although

C

these were epoch-making conclusions, the discovery of introns in 1977 (Berger SM et al 1977 Cold Spring Harbor Symp Quant Biol 42:523; Broker TR et al 1977 Cold Spring Harbor Symp Quant Biol 42:531) showed that not all genes are contiguous. Also, even in the small DNA virus ϕ X174 several genes overlap and this is a common phenomenon in eukaryotes as well (Boi S et al 2004 Curr Genomics 5:509). ▶degenerate code; ▶ ϕ X174genetic code; Rédei et al 2006 Adv Genet 56:53.

Commensalism: Commensalism is the condition in which, species share the same natural resources without necessarily benefiting or suffering from the relationship. ▶symbiont, ▶pathogenic

Commingling Test: The commingling test analyzes whether the phenotypic distribution in large populations is based on the contribution of a single group or by an admixture of several groups. Such a study may be important for the analysis of quantitative traits, and in genetic epidemiology. (See Khoury MJ et al 1993 Fundamentals of Genetic Epidemiology. Oxford University Press, New York).

Commissure: The joining of corresponding parts of organs, e.g., of the lips of the mouth or vagina or between the axons crossing the midline of the body.

Commitment: ▶determination

Commitment Point: The determination (start) point of the cell division cycle. ▶cell cycle, ▶restriction point

Common Denominator: In mathematics, the term common denominator is used to bring different fractions to a denominator that can be used with all appropriately adjusted nominators to facilitate further manipulations (e.g. additions, subtraction). In molecular biology, the common denominators are the elements shared among different protein isoforms encoded by the same open reading frame. ▶isoform, ▶open reading frame

Common Variant/Common Disease Hypothesis: The common disease hypothesis states that quantitative differences among different alleles may account for common (complex) disease. (See Lee MP 2005 Methods Mol Biol 311:39).

Comorbid: A condition in which, an additional disease occurs along with the primary disease. It may alter the diagnosis and may aggravate the condition.

COMP (cartilage oligomeric matrix protein): A pentameric member of the thrombospondin family. See ▶thrombospondin, ▶pseudoachondroplasia; Oldberg A et al 1992 J Biol Chem 267:22346.

CompP: A *Bacillus subtilis* kinase affecting competence through regulator ComA.

Compaction: The tight binding of cells to each other such as occurs when the blastomeres of the embryo form the morula. ▶morula

Companion Cells: Conductive tissues in plants, associated with sieve tubes. ▶sieve tube

Comparative Anchor Reference Loci (CARL): CARL span the genomes and facilitate comparative genome mapping of different species of mammals. (See for data Lyons LA et al 1997 Nature Genet 15: 47; Margulies EH et al 2005 Proc Natl Acad Sci USA 102:4795).

Comparative Chromosome Painting: Comparative genetic mapping and comparative chromosome painting are suitable means to shed light on the evolution of the chromosome complement. During evolution, chromosome numbers might have increased (polyploidy) or decreased by reciprocal translocations, inversion, insertions, deletions of fusion of chromosomal arms or their parts. Chromosome painting may reveal the homology of the present day species to each other and/or ancestral species. *Arabidopsis thaliana* has five pairs of chromosomes but other related cruciferous plants have a higher chromosome number. *Arabidopsis lyrata* has eight pairs of chromosomes. Analysis of pachytene chromosomes by hybridizing bacterial artificial chromosome-carried *A. lyrata* contigs painted with different fluorochromes revealed their position in the *Arabidopsis thaliana* genome, and permitted the reconstruction of the cytological events that lead to the reduction of chromosome number in *A. thaliana* to five from the ancestral eight still conserved in *A. lyrata* (Lysak MA et al 2006 Proc Natl Acad Sci USA 103:5224). Similar changes are detectable among other plant and animal species. ▶chromosome painting, ▶contig, ▶chromosomal rearrangements, ▶evolution of the karyotype, ▶comparative genomic hybridization, ▶chromosome banding

Comparative Expressed Sequence Hybridization (CESH): CESH is a relatively rapid method, which gives a genome-wide view of chromosomal location of differently expressed genes within tissues. mRNA or cDNA prepared from two different tissues, e.g., healthy or cancerous is differentially labeled with fluorochromes before hybridization. No prior knowledge of genes or cloning is necessary, and minimal amounts of tissue can be used. Expression profiles are achieved in a manner similar to the identification of chromosomal imbalances by comparative genomic

hybridization analysis. The method reveals chromosomal regions where genes are overexpressed as a consequence of drug-resistance, cancer, or other functional differences. ►comparative genomic hybridization; Lu Y-J et al 2001 Proc Natl Acad Sci USA 98:9197.

Comparative Genomic Hybridization (CGH): CGH is a method of cytological localization of a mutant DNA sequence. The normal sequence and the mutant sequence of DNA are labeled by different fluorochromes, and the mixture is used for in situ hybridization. The relative hybridization signals of the bands are monitored by fluorescence microscopy. Alternatively, microarray hybridization can be used for the analysis. This method permits the analysis of DNA sequence dosage (loss or gain) in cancer tissues compared to normal cells. It is also suitable for scanning genomes for evolutionary studies, developmental studies, and for prognosis of cancer. ►fluorochromes, ►in situ hybridization, ►microarray hybridization, ►FISH, ►hyperbranched strand displacement amplification, ►RDA, ►diagnosis; Pinkel D et al 1998 Nature Genet 20:207; Lomax B et al 2000 Am J Hum Genet 66:1516; Lin JY et al 2002 Genome Biol 3:research 0026.1; Pinkel D, Albertson DG 2005 Annu Rev Genomics Hum Genet 6:331, copy number search: <http://bioinfo-out.curie.fr/CAPweb/>, copy number and expression profile: <http://isacgh.bioinfo.cipf.es/>.

Comparative Genomics (sequenced genomes): The prospects for comparable DNA sequences among various prokaryotic and eukaryotic genomes across phylogenetic ranges. The study may involve genic, regulatory and non-coding sequences as well as gaps, fused genes, split genes, and evolved orthologous and paralogous genes. The comparisons may better define the function(s) of genes and non-coding sequences. The proteome of mammals is very similar; generally less than 1% difference exists among mammalian species, but 4% of the *Caenorhabditis* genes have no matches in the *C. briggsae*, a related species. Comparative genomics of primates—about 300 species—is of particular interest because it can shed information on the evolution and function of the human genome. The closest relatives to humans are the hominoids such as the chimpanzee, bonobo, gorilla, orangutan, and gibbon. The Old World Monkeys such as the colobus, baboon, and the rhesus monkey are somewhat further away in the phylogenetic tree. Even further apart are the New World Monkeys: the woolly monkey, the capuchin, and the marmoset. The tarsius, galago and lemur are on the lateral branches. The most likely relationships cannot be determined until complete genome sequences are

available. The classical morphological analysis is not in complete agreement with the limited DNA information. The estimates of the age of divergence are not entirely consistent with the other known data. It appears that the lineage of the closest human relative, the chimpanzee, diverged about 5–7 million years ago (mya), but this estimate may be biased because the effective population sizes as well as the initial gene flow are unknown. The seemingly closest, extinct hominoid species, the Neanderthals apparently split from the human lineages 350,000 years ago. Their mitochondrial DNA is different and their contribution to the human gene pool is uncertain but most likely minimal. Genetic diversity within the human species is much smaller than in other primates despite the larger population size. This fact may indicate recent origin and rapid population expansion. Chromosomal rearrangements, particularly duplications, open opportunities for gene evolution. Transposon and retrotransposons (representing ~45% of the human genome) provide chances for genome evolution. Insertion elements seem to have increased the size of the human genome by about 1%, compared to that of chimpanzee and apparently contributed to the different regulation of the human genome. Insertion and deletions may occur 1/1,000 sequences between humans and chimpanzees. In human chromosome 21 and its chimpanzee homolog (Chr. 22), 68,000 indels were detected in 3.3 million compared base pairs. This resulted in 83% amino acid differences of 231 coding sequences (Watanabe H et al 2004 Nature 429:382). Microsatellite sequences in humans appear 2-bp longer than in chimpanzees (Webster MT et al 2002 Proc Natl Acad Sci USA 99:8748). Mutation rates—especially in the CpG dinucleotides, which are subject to methylation—may vary also between and among related species and have functional consequences. Recombination rates may vary among related species and are a factor in genome evolution. Comparative microarray analysis of the genes reveals expression profiles and species differences. Selectively advantageous alterations in a species can be determined from the Ka/Ks amino acid substitutions; the greater Ka indicates positive selective advantage, and not merely neutral change. ►alignment, ►TWINSCAN, ►GENSCAN, ►SGP, ►SLAM, ►ETOPE, ►browsers, ►dog, ►Trypanosomatids, ►Neanderthal, ►microarray hybridization, ►microsatellite, ►Ka/Ks, ►language; Cliften PF et al 2001 Genome Res 11:1175; Wassenaarman KM et al 2001 Genes Dev 15:1637; Sidow A 2002 Cell 111:13; Kellis M et al 2003 Nature [Lond] 423:241; Miller W et al 2004 Annu Rev Genomics Hum Genet 5:15; Enard W, Pääbo S 2004 Annu Rev Genomics Hum Genet, 5:351; genome sequence alignment and

C

annotation database (GALA): Giardine et al 2003 Genome Res 13:732; comparative genomics of model plants: Borevitz JO, Ecker JR 2004 Annu Rev Genomics Hum Genet 5:443; relationship between sequence diversity, specificity and sensitivity of analysis of different genomes: Stone EA et al 2005 Annu Rev Genomics Hum Genet 6:143; <http://www.ncbi.nlm.nih.gov/COG>; comparative regulatory genomics; <http://corg.molgen.mpg.de/>; <http://gib.genes.nig.ac.jp>; comparative plant genomics: <http://plantbpb.uoregon.edu/>.

Comparative Maps: Comparative maps would reveal the evolutionary conservation of genes and nucleotide sequences across phylogenetic boundaries. For this purpose comparative anchor-tagged sequences (CATS) are needed in the species where substantial amount of nucleotide sequence information is available. The information available in various species suggest that 1 to 10 chromosomal rearrangements might have occurred per million years. Conserved sites indicate the functional importance of that DNA sequence. ▶ [comparative anchor reference loci](#), ▶ [unified genetic maps](#), ▶ [mouse](#), ▶ [evolution](#); Smith EJ et al 2001 Poultry Sci 80:1263.

Comparative Regulatory Sequences (CORG): The conserved non-coding blocks of ten vertebrates: <http://corg.eb.tuebingen.mpg.de/cgi-bin/index.pl>.

compartmentalization: Certain groups of cells give rise to clones, which are different by morphology and/or function from their surrounding tissues. Adjacent compartments do not intermingle. The compartment may further differentiate during development. Compartmentalization takes place within the cells as well, by assignment of special functions in a polar fashion or to special subcellular organs. Temporal/diurnal compartmentalization includes the circadian rhythm or various oscillatory functions. ▶ [mRNA targeting](#), ▶ [differentiation](#), ▶ [morphogenesis](#), ▶ [circadian rhythm](#), ▶ [oscillators](#); Helweg-Larsen J et al 2001 J Clin Microbiol 39:3789.

Compass: The protein complex involved in histone 3 lysine 4 methylation is a homolog of human MLL. ▶ [MLL](#), ▶ [histone methyltransferase](#)

Compatibility: Crossing or mating of compatible parents results in (normal) offspring. Also, compatible tissue transplantation does not involve adverse immunological reaction. Simultaneous treatments are compatible if they can be withstood without undesirable consequence(s). incompatibility.

Compatibility Group: Plasmids that may or may not co-exist in the same bacteria.

Compatibility of Organelle and Nuclear Genomes: Compatibility of organelle can be determined in species where biparental transmission occurs and organelles can be transferred between species. Also on the basis of cybrids, it appears that compatibility differences are real, and thus various cytoplasms can be classified. The reciprocal crosses are usually informative. ▶ [plasmid male transmission](#), ▶ [paternal leakage](#), ▶ [ctDNA](#), ▶ [mtDNA](#), ▶ [cybrids](#)

Compensasome: The RNA and protein complex that mediates dosage compensation. ▶ [dosage compensation](#)

Compensatory Mutation: A compensatory mutation mitigates the genetic disadvantage of another mutation. The streptomycin resistance gene in *Salmonella* or *E. coli* endows the cells with great selective advantage on streptomycin media, but under conditions where the antibiotic is not present the primary mutants are disadvantaged because of the modified ribosomes (conveying the resistance) are less efficient in translation. Several passages through streptomycin-free media. the fitness of the bacteria improves without reversion to the wild type gene. The improvement is generally due to mutations that compensate for the shortcoming of the ribosome. ▶ [fitness](#), ▶ [reversion](#), ▶ [second site reversion](#); Guan Y et al 2001 J Virology 75:11920; Kulathinal RJ et al 2004 Science 306:1553.

Competence, Embryonal: A state of being receptive to stimuli for differentiation. It may depend on specific transcription factors, presence of the right signaling molecules, absence of interfering signals, presence of the appropriate receptors and ligands, modifying factors such as kinases, phosphatases, availability of the proper environmental cues, etc., and their complex interactions. (See Duranthon V, Renard JP 2001 Theriogenology 55:1277).

Competence of Bacteria: A physiological state of the (bacterial) cell when transformation (uptake and integration of DNA) is successful. Competence generally coincides with the second half of the generation time or its peak is near the end of the exponential growth phase. Divalent cations and their combination can induce competence. For more than four decades *E. coli* was refractory to transformation, until in 1970 it was discovered that cold CaCl_2 makes possible the uptake of phage DNA. 1 mg supercoiled plasmid DNA yields 10^5 to 10^6 transformations. This frequency can further be increased by two to three orders of magnitude by the use of improved protocols involving also DMSO (dimethylsulfoxide, a wide-range solvent

and penetrant). The bacteria so treated keep their transformation competence if stored at -70°C .

Competence in *Bacillus subtilis* is regulated by the secreted competence-stimulating factor (CSF, 520-720-Da peptide) and the pheromone ComX (the ≈ 10 amino acid C-terminal section of the 55 amino acid peptide). The process of competence development requires transcription factors and specific nutritional conditions. *Bacillus subtilis* has more than 15 proteins for single-stranded DNA internalization that are co-localized at the cell poles along with Rec proteins (Kidane D, Graumann PL 2005 Cell 122:73). In the *Neisseria* bacteria, competence is expressed constitutively. In *Haemophilus influenzae*, arrest of cell division results in competence. In *Streptococcus pneumoniae* and *Bacillus subtilis*, stress signals such as created by certain antibiotics, stimulate competence for transformation. The increased transformability increases the chances of acquiring resistance to new antibiotics and evolution of virulence (Prudhomme M et al 2006 Science 313:89). ▶[transformation genetic](#), ▶[exponential growth](#), ▶[supercoiling](#), ▶[DNA uptake sequences](#), ▶[ComEA](#), ▶[fratricide](#); Grossman AD 1995 Annu Rev Genet 29:477; Peterson S et al 2000 J Bacteriol 182:6192; regulatory circuits in *B. subtilis*: Süel GM et al 2006 Nature [Lond] 440:545.

Competition: The rivalry between or among free-living organisms for available resources. It may be a passive *exploitative* process when one or more competitors use up the resources and for others the facilities or supplies become limited. In *interference*, one organism actively attacks or eliminates another or others by the production of deleterious substances or mechanical obstacles. An *apparent* competition results when an organism of certain genotype evokes a host defense mechanism that prevents others from infecting the same host. ▶[pollen competition](#), ▶[selection](#), ▶[superinfection](#), ▶[frequency-dependent selection](#)

Competitive Exclusion: As per competitive exclusion, two similar species generally do not coexist in the same niche indefinitely. They will either coalesce (be interbreeding) or one will be extinguished.

Competitive Inhibition: The inhibitor competes with the substrate for the active site of the enzyme and its blocking effect can be relieved by an increase in the concentration of the substrate. ▶[regulation of enzyme activity](#); Takahashi Y, Kamataki T 2001 Drug Metab Rev 33:37.

Competitive Regulation: In competitive regulation, besides the minimal enhancer, accessory cis elements are needed to ensure proper gene expression during the different developmental stages.

Competitive Release: Competitive release refers to the phenomenon in which, under conditions when there are limited or no competitive species, races or species are selected for general performance rather than to high adaptive specialization.

Complement: The complement is activated when antigen and antibody form a complex in the Fc domain of the heavy chain of IgG and IgM ▶[antibody](#). The complement has numerous functions, one of the most important of which is mediated through the antibody related lytic pathway and the other is the antibody-independent pathway, outlined. Apart from this, the complement may protect the immune complexes from precipitation, facilitate the solubilization of the immune complex, and make possible its transportation by the circulatory system of the body. The complement (except C5b-9) may interact with surface receptors of the hematopoietic cells of the immune system to stimulate inflammation and to mount an immune response. The complement may promote opsonization by macrophages. Graft rejection may be based on the activation of the complement system. Non-biological, foreign material used during surgery or other medical interventions (various drugs, radiographic contrast media) may activate the complement system. Medical treatments may apply complement deactivating or neutralizing drugs (e.g. aspirin, cobra venom, specific antibodies, and protease inhibitors) in autoimmune or other inflammatory disease. The complement consists of about 30 different proteins that facilitate the destruction of the foreign cells by lysis and activate the leukocytes to engulf the invaders by phagocytosis. Immunoglobulin M (IgM, 950-kDa) and the sub-classes of immunoglobulin G (IgG, 150-kDa) bind complement C1q (459-kDa) components of C1 protein, encoded in human chromosome 1p34-p36.3. The binding causes the sequential activation of C1r (83-kDa, a serine protease encoded at 12p13), C1s (83-kDa is also a serine protease component, encoded at 12p13), C4 (95, 75, 33-kDa, encoded at location of the MHC III in chromosome 6, activator of C2, C3, C5) and C2 (90 to 102-kDa, encoded at the MHC locus), and the cleavage of C3 (185-kDa, encoded at the end of 19q). C2 binds to C4b to form C4b2, which after cleavage by C1s forms the C4b2a complex and then activates C3. There are a number of other proteins that modulate these reactions. C1-inhibitor (C1-INH is a serpin [serine-protease inhibitor], 71-53 kDa, encoded at 11p11.2-q13). C4b binding plasma glycoprotein 570-kDa, encoded in 1q) is an inhibitor of C3 convertase (cleaving protein). IgA, IgE, polysaccharides, and endotoxins can activate the cleavage of complement component

C

C3 as well (for structure and function of C3 see Janssen BJC et al 2005 Nature [Lond] 437:505). Proteins B (93-kDa, encoded in the MHC complex), D (24-kDa), P (properdin, 220-kDa, encoded at chromosome Xp), Factor I (dimeric 50- and 38-kDa, serine protease), and a modulator H (155-kDa encoded in chromosome 1q31) are also involved in the cleavage of C3. Conformational change mediates the transition of C3 into C3b (1,560 amino acids in 12 domains) and facilitates the binding of proteins and receptors. Its crystal structure has been revealed (Janssen BJC et al 2006 Nature [Lond] 444:213; Wiesmann C et al 2006 *ibid.* p. 217; Ajees AA et al 2006 *ibid.* p. 221). The largest fragment of C3b then interacts with another protein group, properdin, and participates in a positive feedback system to stimulate the cleavage of C3. Finally, C3b initiates the cleavage of complement components C5 (192-Da, human chromosome 9), C6 (104 to 128-kDa), C7 (92.4 to 121-kDa), C8 (152-kDa, 9q), and C9 (71-kDa). Proteins 6, 7, and 9 are encoded in chromosome 5p, and form the so-called MAC (membrane attack complex). In the so-called *classical pathway*, proteins C1q, C1r, C1s, C4, C2 and C3 are involved. The alternative means of activation follows the “lectin” or *mannose-binding* protein (MBP/MBL) path involving C4, C2, C3, and the mannose binding-associated serine proteases (MASP). This alternative MBP pathway—in contrast to the classical pathway—attacks the foreign proteins without prior antibody synthesis. The majority of the Gram-negative bacteria activate the MBP reactions but some Gram-negatives do not. Activating the binding of the H protein to C3b may prevent the activation. A variety of the components of the cell wall of the pathogens also prevent the initiation of the MBP pathway. The complement components react with cell-specific receptors and some receptors react with more than one complement component. This reaction results in enhanced phagocytosis, antibody dependent cellular cytotoxicity (ADCC), lysis, B-lymphocyte proliferation, etc. Components C1, C4, and C2 attack viral invaders, and their interaction increases permeability. C3a and C5a have anaphylatoxic effects, including the release of cellular histamine, and they regulate humoral immune reactions. The C1q molecules may bind to specific receptors (C1q-R) such as the collectin receptor (60-kDa cC1q-R) or the 100-kDa cC1q-R or the 30-kDa gC1q-R, present in a variety of cells. C3b and C4b bind to surface receptors of several mammalian cells and to bacteria and cause their destruction. According to the “doughnut hypothesis” C5b-C9 components of the complement form transmembrane channels (maximally 10-nm in diameter) through which the lytic components can

penetrate the attacked cells. The target cells may be protected by elimination of the C5b-9 channels. The presence of Ca^{2+} may assist in the (partial) elimination of the channels but Ca^{2+} may also enhance cell death. C5b-9 binding initiates hydrolysis of membrane lipids and in small amounts, C5b-9 may lead also to the synthesis prostaglandins, leukotrienes, growth factors, and a number of cellular proteins. The complement plays a particular role in defense before antibody formation is completed. HIV and human T cell leukemia virus are, however, resistant to the human complement. Gal(α 1-3)Gal terminal carbohydrate antigens are present in the endothelial lining in most mammals, except humans, because human cells do not possess this type of functional galactosyltransferase (although several galactosyltransferases are encoded by the human genome). If the porcine enzyme is transfected into human cells, the retroviruses become sensitive to the human serum.

Immunochemical and hemolytic properties measure the amount of the complement. CH_{50} is a measure of the complement indicating that 50% of the antibody-sensitized erythrocytes release their hemoglobin. Genetically determined deficiencies are known for the complement proteins. Homozygotes may entirely miss a particular protein, whereas heterozygotes may display only a limited quantity. *Lupus erythematosus*, an autoimmune disease, is caused by C2 deficiency. Other deficiencies in the terminal components of the complement pathway may contribute to the symptoms of rheumatoid immune diseases. Susceptibility to various types of infections is also related to deficiencies in the components of the complement proteins. The complement is basically an innate component of the immune system and is complementary to the function of the macrophages, mast cells, T cells, and B cells. The complement can be activated not only by binding of the antibody and antigen, but also by surface structures of microbes and, in an antibody-independent manner, by serine proteases associated with mannan-binding lectin. Hereditary deficiencies have been identified for most complement components. Many of these deficiencies are not lethal per se but make the individuals more susceptible to infections.

▶leukotrienes, ▶TCC, ▶opsonins, ▶MCP, ▶decay accelerating factor, ▶vitronectin, ▶membrane attack complex, ▶Niemann-Pick disease, ▶anaphylatoxins, ▶allograft, ▶xenograft, ▶hyperacute reaction, ▶CD35, ▶CD21, ▶CD11/CD18, ▶C5a -R, ▶Gala1-3Gal, ▶SIGN-R1; Morley BJ, Walport, MJ (eds) 2000 The Complement Facts Book. Academic Press, San Diego, California; complement minireview: Roozendaal R, Carroll MC 2006 Cell 125:29.

Complement Fixation: A serological measure of the degree of antigen-antibody reaction. ▶antibody detection, ▶complement, ▶CH₅₀

Complementarity: Complementarity of nucleic acid bases means that Adenine pairs with Thymine and Guanine with Cytosine by two and three hydrogen bonds, respectively, and two complementary polynucleotide chains pair in an antiparallel manner. ▶DNA structure, ▶Chargaff's rule

Complementarity Determining Region: ▶CDR

Complementary Alleles: Complementary alleles belong to different gene loci, although partial complementation may occur between alleles that belong to different cistrons of the same gene locus. ▶allele, ▶allelism test, ▶cistron, ▶complementation mapping, ▶complementation test in vitro

Complementary Base (nucleotide) Sequences: Nucleotides can form hydrogen bonds according to the base pairing rules in double-stranded DNA or double-stranded RNA. ▶hydrogen bonding, ▶Chargaff's rule

Complementary DNA: ▶cDNA

Complementary Genes: Homozygosity of recessive alleles located at different loci but controlling functions in the same biosynthetic pathway may be expressed by identical (or very similar) phenotype, and in the F₂ of a double heterozygote is expected to display the phenotypic proportion of 9 wild type and 7 mutants (homozygous for one [3] + for the other [3] + for both [1] of the recessive alleles = 7). This is a modification of the 9:3:3:1 (9/16, 3/16, 3/16, 1/16) ratio. ▶modified Mendelian ratios

Complementary Segregation: ▶complementary genes

Complementary Sex Determination: Complementary sex determination may occur in animals with arrhenotoky. The females are heterozygous for complementary alleles at the sex locus and diploid. There is greater relatedness among sisters of a mother (queen) than between mother and daughters. The normal males are haploid, whereas diploidy in the males is deleterious or lethal. ▶arrhenotoky

Complementation, Donor Strand: The formation of a stable complex by the interaction of two proteins. One such a donor may be a chaperone molecule. ▶chaperones

Complementation, Extracellular: By diffusion, the product of one gene may compensate for the defect in a nearby cell. ▶complementation

Complementation Groups: Recessive mutations that complement in trans-arrangement belong to different complementation groups, i.e., they represent different gene loci, whereas the noncomplementary alleles belong to the same complementation group (see Fig. C142). ▶trans, ▶cis, ▶allelism

Figure C142. Allelic complementation may be based on random cytoplasmic association of protein subunits of the multimeric enzymes. The mutant subunits may not be functional, yet if they assemble favorably some enzyme molecules can show activity

Complementation Mapping: Complementation mapping is used to determine the pattern of the genetic differences among complementary alleles and the extent of the genetic lesions involved (see Fig. C143).

Figure C143. On the basis of partial (allelic) complementation of various alleles of a locus controlling a multimeric enzyme, genetic mapping is possible. This is not necessarily a physical map, rather a functional one and it may not always be therefore linear. Open circles indicate lack of complementation, solid circles stand for complementation of recessive alleles identified here by A, B, C, D, E, and F. (From Catcheside DG 1960 In: Hayes W, Clowes RC (eds) *Microbial Genetics*. Cambridge University Press, Cambridge, UK)

Complementation Test: A test for allelism. Recessive alleles of the same cistron generally fail to complement in trans-arrangement in heterozygotes, e.g., the *Ab/aB* heterozygote is non-mutant if *a* and *b* alleles belong to different loci. If two recessive mutations in the F_1 display mutant phenotype, the two mutants are allelic. ▶ [allelism](#)

Complementation Test, In Vitro: The complementation test is carried out by cell extracts (enzyme assays). This is the most reliable test of complementation because the genes are regulated in vivo and that may boost complementation when the complementation is weak. E.g., 5% of the activity of an enzyme may appear as if it would be of wild phenotype in vivo but in vitro, in the absence of regulation, it can be readily distinguished from 100% activity. ▶ [allelism](#); Loper JC 1961 *Proc Natl Acad Sci USA* 47:1440.

Complementation, Tetraploid: ▶ [tetraploid complementation](#)

Complementation Unit: A cistron. ▶ [cistron](#), ▶ [complementation test](#)

Complete Digestion: In complete digestion, the reaction with a restriction endonuclease is continued until the enzyme cleaves all potential cutting sites in the DNA. ▶ [restriction enzymes](#)

Complete Dominance: In the presence of a completely dominant allele, the phenotype controlled by the recessive allele is not detectable under the conditions of study. ▶ [Mendelian laws](#), ▶ [Mendelian segregation](#), ▶ [Modified Mendelian ratios](#), ▶ [semidominance](#), ▶ [codominance](#)

Complete Flowers: Complete flowers have sepals, petals, stamens, and carpels. ▶ [flower](#), ▶ [differentiation](#)

Complete Linkage: Genes fail to recombine because of their extreme closeness in the chromosome or because of genetic factors interfering with crossing over (chromosomal aberrations), inviability of the recombinants (deficiency or duplication gametes in inversion heterozygotes), or absence of recombination in the heterogametic sex of male *Drosophila* or female silkworm. ▶ [recombination](#), ▶ [linkage](#); Sturtevant AH, Beadle GW 1939 *An Introduction to Genetics*. Dover, New York.

Complete Medium: A complete medium contains all the nutrients that potentially auxotrophic cells may require for growth. ▶ [minimal medium](#), ▶ [auxotroph](#)

Completion: The production of high-quality nucleotide sequence map of both unique and repetitive DNA of a genome. ▶ [high-quality sequence](#), ▶ [genome projects](#), ▶ [finishing](#)

Complex: Complex, as a noun refers to a functional aggregate of molecules without inter-molecular covalent bonds. As an adjective, the function of a complex may not be entirely predictable from the components because it may be qualitatively different than the sum of its components.

Complex Diseases: Multiple genes and diverse environmental factors determine complex diseases and susceptibility to them. Neither statistical nor molecular analyses have been found to facilitate, to an entirely satisfactory extent, the identification of the factors and mechanisms involved, although several approaches are available. ▶ [PAF](#), ▶ [QTL](#), ▶ [correlation](#); Altmüller J et al 2001 *Am J Hum Genet* 69:936.

Complex Heterozygote: Complex heterozygotes are viable heterozygotes for multiple reciprocal translocations A when translocation homozygotes are lethal (see Fig. C144). It is actually a balanced lethal system and heterozygosity is permanent for the genes within the translocation complexes. If there are two multiple translocation complexes, it appears as if there would be only two groups of linked genes even when the basic number of chromosomes is larger. In meiosis, the distribution of the chromosomes is alternate and paternal and maternal complexes always go to opposite poles. Recombination between the complexes is rare but if it occurs it may change the

complexes. The size of the complexes may vary depending upon the number of chromosomes involved in the reciprocal translocation complexes. *Oenothera lamarckiana* carries the seven-chromosome *gaudens* complex (Latin for happy, i.e., the chromosomes do not contain dominant or semi-dominant deleterious genes) and the seven-chromosome *velans* translocation complex (Latin for concealing, since it contains semidominant genes that are responsible for paler color and narrower leaves). *Oenothera hookeri* also has 14 chromosomes but they are not involved in reciprocal translocations. When these two *Oenotheras* are crossed the F_1 is not uniform as in normal Mendelian crosses, instead “twin hybrids” are formed. The maternally transmitted *gaudens* complex makes the hybrids normal in shape and color, whereas hybrids containing the maternally transmitted *velans* complex are pale and have narrow leaves. Thus, because of the two complexes, the F_1 is reminiscent of a testcross involving a pair of heterozygous alleles. In *Oenothera*, these complexes behave differently; some kill the male, others kill the female gametes, and yet others cause zygotic lethality in the homozygotes. Only the complex heterozygotes are found in the sporophytic plants. The light microscope identifies the multiple translocations as translocation rings. Such systems are common among *Oenothera* plants but occur also in other species. ▶translocations, ▶*gaudens*, ▶*Oenothera*, ▶beta complex, ▶zygotic lethal; Cleland 1972 *Oenothera*: Cytogenetics and Evolution, Academic Press, New York.

Figure C144. Chromosome pairing multiple translocations

Complex Inheritance: Complex inheritance occurs when multiple loci and interactions are involved in the expression of the gene products. N.E. Morton (Proc Natl Acad Sci USA 93:3471 [1996]) published parametric and non-parametric statistics for estimating linkage, by considering various such pedigrees. ▶polygenic inheritance, ▶multifactorial trait,

▶QTL, ▶complex trait; Zwick ME et al 2000 Annu Rev Genomics Hum Genet 1:387.

Complex Locus: A generally large cluster/complex of functionally related but not entirely similar cistrons and alleles within the locus may show partial complementation (*scute* in *Drosophila*, *t* in mouse, HLA and immunoglobulins in mammals, *R* in maize). Some of the complex loci appeared to be more mutable than other genes because unequal crossing over between the repeated sequences generated new phenotypes. ▶pseudoallelism, ▶allelic complementation, ▶step allelomorphism, ▶Bar, ▶operon; Carlson EA 1959 Quart Rev Biol 34:33; Demerec M et al 1955 Proc Natl Acad Sci USA 41:359.

Complex Promoter: The complex promoter contains—besides the usual promoter elements—an insertion element (e.g., Ty) with its own promoter situated within the long terminal repeat. As a consequence, transcription may initiate from the Ty promoter (δ) located within the interval between the TATA and the UAS sequence, and the transcript of the yeast gene involved may not be functional. The δ promoter also contains binding regulatory elements. ▶promoter, ▶Ty; Pilpel Y et al 2001 Nature Genet 29:153.

Complex Trait: The inheritance of a complex trait is not based on a single dominant or recessive allele but may involve multiple factors. Various environmental effects contribute to the expression of these factors. ▶QTL, ▶complex inheritance; Moore KJ, Nagle DL 2000 Annu Rev Genet 34:653; Glazier AM et al 2002 Science 298:2345; *Drosophila* as model for complex human traits and disease: Mackay TFC, Anholt RRH 2006 Annu Rev Genomics Hum Genet 7:339; <http://www.complextrait.org/>.

Complex Transcription Unit: The transcript of the gene may be processed in more than one way and the translated products vary according to cell- or tissue-specific functions.

Complexin: The proteins of the nerve termini, binding syntaxin. They regulate Ca^{2+} -dependent release of neurotransmitters. ▶syntaxin, ▶neurotransmitter, ▶synaptotagmin; Reim K et al 2001 Cell 104:71.

Complexity of DNA: The complexity of DNA indicates the size of the DNA molecule as determined from the c_0t curve. ▶ c_0t curve, ▶ $c_0t_{1/2}$, ▶kinetics, ▶kinetic complexity, ▶BLAST

Complexity of Function: Complexity can be defined as the number of metabolic steps required for biological function(s). Before different genomes had been sequenced, the assumption that the number of genes determines biological complexity appeared valid. In broad terms, this is still valid because the MS2 phage

C

requires only 4 genes whereas the bacterium *E. coli* contains 4,288 protein-coding genes. However, the simple worm, *Caenorhabditis elegans*, has 18,424 genes, whereas the more complex fruit fly, *Drosophila melanogaster*, has only 13,601 and the small plant *Arabidopsis* about 25,498. Therefore, there must be a better way to define biological complexity. Since genes may be spliced in alternative manners, this feature of the genes may boost complexity. Also, the expression of not-housekeeping genes is highly regulated by the recruitment of specific transcription factors and effector proteins. There is apparently a great variety of ways in which, the different proteins can enter into complexes and single polypeptide chains may participate in several functionally different aggregates. Therefore, it appears that the cooperating (enhancing and inhibitory) networks have a major role in determining biological complexity. ▶microarray hybridization, ▶proteome; Szathmáry E et al 2001 Science 292:1315.

Compliant Mutation: Compliant mutation is readily identifiable by genetic testing and reveals the existence of certain risks for disease. ▶genetic testing

Complicon: The complex chromosomal translocation that commonly co-occurs with oncogenic transformation. ▶cancer; Zhu C et al 2002 Cell 109:811.

Composite Cross: In a composite cross, individuals of various genetic constitutions are hybridized in a mass for the purpose of studying the effect of natural selection or to obtain improved varieties.

Composite Promoter: ▶complex promoter

Composite Transposon: A composite transposon carries genes (e.g., antibiotic resistance) beyond those required for transposition. ▶transposon, ▶insertion element

Compound Chromosome: A compound chromosome is the result of the fusion of a telocentric chromosome into a bi-armed monocentric, or of Robertsonian translocation between acrocentric chromosomes, or of translocations, or of intrachromosomal transposition. ▶telocentric, ▶Robertsonian translocation,

▶translocation, ▶transposition, ▶compound X chromosome

Compound Eye: In Arthropods (insects), the eye is composed of several, each structurally complete, elements (ommatidium, about 800 in each eye of *Drosophila*) (see Fig. C145). ▶photo at right, ▶ommatidium, ▶*Drosophila*, ▶CIB

Figure C145. Compound eye

Compound, Genetic: A genetic compound is a heterozygote for 2 mutant alleles of the same gene and may display a phenotype that is intermediate between those of the 2 recessive homozygotes. The loci may be in cis or trans position. ▶cis

Compound Heterozygote: A compound heterozygote carries different (defective) alleles at the same gene locus.

Compound Leaf: The compound leaf is composed of several leaflets (see Fig. C146).

Figure C146. Compound leaf

Compound X Chromosome: In a compound X chromosome, two X chromosomes are fused to the same centromere (see Fig. C147). E. Novitski distinguished the following six types: (i) reversed metacentric or attached X (RM), (ii) reversed acrocentric or double X (RA), (iii) reversed ring (RR), (iv) tandem

Figure C147. Compound X-chromosomes of *Drosophila*. The heavy lines represent heterochromatic regions; centromeres are red

metacentric or tandem attached X (TM), (v) tandem acrocentric (TA), (vi) tandem ring (TR). (See Novitski E 1954 Genetics 39:127).

Compressions in Gels: In DNA sequencing gels, abnormal intra-strand structures may form and cause anomalous pattern of migration, especially in DNAs with high G + C content. The compression may be avoided by using another DNA polymerase or by 2'-deoxyinosine-5'-triphosphate or 7-deaza-2'-deoxyguanosine-5'-triphosphate. ▶DNA sequencing, ▶deaza-nucleotides, ▶base-calling; Bowling JM et al 1991 Nucleic Acids Res 19:3089.

Compton Effect: According to the Compton effect, as the energy of electromagnetic radiation increases above 0.5 MeV, the radiation of electrons may scatter and recoil depending on the surface hit and the angle of the incidence of the radiation. This may affect the effective dose absorbed by the object and may create hazards if the source is not protected in all directions. ▶X-ray, ▶cathode rays, ▶MeV; van't Veld AA et al 2001 Med Phys 28:738.

Computer Terms (Webopedia): The online dictionary of computers: <http://www.webopedia.com/>.

Computerization of DNA and Protein Sequence Data:

The information of DNA sequences must be entered in a computer file. For proper handling, there may be a need for a *sequence manipulator* that is included with the software. Some programs have an audio feature (e.g. SeqSpeak) that spell out the data as entered. The data entered should be saved in "text files" or ASCII (American standard code for information exchange). The files are supposed to contain the relevant laboratory identification as well. Various software packages use different formats. If the quality of the sequencing gel is good, digitizing pads permit reading the sequence information directly from the autoradiogram. Automated gel readers are available commercially. When a multiplex method is used, a known sequence can be incorporated as an internal standard along with the gel. Automated DNA sequencers use special fluorochrome-tagged primers and no manual work is required for the entire operation. The automated scanners may be equipped with editing features so if a mistake is made it can be manually corrected. To minimize sequencing errors, generally both strands are sequenced and that too, more than once. Also the reading may need to be repeated. Homology Searching can automatically align the data for comparisons. The sequencing programs usually include a means to predict the presumable collinear amino acid sequence of the open reading frames. Programs may detect fragment sequence overlaps in order to generate contigs. The contigs can then be compared with restriction maps, if

available. Some available programs may generate graphic restriction maps. For the identification of functional regions, the detection of repeats, stem-loop structures in DNA or RNA may be used. The GC/AT content may reveal Z DNA or bent DNA structures.

Some programs assist in the identification of likely secondary structures (stem-loop) and folding of the RNA, including base stacking. Programs exist for the design of PCR primers. Gene families with related functions could be revealed by the use of degenerate oligonucleotide probes.

In order to identify protein-coding tracts, each strand is translated in 3 reading frames (6 all together) to obtain a contiguous, uninterrupted open reading frame (ORF). It may be difficult to reveal the possible splice sites, although various programs have this goal. A scoring matrix that quantitates the amino acid changes per 100 amino acids detects evolutionary changes in protein sequences.

The Basic Local Alignment Search Tool (BLAST) permits homology searches even through the Internet. FASTA serves similar purpose through e-mail. Helpful publications and software sources are listed in Ausubel FM et al (eds) 1999 Short Protocols in Molecular Biology. Wiley, New York. ▶proteomics

Conalbumin: An egg white iron-binding protein, encoded by a gene with 17 introns and regulated by estrogen and progesterone.

c-onc (cellular oncogene): A normal gene that loses its ability to limit cell divisions and then initiates cancerous growth. ▶v-oncogene

Concanavalins: Agglutinin proteins, which preferentially agglutinate cancer cells, used also as probes for cell surface membrane dynamics. Concanavalins are also mitogenic. ▶lectins, ▶cell adhesion, ▶mitogen; Wallach DF, Schmidt-Ullrich R 1976 J Cell Physiol 89:771.

Concatamer: Concatamers are repeated phage genomes associated in a linear array of DNA molecules in a head-to-tail fashion, formed during normal replication, and they must be cut to head capacity size for packaging into the capsid by a terminase gene product (endonuclease). ▶headful rule, ▶permuted redundancy, ▶non-permuted redundancy, ▶lambda phage, ▶catenane; O'Donnell R et al 2001 Nucleic Acids Res 29:716.

Concatenane: Interlocked DNA rings or chains (see Fig. C148). ▶knotted DNA

Figure C148. Concatenane

C

Conceptacle: A cavity in the fern leaves (fronds) bearing gametangia. ► [gametangia](#)

Conception: ► [fertility](#), ► [fertilization](#), ► [sex hormones](#), ► [hormone receptors](#)

Conceptus (plural concepti): A fertilized egg during its entire development including embryo, and fetus stages, and the extra-embryonic membranes until birth.

Concerted Evolution: In concerted evolution, copies of redundant DNA sequences are rather well conserved in the genomes, although one would have expected divergence by repeated mutations. Ribosomal RNA genes and hemoglobin genes are good examples of concerted evolution (Zimmer EA et al 1980 Proc Natl Acad Sci USA 77:2158); although some exceptions exist (Rooney AP, Ward TJ 2005 Proc Natl Acad Sci USA 102:5084). *Intragenic concerted evolution* may exert more mutational and recombinational pressure on internally repetitive exons of a gene than on the introns. Exons are crucial for the function of the protein product of the gene. As a consequence, extensive homology is observed within species and little homology between related species (such as found in intergenic spacer nucleotides and LINEs). An alternative theory for concerted evolution is the *birth-and-death* evolution, indicating that members of co-evolving genes are lost or new ones emerge, in a dynamic manner. ► [molecular drive](#), ► [LINE](#); Liao D 2000 J Mol Evol 51:305; Gao L-z, Innan H 2004 Science 306:1367; Nei M, Rooney AP 2005 Annu Rev Genet 39:121.

Concordance: The identity of traits within twins or groups of individuals. Among monozygotic twins, the concordance is expected to be ~100%, whereas among dizygotic twins it is between 25 to 50%. Lower concordance is an indication of (substantial) environmental contribution to the phenotype. ► [discordance](#), ► [twinning](#), ► [zygosis](#), ► [monozygotic twins](#), ► [dizygotic twins](#), ► [penetrance](#), ► [expressivity](#), ► [adopted children](#)

Concurrent Control: In an experiment involving certain type of treatment, it is required that an adequate group of untreated individuals will be studied *simultaneously* to permit a reliable comparison and assessment of the effect of the treatment. ► [control](#), ► [historical control](#)

Condensation Reaction: In a condensation reaction, water is released as a byproduct during the formation of a covalent bond.

Condensin: A complex of five protein subunits involved in chromosome condensation in the presence of topoisomerase I during mitosis in association with XCAP-C and XCAP-E. Condensin is activated by phosphorylation using Cdc2 kinase and ATP as phosphate donor. There exist two condensins, I and II and their functions are not entirely overlapping. Aurora B phosphorylates Ser10 on Histone H3 in chromosomal binding of condensin I and in mitotic chromosome condensation (Takemoto A et al 2007 Nucleic Acids Res 35:2403). ► [cohesin](#), ► [XCAP](#), ► [mitosis](#), ► [Cdc2](#), ► [Aurora](#), ► [ATP](#), ► [topoisomerase](#), ► [SMC](#), ► [sister chromatids](#), ► [Mosolov model](#); Hirano T 2000 Annu Rev Biochem 69:115; Kimura K et al 2001 J Biol Chem 276:5417; Kirsten A et al 2003 Nature Rev Genet 4:520; quantitative method to monitor chromosome condensation kinetics in living cells expressing GFP fused to a core histone: Maddox PS et al 2006 Proc Natl Acad Sci USA 103:15097.

Conditional Distribution: In conditional distribution, the distribution of one random variable or the joint distribution of several variables is affected by holding one variable at a fixed value.

Conditional Dominance: ► [dominance reversal](#)

Conditional Lethal: dies under certain conditions (e.g., high, nonpermissive [restrictive] temperature), but is viable under others (e.g., low, permissive temperature). Many auxotrophs are conditional lethal because they survive only when the required nutrient is provided. ► [temperature-sensitive mutation](#), ► [auxotroph](#), ► [conditional mutation](#)

Conditional Mutation: A conditional mutation is expressed only under the condition(s) required. Such mutations may be extremely useful for the study of conditional lethal genes. Conditional expression may also be regulated by agents that affect transcription and/or translation or conformation of the proteins (heat-shock, heavy metals, hormones, repressors, DNA-binding proteins, dimerization of transactivator, signal transduction, etc.). ► [conditional lethal mutation](#), ► [temperature-sensitive mutation](#), ► [auxotrophs](#), ► [and other terms mentioned under separate entries](#); Lewandoski M 2001 Nature Rev Genet 2:743; Genesis vol. 32:49–191 [2002]; Gossen M, Bujard H 2002 Annu Rev Genet 36:153.

Conditional Probability: Conditional probability is not based on absolute frequencies but, e.g., one group is fixed in a matrix. When we have three genotypes AA, Aa and aa, their frequencies add up to one. If one of the groups is fixed then another must be one of the two genotypes. In other words, probability depends

on what events have already taken place. ►Bayes' theorem, ►risk

Conditional Targeting: A gene targeting procedure aimed either at specific tissues or developmental stages or at both. ►targeting genes, ►knock-out, ►knock-in, ►knockdown

Conditionally Dispensable Chromosomes: Same as B chromosomes.

Condom: A rubber shield worn over the penis during sexual intercourse. It prevents pregnancy and also protects both partners from sexually transmitted disease. The effectiveness is not perfect and the failure of protection has been estimated to be 10–20% (Steiner MJ et al 2006 New England J Med 354:2642). The incidence of genital human papilloma virus was 37.8% per-patient years for constant condom use versus 89.3% when in 5% of the time condom was not used (Winer RL et al 2006 New England J Med 354:2645). ►contraceptive, ►papilloma virus

Conductance: In conductance, a non-conjugative plasmid can be transmitted to a recipient cell by cointegration into a mobile, conjugative plasmid. ►plasmid, ►conjugation, ►cointegration

Conductin: An 840-amino acid protein equipped with a β -catenin-, a RGS- (regulator of G protein signaling) and a glycogen synthase kinase-3 β -binding domains. This complex interacts also with various fragments of APC (adenomatous polyposis) tumor suppressor protein. Conductin contributes to the degradation of β -catenin, whereas APC interferes with this degradation. Conductin is homologous to axin and it also capable of similar functions. ►axin, ►catenin, ►RGS, ►adenomatous polyposis, ►GSK; Siderovski DP et al 1999 Crit Rev Biochem Mol Biol 34:215.

Cone: A fruiting structure bearing sporangia, e.g., a pinecone. ►sporangium). Also the retinal cone in the eye is a visual cell. ►retinitis pigmentosa, ►retinoblastoma, ►ommatidium

Cone Dystrophy: A group of dominant diseases involving loss of color vision, photophobia, and reduced central vision acuity occurring at a frequency of $\sim 1 \times 10^{-4}$. Responsible genes have been assigned to 17p12-p13, 6q25-q26, 6p21.1 and Xp21.1-p11.3. The 6p21.1 mutations involve the guanylate cyclase-activating protein. ►ABC transporter; Wilkie SE et al 2001 Am J Hum Genet 69:471.

Cone Pigments: Cone pigments are present in the retina and mediate color vision. ►cone

Cone-Rod Dystrophy: ►ABC transporters

Confidence Intervals: Population parameters can be estimated by *point estimates* and by *interval estimates*. The former specifies the parameter itself; the latter defines the range of values within which, the parameter is expected at a certain level of confidence (probability). If we obtain an average value in a population, we would like to know the range of probability within which, the real, true average might fluctuate by 95% or other confidence of choice. Confidence intervals (C.I.) for reasonably large populations can be determined with the formula: $C.I. = p \pm z \sqrt{pq/n}$ where p and q are the proportions observed ($p + q = 1$), z is the critical value for the normal distribution at a given level of confidence. $z = 1.96$ (for 95%), 2.58 (for 99%), and 3.29 (for 99.9%); it is not very useful to go for even higher z values because then the range will be so wide that it will become almost meaningless. n = the number in the population counted or measured. Example: a population of 140 consists of 2 groups represented by 60 ($p = 60/140 \approx 0.43$) and 80 ($q = 80/140 \approx 0.57$). C.I. for $p = 0.43 \pm 1.96 = 0.43 \pm 1.96 \times 0.04184 = 0.43 \pm 0.08$. Therefore, the frequencies and 0.51 and 0.35 are the 95% confidence limits of the experimentally observed p . Example: a population of 140 consists of two groups represented by 60 ($p = 60/140 \approx 0.43$) and 80 ($q = 80/140 \approx 0.57$). C.I. for $p = 0.43 \pm 1.96 \sqrt{(0.43)(0.57)/140} = 0.43 \pm 1.96 \times 0.04184 = 0.43 \pm 0.08$. Therefore the frequencies and 0.51 and 0.35 are the 95% confidence limits of the experimentally observed p .

Alternatively, the 95% confidence belts can be used. (see Fig. C149); ►inference statistical, ►credible interval

Confidentiality: The code of ethics and many state laws in the US prohibit physicians from disclosing any medical information to a third party, even in court. Some courts permit disclosure if the third party is in imminent danger by a genetic or an infectious disease. ►genetic privacy, ►privacy rules, ►wrongful life, ►counseling genetic, ►paternity test, ►informed consent, ►bioethics; Cohen PE, Wolpert C 1998 In: Haines JL, Pericak-Vance MA (eds) Approches to Gene Mapping in Complex Human Diseases. Wiley, New York, p. 131.

Conflict, Evolutionary: In an evolutionary conflict, the spread of an allele lowers the fitness of the individual or its progeny. In some cases, one allele may be advantageous in one sex but disadvantageous in the other. To neutralize its effect, suppressor genes may evolve. ►meiotic drive

Figure C149. Confidence intervals. Use of the confidence chart: Calculate from the experimental data the frequencies p and q . At the intersections of the vertical line corresponding to “frequency” and the 2 belts (curves) numbered and indicating the size of the sample (population), one can read the percentage of upper and lower confidence. This chart also facilitates an estimate of the (1) repeatability of the fractions obtained, (2) the statistical range of the fractions, and (3) the size of the population where a chosen fraction will be represented by a number of individuals (counts) within the specified range. E.g., the frequency observed is 0.20. The confidence limits at probability 0.95 for a population of 100 will be 29 and 12. Or if the expected frequency is 0.25 and one is willing to accept a latitude of 10% (i.e. a frequency between 0.20 and 0.30), the minimum population size required is 200 at $P = 0.95$ because this latitude is bracketed by the 200 belts. (From Koller S 1956 In: Rauen HM (ed) *Biochem. Taschenbuch*, Springer-Vlg., Berlin)

Confluent: The cell culture that extends over the entire surface of the medium.

Confocal Microscopy: Confocal microscopy permits the formation of a three-dimensional image by focusing laser or other light through a pinhole and with a dichroic mirror to a distinct small area of the object. The fluorescent light emitted from that small focal point is then reflected through another (confocal) pinhole (i.e., this second pinhole is exactly in the focus of that area of the object) and thus a sharp image is received on a detector. The images of the areas not in focus are thus obliterated. Subsequently, the light is focused at several other points and the image of each point is registered on the video screen, thus building

up a three-dimensional integrated picture. If the pinholes are moved in a synchronous manner, a scanning real-time imaging can be obtained. ▶ [microscopy](#)

Conformation: An arrangement of a molecule in space that does not require the severance of any bond because of their freedom of rotation. Point mutations and sequence rearrangements do not substantially alter the original conformation. It has been shown, however, that the nucleotide sequences in the DNA d(CCXGGGACCGG) and d(CCGGTACCGG) crystallize as 4-stranded Holliday junctions. From the 64 permutations of the sequence d(CCnnnN₆N₇N₈GG), evidence was found for B-DNA, A-DNA and

Holliday junctions. ($N_6N_7N_8$ stand for any of the four natural nucleotides and *nnn* are specified to maintain self-complementarity in the sequence, complying with Watson & Crick base pairing). This finding indicates that significant conformational changes result from sequence variations and not from crystal or crystallization effects (Hays FA et al 2005 Proc Natl Acad Sci USA 102:7157). RNAs also fold in special conformation and the native structure is stabilized by peripheral elements tightly bound to the core they surround (Johnson TH et al 2005 Proc Natl Acad Sci USA 102:10176). ►folding, ►chaperone, ►protein structure, ►protein folding, ►morphoein, ►porphyria; Sinha N, Nussinov R 2001 Proc Natl Acad Sci USA 98:3139; conformational changes: <http://molmovdb.org/>.

Conformation Correction: Multimeric proteins may be inactivated by mutation in a subunit that affects the conformation of that polypeptide chain. Another mutation may alter the conformation of another subunit in such a way that the first defect in conformation is corrected and the activity of the enzyme is at least partially restored. It was assumed that some allelic complementation observed is based on such a correction. ►dominant negative, ►allelic complementation; Soto C 2001 FEBS Lett 498:204.

Conformational Diversity: Through conformational diversity, the protein would have the ability to assume more than one conformation, which may enable rapid evolution. ►promiscuous protein; James LC, Tawfik DS 2003 Trends Biochem Sci 28:361.

Conformation-Dependent Immunoassay: The conformation-dependent immunoassay distinguishes between PrP^C and PrP^{Sc} on the basis that a specific epitope is exposed on the surface of the normal prion, but it is hidden in the infectious PrP^{Sc} isoform. It can be used with both the protease-sensitive and the protease-resistant PrP^{Sc} because proteolysis is not required for the assay. ►prion, ►immunoassay

Conformation-Sensitive Gel Electrophoresis (CSGE): CSGE distinguishes DNA segments heterozygous for different sites at a gene. In homozygotes, only a single type of band is formed in the gel, e.g., AB (homoduplex). In heterozygotes, Ab, aB (heteroduplexes) and AA and BB (homoduplexes) are expected.

Confounding: Confounding is the omitting of a particular experimental comparison in order to reduce the error variation. In a factorial design, some, interactive elements are not distinguishable alone but only in combination. Confounding occurs also when the consequence of a specific experimental exposure or genetic condition is not distinguishable from the

effects of other variables that affect the outcome of the treatment. ►factorial experiment

Congeneic: Same as congenic; it is frequently used this way in immunogenetics.

Congener: The term congener refers to an organism/organic substance related to something by origin and/or function, biologically or chemically; or to species belonging to the same genus.

Congenic Resistant Lines of Mice (CR): CR contain a new histocompatibility gene locus introduced from another inbred (or any other) line. Earlier these were called IR (isogenic resistant) lines. Mating inbred line #1 with known histoincompatible line #2 generates such CR lines. The hybrid accepts grafts of #1. In the progeny of hybrids mated inter se, some segregants do not reject transplants of #1. These will be further backcrossed with #1. After 7 backcrosses the "hybrid" will have in over 99% ($1-0.5^7$), the same chromosomes as parent #1.

Upon continued brother-sister matings (usually for 20 generations), an individual may show up that rejects grafts from #1. This is further backcrossed to #1 and the progeny will be selected to resistance against transplants to #1. Such a line is congenic resistant, i. e., almost identical (with the exception of histocompatibility gene) with #1. Some very closely linked genes to the histoincompatibility locus of #2 may not be eliminated, however, from the CR line. Today, the selection may be facilitated by serological assays rather than by expensive transplantation experiments. Also, the desired genes can be transferred by transfection without the need of repeated backcrosses. The development of a large number of CR lines permit the identification of allelism and complementation groups of histocompatibility genes. The serological assays permit the identification of strong and weaker responses, and on this basis major and minor histocompatibility genes can be classified. ►HLA, ►MHC; Fortin A et al 2001 Proc Natl Acad Sci USA 98:10793.

Congenic Strains: Congenic strains are identical, except at one locus or in a very limited region of a chromosome; they are obtained by repeated (10–20) backcrosses. These lines can be used to determine the effect of a particular gene on a selected genetic background. Using eggs obtained by hormone-induced superovulation of prepubertal (three weeks old) mice and in vitro fertilization followed by embryo transfer, the generation time can be shortened to 6 weeks and within a year the desired results may be obtained. ►congenic resistant lines of mouse, ►coisogenic, ►isogenic, ►inbreeding, ►ART, ►substrain, ►subline

Congenital: A congenital condition is a condition one is born with, regardless of whether it is due to direct genetic or developmental causes. ▶familial, ▶hereditary

C

Congenital Adrenal Hyperplasia: Congenital adrenal hyperplasia has a prevalence of about 0.0002–0.0001 but in some populations it may occur in a higher frequency. It is based on the deficiency of an enzyme in cortisol (steroid) biosynthesis. The accumulation of the precursor results in virilization of female babies. The condition can be successfully treated by glucocorticoids given to the mother. The autosomal recessive gene(s) are closely linked to the HLA loci in human chromosome 6. Prenatal identification is feasible by linkage with appropriate DNA probes. There are, however, other types of steroid hydroxylase deficiencies encoded in other chromosomes. ▶genetic screening, ▶cortisol, ▶glucocorticoid, ▶HLA, ▶adrenal hypoplasia, ▶adrenal hyperplasia congenital

Congenital Biplasic Aplasia of the Vas Deferens (CBAVD): An autosomal recessive absence of the excretory channel(s) of the testes resulting in azoospermia. ▶azoospermia, ▶cystic fibrosis, ▶vas deferens, ▶P2X

Congenital Disorders of Glycosylation (CDG): CDG Type Ib (15q22-ter) is a defect in mannosephosphate isomerase, and Type Ia (16p13.3-p13.2) is a defect of phosphomanno-mutase-2. The basic problem is the unsatisfactory glycosylation of glycoproteins. The clinical consequences are neurological defects, blood coagulation problems, eye malformations, heart and kidney disease, abnormal transferrin, etc. The symptoms in the Type Ib disease can be alleviated by mannose. Type Ic (1p22.3) is an abnormality in the transfer of glucose to lipid-linked oligosaccharides. Several other variants have also been distinguished.

Congenital Hypothyroidism: The defective development of the thyroid gland causing goiter, mental retardation, deafness, etc. because of deficiency of the thyroid hormone. ▶goiter

Congenital Trait: A trait that is evident at birth and is due to either hereditary or other causes. ▶familial trait

Congression: The assembly of chromosomes in the metaphase plane (see Fig. C150). Septin protein scaffold is required for congression, orderly segregation, and cytokinesis (Spilotis ET et al 2005 Science 307:1781). Mammalian chromosomes can congress to the equator without being connected to the spindle fibers, although that is generally required for proper orientation (biorientation) so the chromosomes

would be properly distributed toward the poles (Kapoor TM et al 2006 Science 311:388). ▶septins, ▶cytokinesis, ▶mitosis, ▶meiosis

Figure C150. Congression. (Photomicrograph is the courtesy of Dr. Arnold Sparrow)

Congruence Analysis: The congruence analysis tests the appropriateness of conclusions reached by different methods in the study of evolutionary trees. ▶homology, ▶xenology

Congruency: Congruency in a genetic or metabolic network indicates the measure of partner sharing.

Congruent Genes: Genes that share sequences in the chromosome.

Conidia (conidiospores; in singular conidium): Asexual, uninucleate fungal spores that appear externally on a hypha by abstriction. Such a hypha is a conidiophore. ▶macroconidia, ▶microconidia, ▶fungal life cycle; Kellner EM, Adams TH 2002 Genetics 160:159.

Conidiophore: (see Fig. C151). ▶conidia

Figure C151. Conidiophore

Conjugate Redox Pair: An electron donor and the corresponding electron acceptor, e.g., NADH and NAD⁺.

Conjugated Protein: A conjugated protein contains prosthetic group(s); e.g., an iron or magnesium heme in hemoglobin and chlorophyll, respectively.

Conjugation, Bacterial: Conjugation generally means mating. In bacteria, conjugation is the physical contact between F⁺ donor and F⁻ recipient cell and the unidirectional transfer of the (Hfr) chromosome

by a rolling circle replication procedure through the conjugation tube (see Fig. C152). Approximately 12 μ m DNA is transferred per minute. The standard genetic map of bacteria is based on the time in minutes required for the conjugational transfer of genes from donor to recipient.

The conjugational transfer may be clockwise or counter-clockwise depending on the orientation of the (Hfr) element in the bacterial chromosome (see Fig. C153).

The transmission of plasmids from one cell to another requires a conjugational mechanism. Conjugation requires cellular contact, controlled by the mating pair formation system (Mpf). In *Agrobacteria*, besides the T-DNA, multisubunit protein complexes are also transmitted to the eukaryotic cell. The Tra and Mpf proteins organize the conjugative pilus. The transforming plasmids that generally lack the *mob* gene required for mobilization of chromosome (genophore) or plasmid are unable to form recombinant

DNA. For some of the plasmids, the mobilization factor can be provided in trans by a helper plasmid (ColK). Col plasmids code for a protein that opens up the circular DNA at the *nic* site close to *bom* (bacterial origin of mobilization). Some plasmids lack the *nic/bom* system and cannot be transferred through conjugation (non-conjugative plasmids). The latter type is favored for containment of recombinants. In the majority of bacteria conjugation is not a standard mode of reproduction, unlike in true sexual organisms. Recent reexamination of the data indicates linkage disequilibrium in bacterial populations.

In *Mycobacterium smegmatis*, the conjugal transfer is mediated by the chromosome rather than by an F plasmid (Wang J et al 2003 Nature Genet 34:80).

Using the RK2 plasmid system, bacterial DNA can be transferred to yeast cells as well as to Chinese hamster ovary cells (Waters VL 2001 Nature Genet 29:375). ▶Hfr, ▶conjugational mapping, ▶bacterial recombination frequency, ▶relaxosome, ▶*ori_T*, ▶*tra* genes, ▶pilus, ▶non-plasmid conjugation, ▶Fplasmid, ▶linkage disequilibrium, diagram of bacterial conjugation, ▶RK2 plasmid, ▶CHO, ▶conjugation *Paramecia*; Ippen-Ihler KA, Minkley EG Jr 1986 Annu Rev Genet 20:593; Frost LS et al 1994 Microbiol Rev 58:162; Lanka E, Wilkins BM 1995 Annu Rev Biochem 64:141; Matson SW et al 2001 J Biol Chem 276:2372; Frost LS et al 2005 Nature Rev Microbiol 3:722; Christie PJ et al 2005 Annu Rev Microbiol 59:451.

(On the basis of F. Jacob, and E. L. Wollman, 1961. Sexuality and Genetics of Bacteria. Academic Press, New York.

Figure C154. Conjugation mapping

Conjugation Mapping: The transfer and integration of genes of the Hfr chromosome to the recipient in bacteria is measured by interrupted mating and the map is constructed on the basis of minutes required for the linear transfer of a particular marker(s). For the complete transfer ca. 90–100 minutes are required (40–45 kb/2–3 minute intervals). By conjugational recombination, the complementary products of the exchange are not recovered, and the surviving products are the results of double recombination. The single strand transferred becomes double-stranded after entering the recipient (F⁻) cell. (See Fig. C154, ►Hfr, ►conjugation, ►bacterial recombination frequencies, ►F plasmid, ►conjugation bacterial; Jacob F, Wollman EL 1961 Sexuality and the Genetics of Bacteria. Academic Press, New York).

Conjugation, Paramecia: Conjugation in paramecia is the sexual reproduction of these unicellular protozoa that most commonly reproduce asexually by fission (see Fig. C155). During conjugation, two cells of

Figure C155. Conjugation, *Paramecia*

opposite mating types appose and meiosis gets underway in the micronuclei. From the four meiotic products, only one survives in both cells and that divides twice by mitosis generating four haploid nuclei in the two cells, each. One of the gametes is then passed over to the other cell through a conjugation bridge in a reciprocal manner, resulting in mutual fertilization and in two diploid conjugants. Subsequently, the pair separates and, *exconjugants* are formed. The macronucleus has only metabolic but no known genetic role and it disintegrates in both cells. Subsequently, the diploid micronucleus undergoes two mitotic divisions, and two of the four mitotic products fuse to regenerate the macronucleus. The remaining two nuclei form diploid micronuclei. *Paramecia* may reproduce also by *autogamy* in the absence of conjugation. Meiosis may take place and four haploid nuclei arise from which again only one survives. The survivor divides again into two, which after fusion generate a diploid homozygote. If the conjugation lasts for longer periods, cytoplasmic elements are also transferred along with the gametes. ►*Paramecium*; Preer JR 1971 Annu Rev Genet 5:361.

Conjugation Tube: ►pilus, ►conjugation bacterial, ►mating bacterial

Conjugative Plasmids: ►conjugation of bacteria, ►plasmid

Connectin: Same as titin. ►titin

Connection Maps: ►genetic networks, ►signal transduction

Connective Tissue Disorders: Connective tissue disorders involve cells with substantial extracellular matrix, which provides structural support, such as bone, cartilage, etc. In the majority of disorders, collagen synthesis is affected. ▶[skin diseases](#), ▶[osteogenesis imperfecta](#), ▶[collagen](#), ▶[Marfan syndrome](#), ▶[Ehlers-Danlos syndrome](#), ▶[Stickler syndrome](#), ▶[Kniest dysplasia](#), ▶[arthritis](#), ▶[Reiter syndrome](#), ▶[pseudoxanthoma elasticum](#), ▶[lupus erythematosus](#), ▶[HLA](#), ▶[autoimmune disease](#)

Connective Tissue Growth Factor (CTGF, 6q23.1): CTGF is a 38-kDa secreted protein, encoded in the vicinity of c-Myc proto-oncogene and it has some homology to insulin-like growth factor. It is required for growth and development, but its upregulation may contribute to tumorigenesis. ▶[angiogenesis](#); Bradham DM et al 1991 J Cell Biol 114:1285.

Connectivity Map: The connectivity map represents gene expression profiles as affected by small molecules (drugs) and diseases (Lamb J et al 2006 Science 313:1929). It can shed light on the mechanisms of action of certain drugs and the responses of physiological processes (diseases) to various treatments.

Connexins: Connexins provide elements of gap junctions; they are built of six polypeptides. All connexins have four membrane-spanning domains, two extracellular loops, a cytoplasmic loop and cytoplasmic amino and carboxyl termini. Connexins may form connexons, the pore of gap junctions. Connexins may have role in heart diseases, infertility, cataracts, deafness, heterotaxy, etc. Mutations in mouse genes coding for connexin26 (Cx26, in human chromosome 13q11-q120) and/or Cx30 (human chromosome 13q12) are linked to approximately half of all cases of human autosomal nonsyndromic prelingual deafness. Cx26 and Cx30 are the two major Cx isoforms found in the cochlea, and they co-assemble to form hybrid (heteromeric and heterotypic) gap junctions. In the absence of the Cx30 gene, Cx26 expressed from extra alleles was found to completely restore hearing sensitivity and prevented hair cell death in deaf Cx30^{-/-} mice. Up-regulation of Cx26 or slowing down its protein degradation might be a therapeutic strategy to prevent and treat deafness caused by Cx30 mutations (Ahmad S et al 2007 Proc Natl Acad Sci USA 104:1337). Connexins are encoded in human chromosomes 1p35, 6q21-q23.2, 13q11, and Xq13.1. ▶[gap junctions](#), ▶[innexins](#), ▶[deafness](#), ▶[erythrokeratoderma variabilis](#), ▶[ectodermal dysplasia](#), ▶[cataracts](#), ▶[Charcot-Marie-Tooth disease](#), ▶[oculodentodigital dysplasia](#); Kelsell DP 2001 Trends Cell

Biol 11:2; Abrams CK et al 2006 Proc Natl Acad Sci USA 103:5213.

Connexon: ▶[connexins](#)

Conplastic: A conplastic strain has the mitochondrial genome of one strain but the nuclear genome is derived from another. Conplastic strains are obtained by at least ten backcrossing of a female by a nuclear genome donor male. The probability that the nuclear genome is of the donor type is $1-0.5^n$, n = number of backcrosses. ▶[mtDNA](#), ▶[mitochondrial genetics](#), ▶[chloroplast genetics](#)

Conradi-Hünemann Disease: ▶[chondrodysplasia](#), ▶[CHILD syndrome](#)

Consanguinity: ▶[coefficient of coancestry](#), ▶[inbreeding coefficient](#), ▶[genetic counseling](#)

Consciousness: Awareness, sensory discrimination of events in the outside world and the body. Consciousness as a field of scientific inquiry evolved from moral, ethical, and religious notions of the ability and choice between right and wrong. Currently science makes efforts to understand the basic mechanisms how the wiring of the nervous system and the concomitant physiological/molecular functions control consciousness. Unfortunately, neurophysiology does not yet have entirely adequate tools to tackle many of the problems involved. Much progress, however, is underway. (See Crick FC, Koch C 2005 Philos Trans Roy Soc Lond B Biol Sci 360:1271).

Consed: One of the frequently used DNA sequence alignment/editing programs. ▶[PHRED](#), ▶[PHRAP](#), ▶[PolyPhrap](#); Rieder MJ et al 1998 Nucleic Acid Res 26:967.

Consensus: Consensus is the existence of basically common (although generally not entirely identical) nucleotide sequence at certain positions among some DNAs or amino acids in proteins. Consensus is indicative of a common functionally important role such as the TATA box, transcription termination signals, etc. On the basis of the organization of consensus sequences, consensus maps may be constructed indicating phylogenetic relationships. ▶[core sequences](#), ▶[CCDS](#)

Conservation Genetics: Conservation genetics is concerned with the population genetics principles involved in the maintenance of feral species. The maintenance of the populations depends on inbreeding, outbreeding, effective population size, deleterious mutation, reproductive success, adaptation to captivity, reintroduction, vagility, outbreeding depression, extinction, etc. (See ▶[terms under separate entries](#), ▶[species extant](#), ▶[admixture](#); Frankham R 1995 Annu Rev Genet 29:305; goals for mammals;

Ceballos G et al 2005 Science 309:603; large *Felidae* [tigers and others]: O'Brien SJ, Johnson WE 2005 Annu Rev Genomics Hum Genet 6:407).

C

Conservative Replication: An early idea of DNA replication suggesting that after replication each double-stranded molecule would contain either two old or two new single strands. ► [semi-conservative replication](#), ► [replication](#), ► [DNA replication](#), ► [replication fork](#)

Conservative Substitution: In conservative substitution, an amino acid replaces another in a polypeptide chain with similar properties. ► [radical amino acid substitution](#)

Conservative Transposition: ► [transposition](#)

Conserved Domain Database: Database of proteins domains and structure: <http://130.14.29.110/Structure/cdd/cdd.shtml>; <http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi>; evolutionarily conserved proteins; <http://www.everest.cs.huji.ac.il/>.

Conserved Noncoding Elements (CNE): CNE do not code for either protein or RNA, yet they occur across many mammalian genomes. Their function is unknown but it is supposed they have important regulatory roles to have been conserved during evolution. ► [non-coding DNA](#); Kamal M et al 2006 Proc Natl Acad Sci USA 103:2740.

Conserved Sequences: ► [consensus](#), ► [comparative maps](#)

Consilience: The search for scientific/philosophical principles that are very widely applicable.

Consinspector: ► [Genome Inspector](#) (Frech K et al 1997 Comput Appl Biosci 13:109).

Consomic: After 10 or more backcrosses of a male to an inbred recipient female strain, all the chromosomes (0.5^{10}) will belong to the recipient strain—at very high probability—except the Y chromosome. ► [con- plastic](#), ► [chromosome substitution](#)

Conspecific: Conspecific refers to individuals, strains or varieties belonging to the same species.

Constant Genome Paradigm: The constant genome paradigm visualized the genetic material in a stable form because insertion or transposable elements were not yet known. The Fluid Genome idea was developed after the discovery of the mobile genetic elements, which are capable of restructuring the genome. ► [transposons](#), ► [transposable elements](#)

Constitutional: It was present in the individual at birth; it was present in one or both gametes and so all cells

of the individual are expected to carry it except when new mutation occurs during development. ► [acquired](#)

Constitutional Translocation: Constitutional translocation between 11q13 and 22q11 in AT-rich regions is presumably the only recurrent translocation besides the Robertsonian translocations. It leads to different types of human hereditary diseases.

Constitutive Cycling: The function of transmembrane proteins such as receptors, channels, and transporters can be rapidly modulated by plasma internalization and release in response to hormones and other regulatory molecules also involving disease. (Royle SJ, Murrell-Lagnado RD 2003 Bioessays 25:39).

Constitutive Enzyme: Constitutive enzymes function at a rather constant level in all cells, all the time. ► [housekeeping genes](#), ► [inducible enzymes](#)

Constitutive Gene: The rate of the transcription of a constitutive gene is not subject to the effect of regulator gene(s). ► [housekeeping genes](#)

Constitutive Heterochromatin: Constitutive heterochromatin is heterochromatic at all stages and in all cells, indicating that these sequences are never transcribed. ► [heterochromatin](#), ► [euchromatin](#)

Constitutive Mutations: Constitutive mutations are those that lost their regulatory element(s) and are always in an “on” position. ► [constitutive gene](#)

Constitutive Splicing: Constitutive splicing of primary RNA transcripts occurs when the exons are spliced together in a single pattern consistent with their order in the gene. ► [alternative splicing](#), ► [introns](#)

Constitutive Triple Response (CTR): CTR is the reaction of plants to ethylene, in which the plumular hook is retained, geotropic response is prevented, and there is reduction of stem elongation. ► [plant hormones](#), ► [plumule](#); Guzman P, Ecker JR 1990 Plant Cell 2:513.

Constrained Elements: Orthologous genomic DNA is enriched in conserved functional elements saved by purifying selection. In the human genome, in ~1.9 Mbp sequence about 3.9 neutral substitutions were found and these cover approximately 5.5% of the human gene loci (Cooper GM et al 2005 Genome Res 15:901). In humans, about 40% of the constrained elements are within coding regions and 20% overlaps with regulatory stretches. ► [orthologous loci](#)

Constriction, Chromosomal: The primary constriction (C) is the centromere and the secondary constriction may tie an appendage to the end of the chromosome by a relatively thin stalk (see Fig. C156). These secondary constrictions are frequently called *satellites* (S) and are associated with the nucleolus

(nucleolar organizer region). The nucleolus contains RNA and till the early 1930s was believed not to contain DNA at all, hence was also known as SAT for *sine acido thymonucleico* (without thymonucleic acid); DNA then being called thymonucleic acid. ▶centromere, ▶satellite

Figure C156. Chromosomal constriction

Construct: A construct is most commonly used for the designation of a specially built plasmid or engineered chromosome.

Consultand: An individual seeking genetic counseling.

Contact Guidance: The physical environment in the tissue may guide the movement of axons. ▶axon

Contact Inhibition: Normal animal cells are anchorage dependent in culture and grow in monolayer because of inhibition by neighbor cells. Cancer cells lose the dependence on anchorage and constraints in growth by neighbors. This is associated also with changes in cell morphology. The oncogenic transformant cells thus, can pile up in an apparently disorganized manner into tumors.

Some *E. coli* strains are also inhibited in growth when they encounter another strain. The inhibitory strain must have a special growth state and the target cells must express pili. In addition, two proteins CdiA and CdiB are required (Aoki SK et al 2005 Science 309:1245). ▶saturation density, ▶cancer, ▶metastasis, ▶pilus; Baba M et al 2001 Oncogene 20:2727.

Contact Map: A contact map represents the proteins that are in contact. (See MacCallum RM 2004 Bioinformatics 20 Suppl. 1:1224).

Containment: A safe place from where hazardous material, including certain type of biological vectors, cannot presumably escape, and thus can be worked with, safely. ▶laboratory safety, ▶biohazards

Context, Genetic: The contribution or effect of genes outside the locus of primary concern. Many genes perform different role in different organs depending upon the effect of other genes active in the different environment.

Contig: A set of (partially overlapping) DNA fragments. A contig includes a complete region of the chromosome without gaps. For the determination of contigs, large capacity vectors are used, e.g., YACs (up to 1–2 megabase), BAC, (~150 kb), P1 plasmid (100 kb),

and cosmids (40 kb). The genome assemblies are characterized by the degree of sequence continuity expressed as N50. The N50 contig length of the Human Genome Project is ~82 kb and that of Celera is ~86 kb. ▶genome project, ▶Celera, ▶N50 length, ▶YAC, ▶BAC, ▶cosmid, ▶anchoring, ▶tiling; Hall D et al 2001 Genetics 157:1045.

Contiguous Gene Syndrome: Deletions resulting in phenotypes consistent with over-lapping functional sequences of more than one gene. It is synonymous with segmental aneusomy. ▶aneusomatic, ▶deletion, ▶Prader-Willi syndrome, ▶Wilms tumor, ▶polyposis adenomatous, ▶retinoblastoma, ▶Miller-Dieker syndrome, ▶Beckwith-Wiedemann syndrome, ▶Alagille syndrome, ▶diGeorge syndrome, ▶Lange-Giedion syndrome, ▶Angelman syndrome, ▶Norrie disease, ▶granulomatous gene syndrome, ▶muscular dystrophy, ▶McLeod syndrome, ▶glycerol kinase deficiency

Contingenci Loci: ▶SSR

Contingency Table: ▶association test

Continuity, Genetic: Genetic continuity is assured by mitotic nuclear divisions. Equal halves of each chromosome (derived by equational division) are shared between the two daughter chromosomes that are identical to those of the maternal cells (barring mutation, chromosomal breakage or accidents). ▶mitosis

Continuous Trait: A continuous trait displays a range of expression (such as weight, height, etc.) rather than an all-or-none appearance (such as white or red). Continuous traits are usually under polygenic control and subject to substantial environmental influence in expression. ▶polygenes, ▶QTL, ▶continuous variation

Continuous Variation: In continuous variation, a trait shows a range of expression forming a quantitative series, without sharply separate classes. The majority of such quantitative traits are based on the collective effects of numerous genes (polygenic systems) that each may have only small effect but cooperatively they may bring about large variations. Traits subject to continuous variation are characterized by their adaptation to the normal distribution or some classes of it. These variations are affected also by environmental factors and the outcome is a continuous or almost continuous series, and from a relatively small to a relatively large phenotypic effect. Continuous variation cannot be classified into discrete categories such as black or white but they have a running spectrum. The characterization is made by counting or measurements or by systems of grading (such as learning scores, disease susceptibility, etc.). The

study of continuous variation requires statistical tools such as mean, variance, standard deviation, tests of significance, correlation, regression, heritability, etc. (See topics mentioned under separate entries, ►**QTL**)

C

Contraceptives: ►sex hormones, ►hormone, ►receptors, ►menstruation, ►immunocontraceptive, ►STAT, ►mifepristone, ►RU486, ►eppin, ►ensoulment, ►male contraceptive

Contractile Ring: The contractile ring is made of actin filaments and positioned in the cell equator, and it is instrumental in cutting apart the two daughter cells after the completion of mitosis or fission of bacteria. ►cell cycle, ►cytokinesis, ►Fts Z ring; Pardo M, Nurse P 2003 Science 300:1569.

Contractile Vacuoles: Contractile vacuoles occur in ciliated algae near the base of the flagella. ►flagellum

Contralateral: affects both sides (e.g. both breasts) versus ipsilateral. ►ipsilateral

Contrasélection: In contrasélection, selecting for one desirable trait, e.g., high lactation, may prove negative for the breeder, as consequently, producers may become susceptible to disease or otherwise less vigorous. The selection may affect linked genes or physiological correlation.

Control (check): A standard to which experimental data are compared. The standard must be identical and treated identically to the experimental material except of the special condition (genotype, developmental stage, time, chemicals, etc.) being studied. The *negative control* includes all elements except the

genetic (or other) condition under investigation. The *positive control* is a similar sample, e.g., another DNA [female DNA extract if Y-chromosomal DNA is to be studied], just to see that the experimental system works. *Blind control* is used to test for possible contamination of the reagents, e.g., all the extraction and purification steps are taken without the actual sample material. *No-template control* uses all the DNA amplification reagents except any DNA. Use of appropriate controls is indispensable in the objective evaluation of scientific data. ►concurrent control, ►historical control, ►standard

Control Region: Mitochondrial DNA sequences (~1 kb in vertebrates) devoid of structural genes, but containing replicational and transcriptional signals constitute the control region. Aging has been attributed to increased mutation rate in this region of the mtDNA. ►mitochondria, ►mtDNA, ►aging, ►mitochondrial diseases in humans [for map position]; Howell N, Smejkal CB 2000 Am J Hum Genet 66:1589.

Controlled Mating: The chart shows the percentage of homozygosity in successive generations of controlled mating systems and the limit of eventual homozygosity after an infinite number of generations (see Fig. C157). "Controlled" implies that the mating is not random but is controlled by some plan. Different mating systems have important consequences for the genotypic composition of the population.

Controlled mating is generally used by plant and animal breeders and in all types of genetic experiments.

Figure C157. Controlled mating

Controlled mating of humans has been advocated by the discredited negative eugenics movements. The assortative matings based on ethnic, religious, cultural, or other bases within smaller human groups may also be controlled matings with the same biological consequences. Civil and religious laws impose some controlled mating rules involving close relatives. Some state laws prohibited marriage among mentally defective individuals, including even sterilization. Most of the controlled mating laws are no longer enforced in enlightened societies, except for the marriage between close relatives. Controlled mating is very important in animal and plant breeding. Insemination by donor sperm may possibly have some risk since the paternity is generally not known to the offspring and incest may not be prevented. [Chart redrawn after Wright S 1921 *Genetics* 6:167.]
 ▶breeding system, ▶mating system

Controlled Release: Controlled release is an important feature of drugs delivered by porous vehicles that make available the critical substance in a gradient of need.

Controlled Vocabulary: Controlled vocabulary is a term used in bioinformatics for indicating that a standardized form is used in a given application. Enzyme nomenclature is a good example for representing the classes of enzymes according to biochemical reaction. ▶bioinformatics, ▶enzymes

Controlling Elements: The historical term for plant transposable elements that can occupy different positions in the plant chromosome, regulate the expression of various genes, and cause insertional mutations. ▶*Ac-Ds*, ▶*Dt*, ▶*Spm*; ▶*Mu*, ▶*TAM*, ▶transposable elements, ▶insertion elements, ▶insertional mutation

Convection: An alternative term for non-oncogenic transformation of animal cells by exogenous DNA. (▶transformation, ▶transfection)

Convergence: ▶convergent evolution

Convergent Evolution (homoplasy): As per homoplasy, similarity is based not on common ancestry but adaptive values; i.e., species from different lines of descent assume the forms, structure, and function that are most valuable for their survival, e.g., sea mammals (whales, dolphins) are more similar in some traits to fishes than to terrestrial mammals. Convergence at single sites may be achieved by mutation or gene conversion. The regulatory circuits of genetic networks in *E. coli* and *Saccharomyces cerevisiae* indicate convergent evolution (Conant GC, Wagner A 2003 *Nature Genet* 34:264).

▶divergence, ▶gene conversion, ▶genetic networks; Nevo E 2001 *Proc Natl Acad Sci USA* 98:6233.

Conversion: An early, hypothetical step after the first mutational event in carcinogenesis. During this process, the cells become receptive to tumor promotion (propagation of the mutant cell line), and conversion is eventually followed by progression (involving additional stimulatory mutations) and malignancy. ▶progression, ▶malignant growth, ▶carcinogen, ▶cancer, ▶phorbol esters; Boukamp P et al 1999 *Oncogene* 18:5638.

Conversion: In human-rodent fusion hybrid cell lines, only one human chromosome may be retained and in this monosomic condition the recessive allele can be expressed. The human chromosome is thus converted to a haploid state.

Conversion Ascii: ▶gene, ▶conversion. Segregation is not 4:4 as expected without gene conversion (see Fig. C158).

Conversion ascus 5:3 segr.

Figure C158. Conversion ascus

Convertant: ▶gene conversion

Convertase: A large enzyme complex that activates components of the complement. Several enzymes cleave different components. ▶complement, ▶properdin

Convulsions, Benign Familial Infantile (BFIC1, 19q): Dominant epileptic type seizures beginning at age 3 to 12 months. Two additional loci BFIC2 (16p12-q12) and BFIC3 (2q24) have also been identified. ▶epilepsy, ▶ion channels

Cooled Charge-Coupled Imager: The cooled charge-coupled imager is used for FISH images to reduce random noise during long exposure. Modern fluorochromes are recognized, however, by short exposures.

Coolie's Anemia: ▶thalassemia

Coomassie Brilliant Blue (acid blue, anazolene sodium): A stain for proteins and a reagent for quantitative protein determination. It is also an intravenous LD₅₀ for mice is 450 mg/kg. ▶LD₅₀

Coombs Test: The coombs test detects the presence of erythrocyte antigens in blood typing and also in autoimmune and hemolytic diseases. It is called also antiglobulin test (AGT). The polymorphic serum

gamma globulin complex (IgG), present in about 60% of some populations, may interfere with the reaction. ▶immunoglobulins, ▶agammaglobulinemia, ▶gammaglobulin

C

Cooperate Stability: Dimmers and interacting proteins are not degraded as easily as monomers. Such nonlinear proteolysis affects the function of genetic networks (Buchler NE et al 2005 Proc Natl Acad Sci USA 102:9559). ▶genetic networks

Cooperation: Cooperation has been an important evolutionary motif in the origin of cells, chromosomal linkage groups, multicellularity, colony formation, differentiation, establishment of genetic networks, etc. Natural selection favors cooperation if $b/c > k$, where b = the benefit of altruistic act, c = its cost and k = the average number of neighbors (Ohtsuki H et al 2006 Nature [Lond] 441:502).

It is possible to construct a synthetic obligatory cooperative system, termed CoSMO (cooperation that is synthetic and mutually obligatory), which consists of a pair of non-mating yeast strains, each supplying an essential metabolite to the other strain. The behavior of the two strains in isolation, however, was found to reveal unintended constraints that restrict cooperation, such as asymmetry in starvation tolerance and delays in nutrient release until near cell death. However, the joint system is shown mathematically and experimentally to be viable over a wide range of initial conditions, with oscillating population ratio settling to a value predicted by nutrient supply and consumption (Shou W et al 2007 Proc Natl Acad Sci USA 104:1877). ▶prisoner's dilemma, ▶tragedy of the commons

Cooperativity: A requisite for the formation of molecular complexes by one ligand promoting the binding of the following. ▶ligand

Cooptation: The re-use of an old function for a new purpose.

Coordinate: A system of numbering in space, e.g., the consecutive numbering of genes in a map or atoms in a molecule.

Coordinate Regulation: Coordinate regulation implies that a group of genes are controlled by common regulatory elements such as is the case in operons and regulons (see Fig. C159). The regulation may be induction or repression. In the past, coordinated regulation was assumed only in prokaryotes but correlated expression of adjacent genes has been detected also in yeast, a eukaryote. Developmental processes are based on the cooperation of many genes by both positive and negative control. ▶Lac operon, ▶Arabinose operon, ▶regulon, ▶SL1, ▶SL2, ▶homeotic genes, ▶correlated expression, ▶development, ▶junction of cellular networks, ▶morphogenesis; Finnegan EJ 2001 Trends Genet 17:361.

Co-Orientation: By the end of metaphase, the bivalent chromosomes or homologous chromatids tend to assume positions so the centromeres would face the opposite poles in anticipation of anaphase (see Figs. C160 and C161). This is sometimes called biorientation compared to co-orientation in anaphase I of meiosis when both centromeres of the two chromatids of a chromosome face the same pole to facilitate reductional division. Resolution of chiasmata in oocytes requires proteolysis by separase (Kudo NR et al 2006 Cell 126:135). Co-orientation is controlled by Aurora B and monopolin (Monje-Casas F et al 2007 Cell 128:477). ▶chiasma, ▶separin, ▶Aurora, ▶monopolin, ▶meiosis, ▶mitosis, ▶Rabl orientation

Figure C159. Coordinate regulation. Three stages of a hypothetical scheme leading to the expression of a target gene. The lettered symbols stand for proteins in or entering the nucleus. The double black line represents chromosomal DNA. In the first step, D (cube) and G prevent transcription. In the second step, D is replaced by a modified C, yet it is still insufficient for transcription. In the last step, through the joint action of proteins A + H and B + K, a signal transduction path is activated. When complex X, an aggregate of several proteins (smiley face) reaches the chromatin, inhibitor G is dislodged and inactivated. Thus transcription can proceed. Signs indicate blocks ● or transcription ●

Figure C160. Co-orientation (after M. M. Rhoades)

Figure C161. Co-orientation of centromeres

Co-Ortholog: Same as semi-ortholog.

COP1: A 12-subunit ubiquitin ligase protein complex involved in the regulation of photomorphogenesis of plants and lipid metabolism of animals. It is also a negative regulator of p53 (Dorman D et al 2004 Nature [Lond] 429:86). ▶[photomorphogenesis](#), ▶[neddylolation](#), ▶[p53](#), ▶[ubiquitin](#), ▶[obesity](#); Seo HS et al 2003 Nature [Lond] 423:995.

Cop Transport Vesicles: The COPI is built of ARF, coatomer subunits, and a GTPase. mediates the transport within the Golgi apparatus and between the Golgi and the endoplasmic reticulum. The sorting signals are interpreted by GTPase switch ($GTP \rightleftharpoons GDP$) on the COPI vehicles. The COPII vesicles are made of SEC and Sar proteins. Secretory COPII component Sec23a is essential for craniofacial chondrocyte maturation; it mediates traffic between the Golgi apparatus and the endoplasmic reticulum (Lang MR et al 2006 Nature Genet 38:1198). The TRAPPI tethering protein binds Sec23 to the COPII vesicles (Cai H et al 2007 Nature [Lond] 445:941). ▶[clathrin](#), ▶[ARF](#), ▶[Golgi apparatus](#), ▶[endoplasmic reticulum](#), ▶[SEC](#), ▶[SAR](#), ▶[endocytosis](#), ▶[p24](#); Barlowe C et al 1994 Cell 77:895; Lederkremer GZ et al 2001 Proc Natl Acad USA 98:10704.

Cope's Rule: The hypothesis that evolution usually involves increase in body size. The idea does not have general validity.

copia: RETROTRANSPOSON elements occur in all types of eukaryotes; in *Drosophila* they occur generally in 5 – 7 kb sizes with about 300 bp direct and much shorter inverted terminal repeats. They frequently occur in 30–40 families and constitute 5–10% of the genome. The copia elements along with about 30 other insertion and transposable elements are involved in the mutability of the genomes by their movement. The frequency of their rearrangement is within the range of 10^{-3} to 10^{-4} . The long terminal repeats (LTR) encode a viral transposase-like protein. Retrotransposition cycles are initiated from an RNA copy of a transposable element. The transcription begins at the 5' region of the long terminal repeat (LTR) and this transcript is copied into a double-stranded DNA by a reverse transcriptase coded within the transposon. The synthesis of the first DNA strand is primed by the 3'-OH group of a host tRNA that immediately anneals to the LTR (this is called tRNA PBS [primer binding site]).

Integration requires short inverted repeats (4–12 bp) at the end of the LTRs. Integration involves a few bp duplications at the insertional target sites. These duplications are the consequences of the staggered cuts at the target that are filled in by complementary bases after integration. The length of the target site duplications reflects the specificity of the transposon-encoded integrase. *Drosophila* retrotransposons have a number of features corresponding to retroviruses. They contain direct terminal repeats that have the sequences required for the initiation of transcription and polyadenylation. The majority of the *Drosophila* retrotransposons carry short inverted repeats at the end of LTRs. The LTR at one terminus contain TG and at the other CA bases. The majority of the retrotransposons have a purine-rich sequence immediately upstream to the 3'-LTR. These sequences are the priming sites for the second strand DNA (SSP, [second strand primer]). Most *Drosophila* retrotransposons have sequences starting with TGG immediately downstream to the 5'-LTR that is complementary to the 3'-end of the tRNAs (the amino acid acceptor arm). The *Drosophila* retrotransposons have reverse transcriptase (*pol*), and group-specific antigen (*gag*) polyproteins just like the retroviruses of vertebrates. Actually some plant retrotransposon-like elements are also organized in a similar manner but the majority of them are no longer able to transpos because some of their genes were reduced to pseudogenic forms. During retroviral life cycles, extrachromosomal linear and circular DNA elements are formed with one or two LTRs. These features are also retained in some of the copia-like elements. These retrotransposons also produce viral-like elements in the eukaryotic cells quite similar to the real retroviruses. Also, some of the copia-like elements generate

C

“strong-stop” DNA elements in cells like retroviruses. These strong-stop DNAs and DNA–RNA heteroduplexes are leftovers of the first and second strand transcription by the reverse transcriptase enzyme. These copia-like elements transpose quite vigorously in both somatic and germline cells and induce mutations in the germline and the soma. Recombination between the multiple copies of the retroposons may cause in the host all types of chromosomal aberrations, such as deletions, inversions, and translocations. Perhaps the movement (insertion) of these elements causes the majority of the spontaneous mutations in the species that harbor transposable elements. The insertions may cause inactivation of exons but more frequently they insert into AT-rich sequences. The major representatives in *Drosophila* are “17.6” (7.4 kb) occurring in about 40 copies per genome and generating a 4-base duplication at the insertion target site, the LTR being 512 bp. “297” (7-kb) has approximately 30 copies. Its LTR is 415-bp and shows 1.7-kb homology between the right-hand ends with 17.6. Its transposition-replication is primed by a tRNA^{Ser}. “412” (7.6-kb), copy number 40, LTR is 481 bp target site duplication of 4 bases. tRNA^{Arg} primes its transposition. “1731” (4.6-kb) is present in about 10 copies and generates a target site replication of 5-bp. Its reverse transcription is primed probably by a fragment of the initiator tRNA^{Met}. “3S18” (6.5-kb) with target site duplication of 5-bp; occurs in about 15 copies. “BEL” (7.3-kb) is present in about 25 copies and the termini are very similar. “blood” (6-kb) occurs in 9 – 15 copies, LTR 400-bp, and generates a target site duplication of 4. The primer may be tRNA^{Arg} similar to elements 412 and *mdg1*. “copia” (5-kb) is present in 60 copies, its LTR 276-bp with 5-bp target site duplication. Its name indicates the “copious” amount of its polyadenylated transcripts in the cells. The initiator tRNA^{Met} primes for the reverse transcription of the copia RNA. Left end of the element: TGTTGGAATA TACTTATTCAA CCTACAAAG TAACGTTAAA, the right end: TATTAAAGAAA GGAAATATAA ACAACA. “gypsy” [synonymous with *mdg4*] (7.3-kb) with 10 copy number has a LTR of 479-bp, and generates 4-bp target site duplication. These elements are associated with many mutations suppressed by *su(Hw)* [suppressor of Hairy wing], the product of this gene binds to an enhancer-like sequence within *gypsy* and affects the expression of adjacent genes including *gypsy*. The phenotype of some of the mutations caused by *gypsy* insertions is affected by *su(f)* [suppressor of forked]. The *gypsy* element is considered to be a retrovirus and its movement is controlled primarily by the X-chromosomal mutation *flam* (flamingo). “H.M.S.Beagle” (7.3-kb) has 50 copies, LTR is 266-bp, and shows 4 base target site duplication. “*mdg1*” (7.3-kb), may be

present in 25 copies, its LTR is 442-bp and creates 4-bp target site duplication; 14/18 of its primer binding sites are identical to that of 412 as well as the 27-bp adjacent to the left LTRs. tRNA^{Arg} is the most likely primer for their reverse transcription. “*mdg3*” (5.4-kb) has LTR of 267-kb and the target site duplications are 4-bp. “*micropia*” (5.5-kb) hybridizes with *copia* in the Y chromosome of *D. hydei*. “NEB” (5.5-kb), “opus” (8-kb). “*roo*” (8.7-kb, formerly called *B104*) has a LTR 429-bp and generates 5-bp target site duplication. “*springer*” (8.8-kb) with LTR 405-bp generates 6-bp target site duplication. ▶retroviruses, ▶retroposon, ▶retrotransposon, ▶transposable elements, ▶transposase, ▶reverse transcription, ▶polyprotein, ▶tRNA, ▶suppressor, ▶*Cin4*, ▶hybrid dysgenesis, ▶*Drosophila*; Bowen NJ, McDonald JF 2001 Genome Res 11:1527; Mejlumian L et al 2002 Genetics 160:201.

Copolymer: A molecule built from more than one type of component, e.g., a nucleic acid made of adenine and thymine units. If the sequence and quantity of the components do not follow a particular system it may be a random copolymer. If the units display periodic repetitions, it is called a repeating copolymer.

Copper Homeostasis Disease: ▶Wilson disease, ▶Menke’s disease

Copper-Inducible System: ▶metallothionein

Copper Malabsorption: ▶Menke’s disease

Coprocessor: An auxiliary processor to assist the main processor in special heavy tasks. Generally, it also speeds up the processing of computers. ▶processor

Coprolite (fossilized dung): Coprolite reveals the diet and food digestion of extinct species or ancestral populations of modern animals. (<http://www.ualberta.ca/~abeaudoi/stuff/dung.htm> <http://www.scirpus.ca/dung.dung.shtml>).

Coprophagy: Coprophagy is the phenomenon where the nymphs of some insects feed on the feces of adults and utilize the nutrients left therein, while simultaneously ingesting their abundant bacterial symbionts. ▶paratransgenic

Coproporphyrria (CPO, 3q11.2): A dominant deficiency of coproporphyrinogen oxidase resulting in excessive excretion of coproporphyrin III, an intermediate in porphyrin synthesis (see Fig. C162). The protein is mitochondrially localized. Deficiency of coproporphyrinogen oxidase causes abdominal pain, neurological problems, and photosensitivity of the skin. Heme arginate administration and high-carbohydrate diet are effective treatments. The gene has been cloned and the crystal structure of the enzyme has been determined (Lee D-S et al 2005 Proc Natl

Acad Sci USA 102: 14232). ►porphyrin, ►porphyria, ►harderoporphyria; Lamoril J et al 2001 Am J Hum Genet 68:1130.

Figure C162. Coproporphyrin III

Coprospecty: Molecular analysis of coprolites. After *N*-phenacylthiazolium bromide cleavage of protein DNA cross-links, various short DNA sequences can be extracted, amplified by PCR, and sequenced. Information may be obtained on thousands of years old animals and their plant food. ►coprolite, ►PCR

Copulation: Sexual intercourse between female and male. Evolutionary selection of characteristics of the process would indicate that leaving more offspring even at the expense of decreased survival might be favored. Actually, this has been shown by the redback spider (*Latrodectus hasselti*) where hungry females frequently cannibalize their mates that copulate longer and thus transfer more sperm and thereby contribute more of their genes to the population. courtship; Koniyoshi H et al 2002 Genetics 162:1775.

Copy Choice: A hypothesis so named in the 1950s. It assumes that in recombination there may be no physical breakage and union between exchanged strands, but rather a replication and choice. This hypothesis bears similarity to Bateson's (1906) reduplication theory and gene conversion (Lindgren 1949). Recently, evidence has been presented that prokaryotic DNA polymerase III holoenzyme may slip frequently during replicating direct repeats. Recombination between RNA viruses may be brought about by template switching during the elongative RNA synthesis by RNA-dependent RNA polymerases. ►gene conversion, ►recombination in RNA viruses, ►breakage and reunion, ►reduplication hypothesis; M-J Kim, Kao C 2001 Proc Natl Acad Sci USA 98:4972; Moumen A et al 2001 Nucleic Acids Res 29:3814.

Copy Number Estimates: In the human genome, the frequency of deleted and duplicated segments of the average 300–400 kb appears as 1:8 and 1:50, respectively, based on mutation frequency of the Duchenne muscular dystrophy region (van Ommen G-JB 2005 Nature Genet 37:333). High-resolution comparative genomic hybridization using oligonucleotide probes can detect many of such alterations in various disease syndromes and also in normal individuals (Urban AE et al 2006 Proc Natl Acad Sci USA 103:4534). ►duplication, ►deficiency, ►genomic variation; Redon R 2006 Nature [Lond] 444:444.

Copy Number Paradox: The copy number paradox is that the genetically functional copies of organellar DNA appear much smaller than the physical copy number estimates. ►mtDNA, ►chloroplasts, ►C value paradox; Jenuth JP et al 1996 Nature Genet 14:123.

Copy Number Variants (CNV): CNVs are genomic segments of 1 kb or larger that were deleted or duplicated in the genomes of the majority of higher eukaryotes. Two human genomes may differ by more than 20 Mb and it is likely that the full extent of CNV still remains to be discovered. Nearly 3000 human genes are associated with CNV. This high degree of variability between two individuals challenges definitions of normality. Many CNVs are located in regions of complex genomic structure (Kehrer-Sawatzki H 2007 Bioassays 29:311). Single nucleotide polymorphism (SNP) represents 83.6%, and CNVs 17.7% of the average total detected genetic variations in gene expression of 14,702 transcripts taken from wide ethnic population samples. Signals from these two types of variation show little overlap (Stranger BE et al 2007 Science 315:848). CNV breakpoint sequences (physical deletion or duplication boundaries) can be determined with the use of a computer program called *BreakPtr*, for fine-mapping CNVs (available from <http://breakptr.gersteinlab.org>, see also Korbel JO et al 2007 Proc Natl Acad Sci USA 104:10110). small duplications: Conrad B, Antronarakis SE 2007 Annu Rev Genomics Hum Genet 8 Sept.

Copyright: right to reproduce, publish or sell an intellectual property. (See <http://www.loc.gov/copyright>).

Copy-Up Mutation: The copy-up mutation initiates runaway replication of the plasmid, i.e., the copy number increases beyond that in the wild type. ►runaway plasmids; Blasina A et al 1996 Proc Natl Acad Sci USA 93:3559; Toukdarian AE, Helinski DR 1998 Gene 223:205.

CoR-BOX: The amino-terminal ligand-binding domain of the thyroid and retinoic acid receptors. ►N-CoR, ►thyroid, ►retinoic acid, ►ligand

C

Cord Blood (umbilical cord blood): ► [stem cells](#)

Cordate: Heart-shaped.

Cordycepin ($C_{10}H_{13}N_5O_3$): A nucleoside analog (3'-deoxyadenosine) that inhibits transcription and polyadenylation. ► [polyadenylation](#), ► [polyA mRNA](#), ► [polyA tail](#), ► [transcription](#)

Core Binding Factors (CBF): Heterodimeric transcription factors. They are essential for normal development and health. ► [transcription factors](#), ► [runt](#)

Core DNA: Core DNA wraps around the histone octamer in the nucleosome. The DNA (chain) winds around the 8 histones' core but does not include H1 histone. ► [nucleosome](#), ► [histones](#)

Core Enzyme: Prokaryotic transcriptase has two identical α and two β ($\beta\beta'$) subunits and to this core a fifth, σ subunit, may be attached that is not essential for transcription but seeks out the position of proper promoters. ► [RNA polymerase](#)

Core Machine: The essential functional unit of protein complexes.

Core Particle: ► [nucleosome](#), ► [core DNA](#), ► [histones](#) (see Fig. C163).

Figure C163. Core particle

Core Polymerase: Core polymerase is composed of only 3/10 subunits of prokaryotic DNA polymerase III (pol III). These subunits are α (polymerase), ϵ (proofreading 3'→5' exonuclease), and θ (enhances the activity of ϵ). ► [DNA polymerases](#)

Core Promoter: The core promoter is the most essential sequence (~100 bp from the transcription start site [TSS]) within a promoter to carry out transcription (see Fig. C164). The core promoter of the eukaryotic RNA polymerase II usually includes the TATA box and may have also an *initiator site* (Inr), enhancer and the TATA box associated general transcription factors, such as the TFIIB recognition element (BRE), and the downstream promoter element (DPE). DPE, when present, is situated 30 nucleotides downstream of the transcription initiation site. Generally the DPE element has Inr but no TATA box. The TAF subunits of TFIID bind DPE and Inr (Burke TW, Kadonaga JT 1996 Genes Dev 10:711). The core promoter is usually situated ± 40 nucleotides

from the transcription initiation site (TATA box). The TATA box is bound by TBP, which is a subunit of transcription factor TFIID.

Figure C164. Core promoter

At a distance of -50 to -200 bp from the TATA box there are binding sites for NF-1, CBF, NF-Y. In prokaryotes, the core promoter complex includes only the RNA polymerase holoenzyme and the σ subunit. In eukaryotes, instead of the σ , an assembly of the general transcription factors are found. In addition, the TATA box binding proteins (TBP), TATA box associated proteins (TBA), initiator binding protein (IBP), and enhancer binding proteins (EBP) are usually present. The modulation and regulation of transcription requires series activators, co-activators, and different specific transcription factors. ► [transcription factors](#), ► [open promoter complex](#), ► [TBP](#), ► [TAF](#), ► [transcription unit](#), ► [transcription initiation](#), ► [TSS](#), ► [base promoter](#), ► [null promoter](#), ► [NF-1](#), ► [CBF](#), ► [NF-X](#), ► [PWM](#), ► [DSTF](#), ► [Sp1](#), ► [CAAT box](#); Hamada M et al 2001 Mol Cell Biol 21:6870; Morimoto M et al 2001 Arterioscler Thromb Vasc Biol 21:771; Smale ST, Kadonaga JT 2003 Annu Rev Biochem 72:449.

Core, Protein: The region common to the majority of structures in a superfamily or in a common fold.

Core Proteome: The number of distinct families of proteins within a genome. In *Haemophilus influenzae*, of the 1709 protein-coding genes, 1247 (~73%) do not have sequence relatives within the genome. In yeast, there are ~6241 protein-coding genes and from these 4383 (~70%) represent the core proteome. The core proteome in *Drosophila* and *Caenorhabditis* are 8065 (~62%) and 9453 (~51%), respectively. ► [gene number](#), ► [duplications](#), ► [genome](#), ► [proteome](#)

Core Sequences: Usually invariable short tracts within more or less well preserved consensus sequences of the DNA. ► [consensus](#)

cORF (composite open reading frame): cORF occurs by tandem duplication of genes. ► [ORF](#)

Co-Receptor: CD⁸ and CD⁴ T cell surface proteins along with the T cell receptor recognize MHC I and MHC II molecules. The CD cytoplasmic domains associate with a SRC protein tyrosine kinase. ► [CD⁸](#), ► [CD⁴](#), ► [T cell receptor](#), ► [MHC](#), ► [SRC](#), ► [protein tyrosine kinase](#)

Coremium: ► [hypha](#)

Co-Repressor: A metabolite or protein which, in combination with a repressor protein interferes with transcription and thereby with enzyme synthesis. The

co-repressor may not bind to DNA directly. A co-repressor, when recruited to an activator, may turn the latter into a repressor. ►repressor, ►aporepressor, ►repression, ►regulation of gene activity, ►nuclear receptor, ►cAMP receptor, ►Groucho, ►Tup1, ►N-CoR, ►chromatin remodeling, ►co-suppression, ►co-activator; Yoh SM, Privalsky ML 2001 J Biol Chem 276:16857; Zhang Q et al 2002 Science 295:1895.

Coriaceous: Leathery.

Co-Retention Analysis: Co-retention analysis is used in genetic mapping of mitochondrial genes. More or less large deletions frequently take place in the mitochondrial DNA resulting in simultaneous loss concomitant with simultaneous retention of antibiotic resistance markers. The co-deletion and co-retention frequencies provide converse estimates on linkage. Both co-deleted and co-retained markers must be present in groups indicating their physical position relative to each other. ►linkage, ►physical mapping, ►deletion mapping, ►mitochondrial genetics; Heyting C, Menke HH 1979 Mol Gen Genet 168:279.

Corm: Underground shoots, modified for storage (see Fig. C165).

Figure C165. Corm

Corn: ►maize

Cornflower: ►Echinacea

Cornea Plana: The characteristics of the cornea plana condition are extreme farsightedness (hyperopia) and opacity of the cornea especially at the margins. It exists in autosomal dominant and recessive forms; and is most common in Finland. ►eye diseases

Corneal Dystrophy: Corneal dystrophy has been described in various autosomal dominant and recessive forms involving defects in the keratin filaments in the eye. ►filaments, ►keratin

Cornelia de Lange Syndrome: ►De Lange syndrome

Corolla: The collective term for petals. ►flower differentiation

Corona Virus: ►SARS

Coronary Heart Disease (COD): COD generally involves deposition of lipid plaques within the arteries surrounding the heart (atherosclerosis). Low-density lipoprotein in the blood (above 200 mg/100 mL) increases the risk proportionally. On the other hand, high-density lipoprotein is favorable for avoidance. These account

for the majority of all heart diseases and afflict 6–7% of the populations (predominantly males) in Western industrialized countries. The underlying organic defects vary, and many non-hereditary factors (diet, smoking, drug and alcohol consumption, age, etc.) and independent or concomitant diseases and conditions (blood pressure, diabetes, temperament, etc.) aggravate the condition. In Finnish populations, two likely susceptibility loci were found at 2q21-q22 (LOD score 3.2) and at Xq23-q26. The locus at 15q26 encodes the transcription factor MEF2A that has frequently a 21 bp deletion and (in that case) is responsible for COD and myocardial infarction (Wang L et al 2003 Science 302:1578). Familial hypercholesterolemia, apolipoproteinemia (APOB), sitosterolemia, low level of HDL, Tangier disease, and homocystinuria increase susceptibility to COD. Increased expression of 5-lipoxygenase can also be a factor in COD (ALOX5, 10q11.2; ALOX5AP, 13q12; leukotriene C4 synthase, 5q35) are also contributing factors among others. So far no single decisive gene has been identified. Autosomal dominant early coronary artery disease is predisposed by hyperlipidemia, hypertension, diabetes, and osteoporosis. The genetic determinants of these conditions show linkage to a short segment of chromosome 12p, in which a missense mutation in a low-density lipoprotein receptor gene (*LRP6*) encodes a co-receptor in the Wnt (wingless) signaling pathway (Mani A et al 2007 Science 315:1278). Genome-wide association studies of more 23,000 individuals identified a 58-kilobase interval on chromosome 9p21 that was consistently associated with coronary heart disease. This interval, which is located near the *CDKN2A* and *CDKN2B* genes, contains no annotated genes and is not associated with established heart risk factors such as plasma lipoproteins, hypertension or diabetes. Homozygotes for the risk allele occur in 20–25% of Caucasians and have a ~30–40% increased risk coronary heart disease (McPherson R et al 2007 Science 316:1488). Another study showed similar results. Approximately 21% individuals in a population are homozygous for this variant and they have an estimated 1.64-fold greater risk of suffering myocardial infarction than non-carriers. The corresponding risk is 2.02-fold for early onset cases (Helgadottir A et al 2007 Science 316:1491). ►hypertension, ►angina pectoris, ►cardiovascular disease, ►MEF, ►atherosclerosis, ►familial hypercholesterolemia, ►familial hyperlipidemia, ►hyperlipoproteinemia, ►lipoprotein, ►cholesterol, ►Tangier disease, ►diabetes, ►mucopolysaccharidosis, ►pseudoxanthoma elasticum, ►Marfan syndrome, ►homocysteinuria, ►lecithin: cholesterol acyltransferase deficiency, ►myocardial infarction, ►atherosclerosis, ►wingless; Breslow JL 2000 Annu

Coronavirus: Positive-sense RNA viruses of bird and mammals. ▶SARS

C

Corpus: Latin word for body. In information science, it designates a collection of texts regarding a certain area of science or its specified subgroup.

Corpus Callosum: ▶brain

Corpus Luteum (yellow body): The corpus luteum is formed by luteinization of an ovarian follicle after the discharge of an ovum. In case of fertilization of the egg, the corpus luteum increases in size and persists for several months. If there is no fertilization, the CL disintegrates. The CL secretes progesterone. ▶ovary, ▶Graafian follicle, ▶ovum, ▶luteinization, ▶luteinizing hormone-release factor, ▶corticotropin, ▶progesterone, ▶animal hormones, ▶relaxin, ▶abortion spontaneous

Corpuscular Radiation: Corpuscular radiation is emitted by unstable radioisotopes: β particles [electrons] are emitted by ^3H , ^{14}C , ^{32}P , etc. and α particles [helium nuclei] by uranium or fast and thermal neutrons during nuclear fission. ▶physical mutagens, ▶isotopes, ▶ionizing radiation, ▶radiation effects, ▶radiation measurement, ▶radiation hazard assessment, ▶electromagnetic radiation

Correction: ▶DNA, ▶repair

Correlated Expression: In the eukaryote yeast, adjacent genes, irrespective of their orientation in the chromosome, are more likely to be expressed at the same time than non-adjacent ones. Only $r > 0.7$ is accepted as valid indication of correlated expression. The significance of correlated adjacent pairs is determined statistically on the basis of the cumulative binomial distribution by using the formula:

$$p(n \geq n_0) = \sum_{n=n_0}^N p^n (1-p)^{N-n} \left[\frac{N!}{n!(N-n)!} \right]$$

In some cases, only one of the gene pairs carries an upstream activating sequence. Some genes utilize the

same UAS even when they are not immediately downstream from it. On this basis chromosome correlation, maps can be constructed. ▶UAS; ▶coordinate regulation; ▶operon; ▶regulon; Cohen BA et al 2000 Nature Genet 26:183.

Correlation: Interdependence of two variates (see Fig. C166). This relation may be statistical or physiological. The statistical correlation does not necessarily reveal any cause and effect link. The correlation may be positive (when the change of the variables follows the same direction) or negative (when the increase of one variable involves the decrease of the other). Thus, the value of the correlation coefficient may vary between +1 and -1.

The correlation coefficient is independent from the scale of quantitations used, e.g., one can measure the correlation between intelligence and wearing a necktie. For the calculation of the correlation coefficient, *covariance* has to be determined, i.e., the average product of the deviations of two variables from their respective means. It is estimated by dividing the sum of the products of the deviations from their means by the appropriate degrees of freedom. Thus, covariance is: $(w) = \{\Sigma[(x_i - \bar{x})(y_i - \bar{y})]\} / (n - 1)$. For actual calculation, the mathematically equivalent but computationally more convenient equation is used: $(w) = \{\Sigma(X_i Y_i) - [\Sigma(X_i) \Sigma(Y_i)] / n\} / (n - 1)$.

The analysis of covariance has many uses in biology and particularly in genetics. It may be used to separate the genotypic effects from treatment effects. It may reveal the relations among various types of variables. This type of analysis is useful to study the relationships among multiple classifications such as may occur if the experiments involve organisms of different genotypes, in different age groups and developmental stages and environments. In this book it is not possible to work out examples for all these different applications; only the basic procedure is illustrated with step-by-step simple calculations (see Table C6).

The actual use of the formulas can best be shown by a hypothetical example. Let us assume that we measured (*i*) number of variates (in the following case *i* is 1 to 10) in two groups. In the columns x_i and y_i ,

Figure C166. Graphical representation of correlation. The dots correspond to the points of the measured values of two quantitative traits

these measurements are listed from 1 to 10. To make the calculations easier (without changing the outcome) for each measurement, a quantity (the same quantity, close to the means) is subtracted, and we name these X_i and Y_i , respectively, as shown at the top of columns 3 and 4. Column 5 is the product of the lines in columns 3 and 4: $X_i Y_i$. Columns 6 and 7 display the power of values in columns 3 and 4, respectively: $(X_i)^2$ and $(Y_i)^2$.

Indicating that an increase in the values of X involved a positive in the values of Y as shown at the top of columns 3 and 4. Column 5 is the product of the lines in columns 3 and 4, $X_i Y_i$. Columns 6 and 7 display the power of values in Columns 3 and 4, respectively: $(X_i)^2$ and $(Y_i)^2$.

In genetic analysis the coefficient of regression is often used. It measures in quantitative units how much the dependent variable (Y) is changing as a function of the independent variable (X), e.g., we can determine how much the offspring's weight or height regresses to the weight (in kg) or height (in cm) of the parents or to the mother or father. This is in contrast to correlation that could state only plus or minus and strong or weak correspondence but not in actual quantitative units. The coefficient of regression: $b = W/V_x =$ and in the example of the table $b = 20.22/28.71 = 0.704$. For a predictive value, we use the

linear regression equation: $Y = a + bx$ from which $a = Y - bx$, where (a) is the intercept of the straight line on the (Y) coordinate; (b) is the slope indicating how much (y) changes by changes in (x) (see Fig. C167).

Figure C167. The linear regression line is specified by the equation: $Y = a + bx$. In this function, a is the value of the intercept and b defines the slope of the line, equal to the increase in Y per units of x . The solid circles correspond to the intersections of the values of the two variables. According to the table shown on the preceding page, we can consider the X axis for the units of measures of one of the variates and Y as the axis for the measurements of the other variates

Table C6. Computational scheme for covariance (w)

| (1) | (2) | (3) | (4) | (5) | (6) | (7) |
|-----------------|-----------------|---------------------|---------------------|------------------------|------------------------|------------------------|
| x_i | y_i | $X_i = x_i - 150$ | $Y_i = y_i - 150$ | $X_i Y_i$ | $(X_i)^2$ | $(Y_i)^2$ |
| 148 | 149 | - 2 | - 1 | 2 | 4 | 1 |
| 158 | 152 | + 8 | + 2 | 16 | 64 | 4 |
| 150 | 155 | 0 | + 5 | 0 | 0 | 25 |
| 143 | 142 | - 7 | - 8 | 56 | 49 | 64 |
| 162 | 160 | + 8 | + 10 | 80 | 64 | 100 |
| 150 | 160 | 0 | + 10 | 0 | 0 | 100 |
| 156 | 153 | + 6 | + 3 | 18 | 36 | 9 |
| 160 | 159 | + 10 | + 9 | 90 | 100 | 81 |
| 153 | 158 | + 3 | + 8 | 24 | 9 | 64 |
| 150 | 152 | 0 | + 2 | 0 | 0 | 4 |
| $\bar{x} = 153$ | $\bar{y} = 154$ | $\Sigma X_i = + 26$ | $\Sigma Y_i = + 40$ | $\Sigma X_i Y_i = 286$ | $\Sigma (X_i)^2 = 326$ | $\Sigma (Y_i)^2 = 452$ |

Substituting the values into the covariance formula:

$$W = \{\Sigma(X_i Y_i) - [\Sigma(X_i)(\Sigma(Y_i))/n]/(n - 1) = \{286 - [(26) \times (40)]/10\}/9 = 20.22$$

Variances:

$$V_x = \{\Sigma(X_i)^2 - [\Sigma(X_i)^2]/n]/(n - 1) = \{(326) - [(26)^2]/10\}/9 = + 28.71$$

$$V_y = \{\Sigma(Y_i)^2 - [\Sigma(Y_i)^2]/n]/(n - 1) = \{(452) - [(40)^2]/10\}/9 = + 32.44$$

The coefficient of correlation: $r = W/\sqrt{V_x V_y} = 20.22/\sqrt{28.71 \times 32.44} = + 0.663$, indicating that an increase in the values of X involved a positive change in the values of Y .

After substituting the data of our calculations into the equation:

$a = Y - bx$, since $(\bar{y} = Y = 154)$, and $\bar{x} = X = 153$, and $b = 0.704$; thus, $a = 154 - (0.704 \times 153) = 46.29$. Therefore, if the (x) independent variable is 158 kg, the dependent variable (Y) is expected to be $46.29 + (0.704 \times 158) = 157.52$ kg. When the independent variable is 150 kg, the dependent variable (Y) is expected to be $46.29 + (0.704 \times 150) = 151.89$ kg. The example also testifies for the name of regression. Originally it was observed that large and small parents' children both tend to follow more the population's mean, i.e., they regress toward the mean. The offspring–parent regression is actually a measure of heritability. The linear regression is frequently represented graphically as shown above. ►genetic correlation, ►heritability, ►intraclass correlation

Correspondence Analysis: A computational method for the study of associations between variables. It displays low-dimensional projection of the data into a plane so that both variables simultaneously reveal their association. It is applicable to microarray data of different complexities. ►microarray hybridization; Fellenberg K et al 2001 Proc Natl Acad Sci USA 98:10781.

Cortex: The outer layer of various tissues (egg, brain, kidney, tree bark, etc.).

Cortical Granules: Small secretory vesicles under the egg membrane that by releasing some of their contents protect the egg from being fertilized by multiple sperms. ►fertilization, ►polyspermy

Cortical Inheritance: The cytoplasmic organization may affect the expression of a trait without alteration in the genetic material (see Fig. C168). In *Paramecia*, the movement of the cortically located cilia may be oriented in the same direction. If a piece of the cortical cytoplasm is grafted in the reverse orientation, the graft will beat in the opposite direction and this ciliary movement pattern may be transmitted through generations.

Figure C168. Cortical Inheritance. Gullet and vestibule (→) of *Paramecium aurelia* that can be surgically transferred to another site on the animal and it is then cortically inherited. (Courtesy of Dr. Tracy Sonneborn)

Similarly grafted vestibules may appear as an additional ingestatory apparatus in the progeny. These cortical layers contain no DNA or RNA. The pattern of development seems to be fixed within

the organizational structure. ►epigenesis, ►non-Mendelian inheritance; Beisson J, Sonneborn TM 1965 Proc Natl Acad Sci USA 53:275.

Cortical Reaction: ►fertilization, ►cortical granules

Corticobasal Degeneration: A fronto-temporal dementia generally occurring with parkinsonism caused by mutation in the tau protein. ►tau, ►parkinsonism

Corticosteroid: Corticosteroids are 21-carbon steroids that are synthesized in the outer firm, yellowish layer of the adrenal (kidney) gland. The glucocorticoids regulate carbohydrate and protein metabolism, whereas the mineralocorticoids regulate salt and water traffic. ►animal hormones, ►glucocorticoids, ►transcortin deficiency, ►antitrypsin

Corticotropin (adrenocorticotropin, ACTH): A 39-amino acid peptide hormone of the anterior pituitary that regulates the synthesis of corticosteroid in the adrenal cortex. Its release, e.g., in response to stress, is controlled by the releasing factors of the hypothalamus such as the thyrotropic releasing factor (TRF), the luteinizing hormone releasing factor (LRF), and the corticotropin releasing factor. ►opiocortin, ►corticotropin releasing factor, ►stress; Lin X et al 2001 Mol Endocrinol 15:1264.

Corticotropin Releasing Factor (CRF/CRH): CRF is supposed to be associated with the brain cognitive response. In Alzheimer's disease, CRF is very low although CRF receptors accumulate. CRF mediates endocrine, autonomous, behavioral, and immune responses to stress (alcohol and drug withdrawal, etc.). ►Alzheimer's disease, ►urocortin, ►stress, ►maternal tolerance; Eckart K et al 2001 Proc Natl Acad Sci USA 98:11142.

Cortisol: Cortisol is derived from progesterone (along with aldosterone) in the kidney cortex. It is chemically very similar to cortisone. The production of cortisone is controlled by the pituitary hormone corticotropin and cAMP. Glucocorticoids promote gluconeogenesis and the deposition of glycogen in the liver, inhibit protein synthesis in the muscles, mediate fat and fatty acid breakdown in the adipose tissue, and control inflammatory responses. ►glucocorticoids, ►hydrocortisone, ►abortion spontaneous; Johannsson A et al 2001 J Clin Endocrinol Metab 86:4276.

Cortisone: ►cortisol

Corynebacterium: ►diphtheria toxin, ►biological weapons

cos: cohesive ends (12 bp) of phage λ where linearization and circularization of the DNA take place:

pGGGCGGCGACCT- - - - -
- - - - - CCCGCCGCTGGAp

The sequence shown here represents the *cosN* subsite where cutting takes place. For the proper packaging of the genome, additional *cos* sites (*cosQ*, *cosB*) and proteins are also required (Wieczorek DJ, Feiss M 2003 Genetics 163:11). ▶[lambda phage](#); Wieczorek DJ, Feiss M 2001 Genetics 158:495.

COS Cell (cell, origin, Simian): COS cells are African green monkey cells with a chromosomally inserted Simian virus (SV40) DNA, which is defective in the origin of replication but contain the intact T-antigen (see Fig. C169). COS cells thus replicate multiple copies (small circles) of the harmless viral vector and the inserted passenger DNA independently from the monkey cell chromosome. The foreign DNA in the SV40 vector is transcribed and translated into the appropriate protein with the assistance of the metabolic machinery of the cell. ▶[SV40](#), ▶[African green monkey](#); Gerard RD, Guzman Y 1985 Mol Cell Biol.5:3231.

Figure C169. COS cell

Co-Segregation: Analysis for genetic linkage between two different genetic markers, e.g., a visible mutant phenotype and antibiotic resistance.

CO₂-Sensitivity: ▶[symbionts hereditary](#)

Co-Sexual: ▶[hermaphrodite](#)

Cosexuality: In cosexuality, both male and female sexual organs are present within the same individual. ▶[hermaphrodite](#), ▶[monoecious](#)

Cosmetic Surgery: Despite the earlier reservations attached with it, cosmetic surgery has become an accepted medical treatment for psychological problems such as the inferiority complex. The right to cosmetic surgery is part of individual liberty, although in many cases it may be an unnecessary and risky practice.

Cosmic Radiation: Cosmic radiation strikes the earth from interstellar space, partly directly from the radiating bodies, partly (primary) or emanating from the collision of nuclei with cosmic (secondary) radiation in the upper atmosphere. The amount of cosmic radiation varies according to altitude and it is very high at the height at which space vehicles are

located. The amount that falls on the surface of the earth is about 0.028 to 0.045 rad per year and increases substantially at higher altitudes. At 1000 ft it is ~2, at 5000 ft > 20, and at 9000 ft ~70 mrem. One may ingest ~40 mrem from food and water, on an average in the US. These figures should be corrected by a factor of about 0.8 because of protection by housing. For comparison, an average medical diagnostic chest X-ray delivers about 0.2 rad (but the gonads are protected). ▶[isotopes](#), ▶[radiation natural](#), ▶[atomic radiation](#), ▶[radiation hazard assessment](#), ▶[rem](#), ▶[rad](#); Curzio G et al 2001 Rad Prot Dosimetry 93[2]:125.

Cosmids: Approximately 5-kb cloning vectors are derived from phage λ DNA, containing one or two cohesive (*cos*) sites in the same orientation, an origin of replication (*ColEI*), and a selectable marker (*amp^R*). The cloning capacity of the plasmid is about 35–47 kbp because neither substantially smaller nor larger than the λ genome (\approx 49-kbp) can be packaged into the capsid (see in vitro packaging). For cloning, smaller DNAs *charomids* must be used. Into the linearized cosmid, the foreign DNA is ligated at appropriate cloning sites flanked by cosmid sequences. The *concatamer* is cut to head size to fill the capsid, with the assistance of the phage terminase protein (an endonuclease with a specificity of cutting near *cos* sites). After infection from *E. coli*, the cosmid recircularizes within the bacterial cell and due to the presence of the antibiotic resistance marker(s), the bacteria carrying the recombinant cosmid can be isolated. Cosmids can recombine with other plasmids (having homologous sequences) within *recA*⁺-bacterial strains, and the cointegrates can be isolated if both carry independent selectable markers. There may be a problem, however, with rearrangements because of the active *recA*. A number of specially designed cosmids are available and they have been used for particular cloning needs. Cosmid **pJBS** had been used successfully for chromosome walking. After the recombinant cosmid is isolated from a library, the cloned foreign DNA segment can be cut with restriction enzymes without destroying the vector that can be transformed into bacteria and can yield small fragments of potential use as probes for overlapping fragments in the original library. Cosmid **c2RB** carries 2 *cos* sites and ampicillin and kanamycin resistance. Concatenation can be suppressed after insertion of the foreign DNA by phosphatase treatment (that prevents the formation of phosphodiester bonds) or by directional cloning. There are two EcoRI sites in the vector flanking a single BamHI site and this makes it easier to walk from one recombinant site to the next because the two small fragments so generated can be used as probes to re-screen the original library for overlapping clones.

C

Cosmid pcos1EMBL carries tetracycline and kanamycin resistance, and the origin of replication of plasmid R6K (a replicator unrelated to Col1). With these plasmids the screening for recombinants can be carried out in vivo. Special cosmid vectors were developed for the transformation of animal cells. These carry antibiotic markers selectable in eukaryotic cells such as neomycin (*neo*), dihydrofolate (*dhfr*), hygromycin (*hph*), and other eukaryotic genes such as hypoxanthine-guanine phosphoribosyl transferase (*hprt*), thymine kinase (*tk*-), etc. The **pWE** series were used advantageously because of the ease of walking from one cosmid clone to another. They carry the phage T3 and T7 promoters on either side of NotI, an eight-base recognition site (GC↓GCGCGC) restriction endonuclease. The foreign DNA may be cloned into a BamHI site located between the phage promoters. After cloning, the cosmid is cut by restriction enzymes that do not affect the phage promoters. The cleavage products will contain small fragments adjacent to the promoters. The fragments that are downstream of the promoters are then transcribed into labeled RNA. These (radioactive) probes are further used to rescreen the library for overlapping fragments. Since NotI sites are rare in mammalian DNA, on the average about 1500-bp fragments are generated and frequently the NotI digests include the entire cloned fragment. These large fragments facilitate the construction of physical maps and may be useful in transformation because they may include the gene that is to be expressed. Some other pWE vectors may have polycloning sites rather than only the BamHI site. This may make cloning easier but may create problems in the hybridization probes because of background hybridization of the labeled RNAs. Cosmids are also used with plant DNA. ▶**vectors**, ▶**lambda phage**, ▶**charomids**, ▶**Rec**, ▶**library**, ▶**cosmid library**, ▶**directional cloning**, ▶**promoter**, ▶**downstream**; Sambrook KJ, MacCallum P 2006 Molecular Cloning. Cold Spring Harbor Lab. Press.

Cosmid Library: A collection of DNA fragments of a genome cloned in cosmid vectors. ▶**cosmids**, ▶**library**

Cosmid Mapping: Physical mapping of cosmid-contained DNA sequences. ▶**cosmid**, ▶**physical map**

Cosmid Walking: Cosmid walking applies the “chromosome walking” procedure to DNA sequences in a cosmid library. ▶**genome projects**

Co-Speciation: Co-speciation indicates joint evolution of two organisms, e.g., host and parasite. The measure of co-speciation is that the two phylogenies (on the basis of protein or DNA primary structure) are more similar than expected by chance. The simian

foamy RNA virus, a non-pathogenic retrovirus, provides rather strong evidence for co-evolution with Asian and African monkeys and apes based on the viral polymerase and the mitochondrial cytochrome oxidase subunit II structure (Switzer WM et al 2005 Nature [Lond] 434:376). ▶**speciation**, ▶**phylogeny**

Cost-Benefit Analysis: A cost-benefit analysis estimates the tradeoff between expenditure and return in a financial or biological investment.

Costello Syndrome (11p15.5): An autosomal recessive/dominant condition resulting in short stature, skin and hair anomalies, cardiomyopathy, reduced mental abilities, and increased chance of tumors. A deficiency of 67-kDa elastin-binding protein may be one of the basic problems. Mutation in human RAS increases the chance of occurrence of these defects (Aoki Y et al 2005 Nature Genet 37:1038). ▶**RAS**, ▶**cardiomyopathies**, ▶**Marfan syndrome**, ▶**Nonan syndrome**, ▶**cardio-facial-cutaneous syndrome**; Hinek A et al 2000 Am J Hum Genet 66:859.

Co-Stimulator: Cell surface proteins that encourage the interaction between T cell receptors and the antigen-presenting cell. Genes encoding such proteins may be transformed into cancer cells and interleukins, and other cytokines or cytokine-like proteins may reinforce their function. Painting on the tumor cells co-stimulatory proteins is simpler than transfection yet effective in vaccination. The effectiveness may be enhanced by the use of GPI anchors. ▶**CD80**, ▶**CD86**, ▶**CD28**, ▶**CD4**, ▶**CTLA-4**, ▶**tumor vaccination**, ▶**transfection**, ▶**GPI anchor**; Schwartz J-C D et al 2002 Nature Immunol 3:427.

Cost of Evolution: Evolution proceeds by replacing old alleles with new ones and as a consequence some individuals are sacrificed; these pay the cost of evolution according to Haldane. The proportion of eliminated zygotes = sq^2 and the proportion of survivors $\bar{w} = 1 - sq^2$ or in general term the *cost of natural selection*, $C = \int_0^t (sq^2 / \bar{w}) dt$ where s = selection coefficient [$\ln(p_t) - (\ln(p_0))$], q = allelic proportion, \bar{w} = fitness, t = time, dt = integral differentiation. ▶**evolution**, ▶**natural selection**, ▶**fitness**, ▶**selection coefficient**, ▶**allelic frequencies**

Co-Suppression: In co-suppression, when a gene is introduced by transformation into a cell, neither the resident nor the transgene copy of the same gene is expressed (repeat-induced gene silencing) or increasing the gene copy number reduces the degree of expression. Interestingly, in higher plants non-transgenic duplication (polyploidy) does not result in co-suppression. Co-suppression may be complete or incomplete and it may be reversible during development. It may result in sector formation. Co-suppression

was discovered in plants but may occur in other organisms too. The cause of the phenomenon may be methylation of the genes, post-transcriptional degradation of the mRNA, RNAi, special allelic interaction, or antisense RNA. The mechanism might have developed to suppress viral propagation or suppress transposable elements. In *Neurospora*, the *qde-3* encoded RecQ-family DNA helicase is a post-transcriptional silencer. ▶co-repressor, ▶methylation, ▶antisense technology, ▶transgene, ▶RIP, ▶transvection, ▶silencer, ▶paramutation, ▶epigene suppression, ▶quelling, ▶MSUD, ▶imprinting, ▶host-pathogen relationship, ▶QTL, ▶RNAi, ▶repetitive DNA, ▶silencer, ▶post-transcriptional gene silencing, ▶Bloom syndrome, ▶Werner syndrome; De Buck S et al 2001 Plant Mol Biol 46:433; Meza TJ et al 2002 Nucleic Acids Res 30:4556.

$C_{0t}1/2$: The index of the reassociation of nucleic acid molecules when the reaction is half completed. It is proportional to the unique sequences in the reannealing molecules. ▶ C_{0t} curve

C_{0t} Curve (pronounce cot): When single-stranded DNA molecules are mixed they may reassociate, depending on the homology between the two types of strands. The facility of reassociation is determined by the degree of homology of the reactants, their concentration and the time allowed for the annealing. These three parameters are expressed by the C_{0t} curve (see Fig. C170). The reaction depends to a great deal upon the amount of redundant sequences in the DNA and the complexity of the DNAs. Redundant sequences and palindromic DNAs can anneal rapidly because of their similarities. For unique sequences, it takes more time for the complementary sequences to collide.

Figure C170. C_{0t} curve. The time course of an ideal second-order reaction illustrates the features of the C_{0t} curve of nucleic acid reassociation. The ordinate corresponds to the fraction of single-stranded molecules. The abscissa denotes the mole value per liter of the material, multiplied by time (usually in seconds) on a logarithmic scale. (Modified after Britten RJ, Kohne DE 1968 Science 161:529)

For the characterization of DNAs of different types, generally the half C_{0t} values are used, i.e., the time when the reassociation is half-completed (see Fig. C171). The reassociation of *E. coli* DNA generally takes place between C_{0t} values of about 0.1 and 10 (ca. 4.7×10^6 bp, mainly unique DNA), whereas for a large and complex genome of rye containing about 80% redundancy in the 7.9×10^9 bp DNA, it is within five orders of magnitude of C_{0t} (between 0.001 to 100) in contrast to the two orders of magnitude in the bacterium. If single-stranded homologous molecules are allowed to reanneal, the process can be represented as $\frac{dc}{dt} = -kc^2$ where c represents the molecular concentration, t = time of the reaction, and k = constant that depends only on the length of the nucleic acid molecules; d means the differential integral. After integration we get:

$\int_t^0 \frac{dc}{c^2} = -kdt$ and hence $\frac{c_0}{c}(-\frac{1}{c}) = -k_t^0(t)$ and $\frac{1}{c} - \frac{1}{c_0} = kt$ and if $t_{1/2} =$ the time when $c = c_0/2$ and $\frac{2}{c_0} - \frac{1}{c_0} = \frac{1}{c_0} = kt_{1/2}$ and if the concentration is expressed as mass (g/L) then:

$c_0 = C_0/M_r$ where the molecular weight (M_r) is in Daltons and the complexity becomes $C_{0t_{1/2}} = \left[\frac{1}{k}\right]M_r$.

Figure C171. The reassociation kinetics of two genomes (7.9×10^9 bp of rye and 4.7×10^6 *E. coli*) of different complexities. The green shaded area extends to two orders of C_{0t} values and covers most of the range of *E. coli* DNA. In contrast, 11% of the rye DNA reassociated at 0.001 to 100 C_{0t} . The half reassociation value of the non-repeated sequences of rye may be estimated by dividing 7.9 billion by 4.7 million and it is ca. 1,681 and after multiplying this figure by 2.5 (the C_{0t} values at half reaction of the *E. coli* DNA), we obtain $1681 \times 2.5 \approx 4,202$ = the half reassociation value of the non-repeated rye. (Diagram and calculations were modified after Smith DB and Flavell RB 1977 Biochim Biophys Acta 474:82)

Cot Filtration: A procedure for separation of unique DNA sequences from repetitive sequences of the large eukaryotic genomes. The principle of the separation is shown in the entry above. The separated low-copy-number gene-rich fraction then can be cloned and subjected to sequencing, whereas the

highly iterated fraction is rather refractory to routine sequencing (Peterson PD et al 2002 Genome Res. 12:795). ►methylation filtration

C

Cot Sequencing: ►cot filtration

C₀t Value: An index of the rate of reassociation of single-stranded DNA molecules. ►C₀t curve, ►kinetics of reassociation

Co-Transcription: ►operon

Cotransduction: More than a single gene is transferred by transducing phage if the genes are closely linked. ►transduction, ►bacterial recombination

Cotransfection: Cotransfection is transformation (genetic) by two or more genetically linked genes simultaneously. In the calcium phosphate precipitated donor DNA granules, non-linked DNA molecules may also be included and integrated into the animal cell simultaneously. ►transformation genetic [transformation of animal cells], ►calcium phosphate precipitation

Cotransformation: In cotransformation, donor DNA molecules containing closely linked genes may be taken up and integrated simultaneously into the bacterial chromosome or into the chromosomes of other organisms. ►transformation mapping, ►co-transfection

Cotranslational Transport: In cotranslational transport, the proteins synthesized on the ribosomes associated with the endoplasmic reticulum (rough endoplasmic reticulum) pass into the lumen of the endoplasmic reticulum during the process of translation. ►protein synthesis, ►endoplasmic reticulum, ►signal sequence; Wilkinson BM et al 2000 J Biol Chem 275:521.

Cotransport: Cotransport occurs when a transporter ferries two solutes simultaneously through a membrane.

Cotton: ►Gossypium

Co-Twin: A pair of twins. ►twinning, ►zygosis

Cotyledon: Seed leaf (actually an imprecise term because the seed before emergence may already have the initials of several leaves). At emergence, the dicotyledonous plants have two cotyledons, which have a nutritive storage role before and for awhile after germination. The monocots have only a single

very small cotyledon that has frequently a digestive role only. In dicots occasionally three or more cotyledons are formed as a developmental anomaly but tri-cotyledony is only exceptionally inherited (see Fig. C172). In zoology, the cotyledons mean the tufts or subdivisions on the placental surface of the uterus.

Figure C172. Di- and tricotyledonous seedlings

Coulomb (C): A unit of radiation measurement; $1 \text{ C/kg} = 1 \text{ R} \times (2.58 \times 10^{-4})$. ►R

Coulter Counters: Electronic equipments for counting cell numbers in a range of sizes.

Coumarin: A plant metabolic product arising from 4-hydroxycinnamate through oxidation (see Fig. C173). It gives rise to dicoumarol, a vitamin K antagonist. These compounds are abundant in some varieties of sweet clover (*Melilotus*) and if the coumarin content is high, the forage value is much reduced because animals may not eat it because of the bitter taste. After fermentation (silage), dicoumarol is formed that is very toxic due to its anti vitamin K and hemorrhagic effects. Plant breeding efforts have successfully reduced the coumarin content of some *Melilotus albus* varieties. Diethylaminocoumarin is a fluorophore. ►vitamin K, ►prothrombin deficiency, ►coumarin-like drug resistance

Figure C173. Coumarin

Coumarin-Like Drug Resistance: Due to an autosomal dominant gene some individuals are resistant to coumarin-like compounds such as warfarin, bishydroxycoumarin and phen-indione (anticoagulants).

These compounds are therapeutic agents in certain cases of surgery and in thromboembolic (blood clot forming diseases blocking arteries) diseases. ►blood clotting, ►antihemophilic factors, ►warfarin

Counseling, Genetic: Human geneticists can make predictions about the probability of recurrence risks in families affected by hereditary conditions and diseases such as birth defects, metabolic disorders, developmental problems, neurological or behavioral abnormalities, fertility problems, exposure to hazardous environment, consanguinity, pregnancy beyond age 35, etc. These predictions are based on family histories, cytological, biochemical, and molecular analyses. In Northern Europe, almost 12/1,000, and worldwide about 17/1,000 births are affected by single-gene defects. In Africa—although the rate varies regionally—on an average 7.4/1,000 births involved hemoglobin defects (sickle cell anemia). Consanguinity increases the genetic load substantially.

The completion of the physical mapping of the human genome will greatly improve the potentials of accurate genetic counseling by the availability of appropriate probes and nucleotide sequence information. Genetic counseling should be sought before marriage or procreation in families where risk is indicated. Participation is voluntary. The analyses may involve the prospective parents or the fetus may also be examined by amniocentesis. This procedure surgically withdraws with a syringe amniotic fluids 6–20 weeks following conception and analyzes the sloughed off, floating fetal cells by various methods. Under some circumstances of very high risks, termination of pregnancy may be opted for where there are no moral and/or legal objections. Only the family within the limits of the law can make the decision. The physicians or geneticists provide all the relevant facts but do not recommend the action(s) to be taken. Sometimes the counselor may, however, face the dilemma whether to reveal nonpaternity if this information does not entail health-related problems or if the diagnosis would jeopardize the emotional status of the counseled. From the viewpoint of genetics, selective abortion raises problems. If the families compensate for the aborted fetuses with new pregnancies, the frequency of the deleterious genes will rise in the population because the carriers may transmit the defective alleles and the problems are only postponed. If the carriers of serious hereditary defects refrain from reproduction, the frequency of these genes is supposed to decline eventually. The genetic counselor is a physician thoroughly trained in medicine and genetics and its cytogenetic, molecular, and statistical aspects, and is expected to be familiar with all the relevant techniques involved. Very often, because of the small

family size, penetrance, expressivity problems, variability of the syndromes, difficulties in obtaining candid information of family histories, especially about hereditary diseases with social stigmas, even the best qualified counselor may encounter difficulties. Besides being a good geneticist and an experienced physician, he/she must have sufficient background in psychology and ethics. Genetic and medical facts must be explained in terms easily understood by the families involved, whose level of education may vary from case to case. The counseling may be only limitedly effective because of problems in communication or the inadequate biological/genetical education of the counselee. Counseling is not supposed to follow any eugenic goal and is expected to be nondirective. The clients must be aware that genetic counseling may prevent family trauma, and may offer relief from nagging anxieties in cases when the recurrence risks are low, e.g., in the Downs syndrome and some other aneuploidies secures peace of mind. Also, some anomalies may be phenocopies and the genetics risks involved are practically nil. Since 1981, the American Board of Medical Genetics or the American Board of Genetic Counseling certifies genetic counselors. ►risk, ►genetic risk, ►recurrence risk, ►genetic counseling, ►empirical risk, ►utility index for genetic counseling, ►non-directiveness, ►amniocentesis, ►supportive counseling, ►carrier, ►gene therapy, ►OMIM, ►prenatal diagnosis, ►ART, ►confidentiality, ►genetic privacy, ►wrongful life, ►informed consent, ►bioethics, ►psychotherapy, ►selective abortion, ►genetic screening, ►consanguinity; Mahowald MB et al 1998 *Annu Rev Genet* 32:547; Weil J 2002 *EMBO Rep* 3:590; <http://www.genetests.org/>; Christianson A, Modell B 2004 *Annu Rev Genomics Hum Genet* 5:219; <http://www.geneclinics.org/>.

Count per Minute: ►cpm

Countercurrent Distribution: Countercurrent distribution partitions relatively small molecules between two liquids that are polar to a different extent. Both liquids are moved in a special apparatus in opposite direction between steps of equilibration.

Counter-Ion Condensation: The association of ions with the polyelectrolyte DNA; in B DNA there is about one anionic charge per 1.7 Å distance. In case the line charge spacing changes, the DNA may become unstable. ►DNA types; Fahey RC et al 1991 *Int J Radiat Biol* 59:885.

Count-Location Models: Count-location models consider that chiasmata are distributed uniformly and independently along the length of the chromosome. ►chiasma, ►stationary renewal process, ►mapping functions; Browning S 2000 *Genetics* 155:1955.

C

Counterselection: As per counterselection, in a hybrid population the two parental strains (each resistant, e.g., for a different antibiotic) may not survive in a medium containing both the antibiotics but the recombinants endowed with both of the resistance genes will survive. Thus there is a counterselection for the parental cells or strains. ▶[contraselection](#)

Coupled Reaction: In a pair of coupled reactions, the energy released by one reaction is utilized by the next,

Coupling Phase: In this phase, two or more recessive (or dominant) alleles occur in the same member of a bivalent chromosome (e.g., $\underline{A\ B}$ or $\underline{a\ b}$). Some geneticists call this arrangement *cis*. ▶[re-combination](#), ▶[repulsion](#), ▶[bivalent](#)

Courtship in *Drosophila*: Courtship in *Drosophila* is an extensively studied behavioral trait. Many genes are apparently involved but all appear to be pleiotropic and the mutations recovered affect more than one unrelated function. Some are affected in sex determination, others are visual or olfactory mutants or affect female receptivity or male fertility, or circadian rhythm, and others are involved in the “courtship song” of the flies (generated by the vibration of the wings). One component of the normal courtship is the GR68a pheromone receptor (under the control of the gene for double sex) that senses nonvolatile female pheromones. This receptor is located in about 20 male-specific gustatory bristles on the male foreleg (Bray S, Amrein H 2003 Neuron 39:1019). A better understanding of neuronal function and the availability of selection techniques will promote progress in this field. This as well as other behavioral traits can now be subjected to genetic and neurobiological analyses. ▶[behavior genetics](#), ▶[pheromone](#), ▶[copulation](#), ▶[sex determination](#); Greenspan RJ, Ferveur J-F 2000 Annu Rev Genet 34:205.

Cousin: The child of the sibling of an individual’s father or mother is a first cousin. The child of a first cousin is a second cousin or first cousin once removed. The cousins can be twice..... tenth, and so on removed depending on the steps in the relationship. News services reported that Prince Charles and Diana Spencer are 7th cousins once removed (see Fig. C174).

Figure C174. Diagram of the relations of the 7th cousin once removed

Accordingly their pedigree would be as shown. ▶[cousin-german](#)

Cousin-German: A first cousin. ▶[german](#)

Cousin Marriages: Marriages between cousins may increase the chances of defective offspring depending on the coefficient of inbreeding. Infant death rate during the first year of life among children of first cousins is approximately double relative to that in the general population. ▶[coefficient of inbreeding](#), ▶[controlled mating](#). Between 1959 and 1960, 0.08% of the Roman Catholic marriages were inter-first cousins, and among American Mormons during the period 1920–1949, it was 0.61%. In India, the marriages between first cousins, in some communities, were as high as 30% in the not-too-distant past. ▶[inbreeding coefficient](#), ▶[coefficient of coancestry](#), ▶[incest](#), ▶[genetic load](#); Fraser FC, Biddle CJ 1976 Am J Hum Genet 28:522.

Covalent Bond: Chemical linkage through shared electron pairs, e.g., (see Fig. C175).

Figure C175. Covalent bond

Covalently Closed Circle: A circular macromolecule (plasmid) in which all the building blocks are covalently linked and thus there are no open ends.

Covariance: ▶[correlation](#)

Covarian Theory: The covarian theory interprets evolution on the basis of varying codons in a lineage-specific manner among the sites. ▶[codon](#), ▶[evolution](#); Penny D et al 2001 J Mol Evol 53:711.

Coverslip: Usually 0.13–0.25 mm thick glass (plastic) covers on microscope slides for flattening of specimens and/or protecting during examination by temporary or permanent seal.

Cowden Syndrome: Multiple hamartomas. ▶[multiple hamartoma syndrome](#)

Cowpea (*Vigna unguiculata*): A food and fodder crop of the tropics and subtropics primarily. All the 170 species have $2n = 2x = 22$ chromosomes.

Cowpea Mosaic Virus: The genome of the cowpea mosaic virus contains B-RNA and M-RNA. The former codes for Vpg in a polyprotein complex at the carboxy terminus. ▶Vpg

Cox: The symbol for cytochrome oxidase and cyclooxygenase proteins and genes. Mitochondrial DNA encodes three subunits and the nuclear DNA codes for 10. Cox-2-derived prostacyclin protects premenopausal mice from atherosclerosis (Egan KM et al 2004 Science 306:1954). Several drugs contain Cox-2 inhibitors to protect from inflammation, arthritis, and other symptoms of disease. Unfortunately, a higher risk of adverse cardiovascular effect and colorectal neoplasias are known to appear after a few years of use (Bresalier RS et al 2005 New Engl J Med 352:1092). ▶cyclooxygenase, ▶cytochromes, ▶menopause, ▶prostacyclins, ▶prostanoid

Cox Proportional Hazards Method: $\ln h(t) = \ln \alpha(t) + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_q x_q$ where h is the hazard, x_1, x_2, \dots, x_q are the variables of concern, and $\alpha(t)$ is the baseline hazard function at t time. The β values are determined by the maximum likelihood of occurrence. The method is generally used when the outcome is censored. ▶hazard, ▶maximum likelihood, ▶censoring; <http://www.medcalc.be/manual/cox-regression.php>.

Coxsackie Viruses (*Picornaviridae*): Coxsackie viruses have ~7,500 base single-stranded RNA genetic materials in particles of diameter 22–30 nm. Humans, monkeys, and suckling mice are susceptible to them and the viruses may cause damage to the nervous system, the respiratory and alimentary tracts, muscles, and internal organs, and may even induce autoimmune disease. Coxsackie B4 viral infection is associated with insulin-dependent diabetes and shares similarity with the Langerhans islet autoantigen glutamic acid decarboxylase. Many coxsackie virus B viruses interact with DAF (decay accelerating factor) and activate Abl kinase triggering Rac-dependent actin rearrangement that facilitates its movement of tight junctions where it interacts with the coxsackie virus and adenovirus receptor (CAR), and thus by permitting changes in the capsid facilitate release of the phage genome. Alternatively, CAR can interact with Fyn kinase and the phosphorylation of caveolin that transports the virus into the cell (Coyne CB, Bergelson JM 2006 Cell 124:119). ▶picornaviruses, ▶diabetes mellitus, ▶Langerhans islet, ▶CAR1, ▶ABL, ▶RAC, ▶DAF, ▶Fyn, ▶caveolin; Wan YY et al 2000 Proc Natl Acad Sci USA 97:13784.

Coyote: *Canis latrans* ($2n = 78$), the North-American canine; it can interbreed with domestic dogs ($2n = 78$) and the wolf ($2n = 78$).

C1p (C/p): A member of the Hsp100 ATPase family. ▶HSP

CP Complex: A nuclear dimer of Cdc68 and Pob3 proteins that regulates gene expression (activation and repression) by interacting with the promoter of budding yeast and modifying chromatin structure, respectively.

CP1: A mammalian transcription factor binding to the CCAAT box. ▶CDP, ▶CAAT box

CP1 (Cbf1/Cpfl): A centromere-binding ([A/G]TCAC [A/G]TG) yeast protein, it is a part of the kinetochore. The protein may affect chromosome segregation and methionine synthesis. ▶kinetochore

C11p11: A DNA probe used for the identification of certain cancer sequences.

CPB: ▶cetylpyridinium bromide

CPBs: mRNA cap-binding proteins. ▶eIF, ▶translation initiation

CPD: Cross-linked adjacent pyrimidine dimers, photo-products. ▶pyrimidine dimers

cpDNA (chloroplast DNA): The size of the cpDNA varies generally between 8 and 13×10^7 Da, it is a circular double-stranded molecule with 20–40 copies per chloroplast in higher plants and 80 copies in the *Chlamydomonas reinhardtii* alga. ▶chloroplasts, ▶chloroplast genetics, ▶Chlamydomonas

CPE (chemical penetration enhancer): CPE aid dermal absorption of cosmetics and drugs. These must overcome the resistance of the epidermis (corneum striatum) by fluidization of the lipid bilayer and should not cause irritation by denaturing the proteins in this layer. ▶drug development; Karande P et al 2005 Proc Natl Acad Sci USA 102:4688.

CpG Motifs (Cytosine-Guanine): CpG motifs of bacteria in unmethylated state induce murine B cells to proliferate and secrete antibodies. In the mammalian genomes these doublets are most commonly methylated. The methylated cytosine may be transmitted epigenetically through the germline. In the human genome, 78% of the promoters have high CpG content (Saxonov S et al 2006 Proc Natl Acad Sci USA 103:1412). ▶B cell, ▶epigenesis, ▶methylation of DNA

CpG Islands: Regions of 500 bp or less or more in 5' upstream of genes with CpG doublets. Their function is regulatory. The human genome has about 29,000 CpG islands. The doublets in these islands (especially

C

in housekeeping genes) are protected from methylation and are instrumental in the transcription of about half the mammalian genes. The CpG islands of imprinted and lyonizing genes may be methylated and silenced. Methylation may increase by aging and *in vitro* culture. The 5'-CpG role in silencing is mediated by the methyl-CpG binding protein (MeCP) that interacts with a histone deacetylase complex. In cancer cells, the tumor suppressor genes appear to be methylated. Hundreds of genes may be promoter-methylated in a single cancer (Jones PA, Baylin SB 2007 Cell 128:683). Some cancer cells contain hypermethylated CpG islands. The hypermethylation may silence the tumor suppressor genes. By computationally mapping all NotI or other methylation-sensitive restriction enzyme sites, methylation events can be defined with single nucleotide precision through the entire genome. The methylation-sensitive enzymes do not cleave the normal recognition site when the C is methylated. Therefore, the methylation status (silencing/expression) can be assessed in a tissue-specific manner (Ching T-T et al 2005 Nat Genet 37:645). ▶isochores, ▶histone deacetylase, ▶methylation of DNA, ▶trichostatin, ▶housekeeping genes, ▶imprinting, ▶lyonization, ▶tumor suppressor, ▶trinucleotide repeats, ▶RLGS; Jones PA, Taki D 2001 Science 293:1068.

CpG Suppression: CpG suppression is actually not a suppression mechanism. Some regions of the genomes are relatively low in CpG sequences and they may be methylated during most of the life of eukaryotes. ▶CpG islands

cPLA₂: cPLA₂ catalyzes the hydrolysis of glycerophospholipids, yielding arachidonic acids ▶fatty acids and lysophospholipids (membrane lipid). It is activated by MAP kinase in the presence of Ca²⁺. ▶integrin, ▶MAP; Blaine SA et al 2001 J Biol Chem. 276:42737.

cpm (count per minute): A measure of radioactivity; 1 μCurie ≅ 1,000,000 cpm. ▶dpm

Cpn: ▶chaperonins

Cpn10: The mammalian homolog of the bacterial GroEs chaperonin in the mitochondria. ▶GroES

Cpn21: A chloroplast chaperonin (homolog of GroES) encoded in the nucleus; it interacts with Cpn60 (homolog of GroEL). ▶GroEL

Cpn60: Mammalian mitochondrial and plant chloroplast analogs of the bacterial GroEL chaperonin. ▶GroEL

CPP32: A proenzyme of apopain. ▶apoptosis, ▶apopain, ▶cysteine proteases, ▶Yama

Cpr: ▶cyclophilins

CPR (cell cycle progression restoration): Cyclin-dependent human genes involved in relieve of cell cycle arrest by pheromones, function as molecular chaperones and transcription factors, control morphogenetic pathways (carcinogenesis), etc.

CPSF (cleavage-polyadenylation protein factor): CPSF mediates the formation of the 3'-end of the mRNA
▶transcription factors, ▶polyadenylation signal, ▶symplekin

cR: ▶CentiRay

CR Lines of Mice: ▶congenic resistant

CRAb (chelating recombinant antibody): An antibody specific for two adjacent and non-overlapping epitopes of a single antigen molecule, generated by chelating. This increases specificity. ▶epitope, ▶antigen, ▶chelation, ▶antibody

CRAC: Calcium release-activated ion channel (Yeromin A et al 2006 Nature [Lond] 443:226; Prakriya M et al 2006 Nature [Lond] 443:230). ▶ion channels

CRAF-1: A protein factor interacting with the CD40 cytoplasmic tail by a region similar to the tumor necrosis factor receptor (TNF-α) associated factors (TRAF). CRAF is required for CD40- binding and dimerization. CRAF has five Zn-fingers and a Zn-ring finger. It participates in signal transduction. ▶CD40, ▶TRAF, ▶TNF, ▶signal transduction, ▶zinc fingers, ▶ring finger; Luttrell LM et al 2001 Proc Natl Acad Sci USA 98:2449.

CRAFT (Cre Recombinase Reporter Assay for Translocation): CRAFT is used to monitor the nucleoprotein VirB/D4 agrobacterial virulence gene transport system to identify translocation into the plant cell. ▶virulence genes of Agrobacterium; Vergunst AC et al 2000 Science 290:979.

Craniofrontonasal Syndrome (CFNS, craniofrontonasal dysplasia/dysostosis, Xq12): CFNS is probably dominant with greater expression in the heterozygous females than in the hemizygous males. It is characterized by several skeletal and facial abnormalities and wiry hair. Mutations in the EFN1 gene, which encodes the ephrin-B1 ligand for Eph receptors, are involved.

Cranio metaphyseal Dysplasia (CMDD, 5p15.2-p14.1): A dominant malformation (outgrowth and sclerosis) of the head bones. Mutation occurs in the ankylosis gene that encodes a 492-amino acid transmembrane protein controlling pyrophosphate level and it is expressed in the joints and in other tissues. A recessive form (CMDR) is encoded at 6q21-q22. ▶head/face/brain defects; Reichenberger E et al 2001 Am J Hum Genet 68:1321.

Cranioorodigital Syndrome (otopalatodigital syndrome type II): An X chromosomal head/face/brain defect, which has symptoms overlapping with those of otopalatodigital syndrome, and is encoded in the same area of human chromosome Xq28. ▶otopalatodigital syndrome, ▶head/face/brain defects

Craniosynostosis Syndromes: Craniosynostosis syndromes occur in a great variety and involve premature closure of the sutures of the skull, resulting in facial malformations. The defect is in one of the fibroblast growth factor receptors (FGFR). Prevalence is in the 4×10^{-4} range. Most of the syndrome types are under autosomal recessive control. Attenuation of FGFR signaling by pharmacological intervention could be applied for the treatment of craniosynostosis or other severe bone disorders (caused by mutations in FGFRs) that currently have no treatment (Eswarakumar VP et al 2006 Proc Natl Acad Sci USA 103:18603). ▶Crouzon syndrome, ▶Chotzen syndrome, ▶Apert syndrome, ▶Pfeiffer syndrome, ▶Marfanoid, ▶Shprintzen-Goldberg syndrome, ▶Gorlin-Chaudhry-Moss syndrome, ▶Muenke syndrome, ▶Antley-Bixler syndrome, ▶MSX; Cohen MM Jr, MacLean RE eds. 2000 Craniosynostosis, Oxford Univ. Press, New York.

Cranium: The skeleton of the head, excluding the bones of the face. It is the container of the brain. ▶brain human; Helms JA, Schneider RA 2003 Nature [Lond] 423:326.

Cranium Bifidum: Cleft or fission on the head. ▶frontonasal dysplasia

Crassulacean Acid Metabolism: Some succulent plants can store large amounts of acids (malate), which are formed during the night and whose level drops during the day. This system of photosynthesis fixes carbon with the aid of phosphoenolpyruvate carboxylase, and generates the C_4 oxaloacetate, as in other C_4 plants, rather than through ribulose-1,5-bisphosphate carboxylase/oxygenase, as in C_3 plants. ▶ C_3 plants, ▶ C_4 plants; Luttge U 2000 Planta 211:761.

CRB: A cell cycle checkpoint protein recruited to DNA breakage sites. It is regulated by methylation of Histone 4 lysine 20. ▶checkpoint; Sanders SL et al 2004 Cell 119:603.

CRE: Cyclic AMP-response elements (TGACGTCA), with DNA sequences ~100 nt (nucleotide) upstream of the TATA box of the transcription unit of genes responding to cAMP. Gene expression by cAMP also requires protein kinase A action on the 43-kDa

accessory protein CREB. ▶CREB, ▶TATA box, ▶cAMP, ▶TORC, ▶protein kinase, ▶Cre/LoxP

Creatine ([N-aminoiminomethyl]-N-methylglycine): Creatine, in the form of phosphocreatine, is a major source of energy generation (kcal/mol = 10.3). Creatine kinase catalyzes the reaction: phosphocreatine + ADP \rightleftharpoons ATP + creatine.

Creatine Deficiency: Guanidoacetate methyltransferase deficiency (GAMT, 19p13.3). Amidinotransferase catalyzes the conversion of glycine into guanidoacetate, and from that GAMT generates creatine with S-adenosylmethionine methyl donor. The clinical symptoms involve postural and locomotive defects due to brain and muscular anomalies and very low creatine excretion. A creatine transport defect (CT1/SLC6A8, Xq28) also generates creatine deficiency. Salamons GS et al 2001 Am J Hum Genet 68:1497.

Creationism: The doctrine about how the universe came into existence based on an oracle, and suggesting that organisms are as we see them at present because they have been so created and ordained. Another important aspect is “that the intellectual soul is created by God at the end of human generation, and this soul is the same time sensitive and nutritive” (Thomas Aquinas, 13th CE). According to the Tertullian (2nd–3rd CE) *transducianism*, both soul and body are conceived and formed at exactly the same time. Some types of creationist ideas exist in many religions, including Hinduism (Hare Krishnas), and native American and Pagan religions. Creationism is not an entirely monolithic view, variations exist but all creationist ideas are united in negating evolution as presented by modern science. Several Christians, Roman Catholics, and Protestants accept evolution by assuming that God could have created the evolutionary mechanism, which led to the development of the biological systems as we experience them. The fossil record is a serious obstacle to the logic of creationism, and posits a difficulty in explaining its divine purpose. It is unfortunate that science be mixed with faith or politics. Of course, scientists may be religious and may assume political views. Karl Popper (The Logic in Scientific Discovery. Hutchinson, London, p. 48) succinctly put forth the essence of science: “...I refuse to accept the view that there are statements in science which we have, resignedly, to accept as true merely because it does not seem possible, for logical reasons, to test them.” ▶evolution, ▶intelligent design, ▶paranormal; Numbers RL 1982 Science 218:538; Evans EM 2001 Cognit Psychol 42:217; Pennock RT 2003 Annu Rev Genomics Hum Genet 4:143; evolution teaching web sites: <http://www.nationalacademies.org/evolution>; <http://evolution.berkeley.edu/>, human evolution: <http://www.talkorigins.org/faqs/homs>.

C

Creativity (<http://www.crea.server.de/>): Creativity in research implies the impact of work for the advancement of a particular scientific endeavor. The goals are to identify individuals and institutions, both in Europe and the USA, which have a record of creative research. The aim is to identify knowledgeable experts in targeted categories such as in the fields of human genetics and nanotechnology, and to then ask these experts to nominate highly creative research. The aim is an understanding of the institutional and organizational conditions under which creative researchers have worked. It is hoped that the knowledge gained from the case studies will facilitate recommendations about the design of science policy to support innovative research.

CREB: A CRE (cyclic AMP-response element) binding protein that requires phosphorylation at a serine residue at position 119 or 133 for transcriptional activity. Transactivation of CREB by PK-A requires the glutamine-rich constitutive activator domain (Q2) and the kinase inducible domain (KID, 58 amino acids modulatory sequence), which endow it with independent functions but may work synergistically. KID recognizes PK-A and the transcription complex, and is important for transactivation. There are about 50,000 CREB molecules/cell, mainly bound to chromatin. The CREB family also includes CREM and ATF-1, all subject to phosphorylation by protein kinase A. Active calcium channels also stimulate CREB activity.

CREB apparently activates T lymphocytes involving phosphorylation of CRE and that induces transcription factor AP1, leading to the production of interleukin-2 and to the progression of the cell cycle (see Fig. C176).

Figure C176. CREB. One of the functions of the CREB protein. CRE (cyclic amp response element) is bound by CREB that is phosphorylated by CBP (CREB-binding protein). TBP (TATA box binding protein) And The General Transcription Factors TFIID, TFIIB as well as TAF130 (transcription-associated protein) congregate at the TATA box. RHA (an RNA helicase) and POLII (RNA polymerase II) are required for transcription. The system may require activation by hormones through G proteins, cAMP, protein kinase A (PKA) and the RAS, RAF, MEK, RSK signal transduction pathways. (Modified after Shaywitz AJ, Greenberg ME 1999 Annu Rev Biochem 68:821)

The CREB kinase is apparently identical with RSK2, a member of the RAS family. Mutations in CREB have been implicated in the Rubinstein-Taybi syndrome, in fusions with the MOZ (monocytic leukemia zinc finger protein) in case of acute amyloid leukemia (AML), and histone acetyl transferase displacement by AP1, leading to transformation. The CREB-binding protein, CBP and p300, by histone acetyltransferase activity, assist the assembly of the transcriptional complex at the promoter. Credible Interval: The credible interval is similar to the confidence interval; and is calculated on the basis of posterior probability distribution. It indicates the range within which a certain parameter is expected to occur. [confidence interval](#)

Cre/loxP: A P1 phage recombinase system affecting specific target sites. It can also be used in various eukaryotes for mediating site-specific recombination or chromosomal breakage (see Fig. C177). The Cre/loxP system has been successfully exploited for site-specific recombination and the generation of knock-outs. The Cre protein (38-kDa) is a recombinase with specific recognition for the 34 bp *locus of crossing over of P1 (loxP)*, a pair of palindromic sequences and recombination takes place within the 8 base central core (underscored at the sites delineated by red line. Note the inverted repeats left and right from the underscored octad signs (see Fig. C178). When Cre cuts the DNA, a phosphotyrosine intermediate is formed. Eliminating the phosphodiester bonds at \sim allows recombination to take place. The Cre recombinase can be targeted by choosing tissue-specific promoter (Zhou L et al 2002 FEBS Lett. 523:68).

Figure C177. Recombination at loxP

Figure C178. Cre recognition site

In animal cell cultures, the Cre recombinase may induce single and double-strand breaks in the DNA and may slow down cell proliferation. At low concentration, the disadvantageous features can be avoided. ►site-specific recombination, ►Flp/FRT, ►chromosomal rearrangements, ►targeting genes, ►integrase, ►resolvase, ►homing endonuclease, ►ligand-activated site-specific recombination, ►knockout; TAMERE, *Genesis* 2000, 26:99–165; Sauer B 1998 *Methods* 14:381; Zheng B et al 2000 *Mol Cell Biol* 20:648; Van Duyne GD 2001 *Annu Rev Biophys Biomol Struct* 30:87; Loonstra A et al 2001 *Proc Natl Acad Sci USA* 98:9209; Pfeifer A et al 2001 *Proc Natl Acad Sci USA* 98:11450; Seligman LM et al 2002 *Nucleic Acids Res* 30:3870.

CREM a and b (modulator of CRE): CREB-related transcriptional repressors, but CREB is a transcriptional activator. ►CRE, ►CREB, ►ACT

Cremello: A color of horses (see Fig. C179) of *AabbCCDD* genetic constitution.

Figure C179. Cremello

Crenate: has a tooth-like round protrusion.

Crepis: Composite flowers with chromosomes favorable for cytological studies (see Fig. C180). *C. capillaris*, 2n = 6; *C. tectorum* 2n = 8; *C. rubra* 2n = 10; *C. flexuosa* 2n = 14; *C. biennis* 2n = 40.

Crest (calcium-responsive activator of transcription): A nuclear protein interacting with CREB-binding protein. It regulates dendrite development in the brain ►CREB, ►dendrite; Aizawa H et al 2004 *Science* 303:197.

Cretaceous Period: 137 to 63 million years ago when the first human ancestors appeared. ►geological time periods

Cretenism: A hereditary or congenital deficiency of thyroid hormone, causing mental and physical retardation. ►goiter

Creutzfeldt-Jakob Disease: A degenerative nerve disorder that begins with forgetfulness and nervousness, most commonly at middle age, and sometimes earlier or later, and after a year or two progresses into jerky movement of the hands, insecure walk, and expressionless face. These symptoms overlap with Gerstmann-Straussler disease and the two are probably identical basically, although within both diseases different types of manifestations have been observed. The diseases are not limited to humans but in sheep (scrapie), goat, and rodents highly similar nerve degenerations have been described. Amyloid protein deposits are found in the brain of afflicted individuals. The biochemical bases of the disorder was attributed to defects in the prion protein (PRP), a 27 to 30-kDa glycolipoprotein. The structural gene of PRP was assigned to mouse chromosome 2, and another gene in chromosome 17 was held responsible for the length of the incubation period of the disease. In humans, the PRP gene is located in chromosome 20p12-pter. It appears that PRP is a normal protein of the nervous system but proteolytic cleavage, amino acid replacements, insertions of 144 to 150 base pairs, and insertions of 5 to 9 or more octapeptide repeats in between the amino acids encoded by codons 51 and 91 may trigger the disease. The most commonly observed Pro→Leu replacement at codon 102 was attributed to the ataxia symptoms, but changes at

codon 117 (Ala→Val), 200 (Gln→Lys) and others were found to be associated with the degenerative phase of the PRP.

The injection of infected brain material into chimpanzees and other animals reproduces the disease. Since the infectious material does not contain any detectable amount of nucleic acid, scrapie, Creutzfeldt-Jakob (CJS), and the Gerstmann-Straussler (GSS) diseases are considered to be the first infectious protein diseases. These diseases occur in a familial manner, and it is not exactly known when and how the genetic determination of the degeneration occurs. It has been detected among all ethnic groups; in some its frequency is much higher than in others. Among the Jews of Libyan origin, the incidence was reported to be 4×10^{-5} , nearly 50 times higher than in the general population. In addition, 41 to 47% of the cases observed were familial whereas in some other populations only 4 to 8% appeared familial. The nv (new variant) CJS is supposed to be the result of human infection by animal encephalopathy inducing prions. Administering first an intracerebral injection of low effectiveness prion protein (SY) to mice, and subsequently an inoculation with a highly aggressive prion, FU, substantially delayed the expression of the disease. (Manuelidis L, Lu ZY 2003 Proc Natl Acad USA 100:5360). This observation appears similar to that involving the prevention of viral superinfection by another strain of the virus.

Between 1983 and 1985 in France, 968 children were treated with human growth hormone contaminated by CJS prions of human brain, and by 2005, 101 had died from the disease and several others infected (Casassus B 2005 Science 307:1711).

►prion, ►kuru, ►encephalopathies, ►Gerstmann-Straussler disease, ►bovine spongiform encephalopathy, ►fatal familial insomnia, ►Alpers progressive infantile poliodystrophy, ►superinfection; <http://www.cdc.gov/ncidod/diseases/cjd/cjd.htm>; <http://www.cjd.ed.ac.uk>.

Cri du Chat (cat cry): A deletion in the short arm of human chromosome 5 involves mewing like voice, mental and growth retardation and other disorders.

Cricket (*Gryllus campestris*): Orthoptera, 2n male = 29, female 2n = 30. The Mormon cricket (*Anabrus simplex*) of North America (see Fig. C181) is a migrating species (traveling 2 km/day); the migration is driven by the need of salt of the large population. The paucity of protein food promotes cannibalism of peers (Simpson SJ et al 2006 Proc Natl Acad Sci USA 103:4152).

Figure C181. Cricket

Crigler-Najjar Syndrome (bilirubin/uridine glucuronosyl transferase deficiency, UDPGT): A recessive, human chromosome 1q21-q23 defect; causes a non-hemolytic jaundice, hyperbilirubinemia and, in case of total deficiency of UDPGT, early infant death results in case of kernicterus. Phototherapy and liver transplantation are possible treatments. Helper-dependent adenoviral vector (free of viral coding sequences) carrying the UDPGT 1A1 gene transferred to rat disease model and expressed in the liver, has been seen to reduce bilirubin glucuronides from 5 mg/dl to <1.4 mg/dl (wild type level) at negligible toxicity (Toietta G et al 2005 Proc Natl Acad Sci USA 102:3930). Partial deficiency of the enzyme (in type II form) is tolerated. ►uridine diphosphate glucuronyl transferase, ►hyperbilirubinemia, ►Dubin-Johnson syndrome, ►Gilbert syndrome, ►kernicterus, ►gene therapy, ►adenovirus

Criminal Behavior: Criminal behavior may have some genetic component but the overwhelming motivation is provided by the family and social and economic conditions. The use of drugs, alcoholism, broken family ties, poverty, unemployment, etc. are major causative factors. ►behavior in humans, ►behavior genetics

Crinkly-4: A plant TNF/EGF transmembrane receptor. ►TNF

CRIP: A group of proteins with LIM and additional domain(s). ►CRP, ►PINCH, ►LMO, ►LIM

Crisis in Animal Cell Culture: ►Hayflick's limit

CRISPR (clustered regularly interspaced short palindromic repeats): CRISPR are distinctive features of the DNA genomes of most bacteria and archaea. After viral challenge, bacteria integrate new spacers derived from phage genomic sequences. Removal or addition of particular spacers modify the phage-resistance phenotype of the cell (Barrangou R et al 2007 Science 315:1709). ►virus resistance

Criss-Cross Inheritance: Criss-cross inheritance is characteristic for X-chromosome linked recessive mutations. The recessive genes follow the pattern of inheritance of the X chromosome; they are expressed in the hemizygous male but only in the homozygous female (see Fig. C182).

In case the female is heterogametic and the male is homogametic, like in the *Lepidoptera* or birds, the inheritance follows the mirror image of what is shown in the diagram. ▶[sex linkage diagram](#)

Criss-cross inheritance can be observed in humans as well. All the offspring of a red-green color-blind father is expected to be normal but all the male children of a color-blind mother are expected to be affected. Some of the male grandchildren of color-blind grandfathers will be color-blind, although their sons (the fathers of the grandsons) have normal vision.

Cristae: Invaginations of the inner membranes of the mitochondria. ▶[mitochondria](#)

Critical Population Size: Although in a monogenic Mendelian F2 generation, 1/4 of the population is expected to be homozygous recessive, it rarely happens that every fourth individual meets this expectation. Therefore, it may be important to know how many individuals are needed in F2 to find at least one of this desired phenotype. The statistical solution is a device that rules out the case where all the individuals would be of the undesired type (3/4), e.g., $(3/4)^n = 1 - P$ where the (3/4) is the non-recessive class, (n) the number of individuals required in the population, and P = probability. Thus, $(3/4)^n = 1 - 0.95$ must be solved for (n), $n(\log 3 - \log 4) = \log 0.05$,

hence $n = (\log 0.05)/(\log 3 - \log 4) = -1.30/(0.477 - 0.602) = 10.4$, i.e., 11 (because fractions of individuals do not exist and the 0.95 probability is valid for 10.4 or more). Therefore, at 0.95 probability, only 11 individuals give an assurance of finding at least one double recessive. The procedure is similar to that, when we wish to determine the critical population size with a segregation ratio of 15:1 at 0.99; $n = \log 0.01/(\log 15 - \log 16) \approx 72$. Similar calculations are useful for calculating the minimal population size required for the recovery of a mutant individual after mutagenic treatment if we know (or guess) the induced mutation rate. ▶[genetically effective cell number](#), ▶[mutation rate](#); Mather K 1957 The measurement of linkage in heredity, Wiley, New York.

Critical Value: The critical value must be exceeded to reject the null hypothesis in a statistical test.

Criticism of Genetics: The criticism of genetics essentially shares the same elements as those of other scientific fields. In most cases where genetics is criticized, the motivation to do so can be attributed largely to perverse political systems. However, some biologists too deserve to be condemned for their attempts to pursue negative eugenics, racism, experimentation with biological warfare, inappropriate use of atomic energy, careless use of industrial, agricultural and medical chemicals, distortion of population genetic principles applied to environmental problems, cloning of animals and possibly humans, genetic discrimination on the basis of genotyping information, modifying genes of plants, animals and humans by genetic engineering or selecting special
